are no kinematically forbidden reflections. Thus, the lattice type is determined to be primitive P.

Possible space groups which satisfy point group $4/mmm$ and primitive lattice type P are those of Nos. 123–138 in Table 2.5.3.9. In Fig. 2.5.3.15(a), the dynamical extinction line A_2 is seen in the 100 disc and in the equivalent 010 disc. By consulting Table 2.5.3.9, four space groups $P4/mbm$, $P4/mnc$, $P4_2/mbc$ and $P4_2/mnm$ are selected. In Fig. 2.5.3.15(b), the dynamical extinction line A_2 is seen in the 010 disc but not in the $10\bar{1}$ disc. Two space groups $P4/mnc$ and $P4_2/mnm$ are selected from the four. To distinguish the two space groups, it is found from Table 2.5.3.9 that a CBED pattern taken with the [110] electron incidence should be examined. Fig. 2.5.3.15(e) shows a CBED pattern taken with the [110] incidence at 100 kV, where the 001 reflection is exactly excited. The $hh\bar{1}$ reflections are kinematically allowed for space group $P4_2/mnm$ but kinematically forbidden for $P4/mnc$. Since in the case of $P4/mnc$, no *Umweganregung* (multiple scattering) paths to the 001 reflection exist in the zeroth-order Laue zone, only the intensities of HOLZ lines, which are caused by *Umweganregung via* HOLZ reflections, are expected to appear in the 001 disc. If such *Umweganregung* is not practically excited, the 001 reflection must have no intensity. However, strong intensity produced by two-dimensional interaction is seen in the 001 disc of Fig. 2.5.3.15(e). This indicates that the reflection is an allowed reflection. Therefore, the space group of rutile is determined to be $P4_2/mnm$, which agrees with the space group already known.

Samarium selenide (Sm_3Se_4). Sm_3Se_4 has the Th_3P_4 structure type with space group $I\bar{4}3d$ at high temperatures. The lattice parameters are $a = b = c = 0.8885$ nm. It was expected that Sm_3Se_4 would transform to an ordered state of electrons with two valences of +2 and +3 around 150 K. The determination of the space group of the material was conducted at 100 K and room temperature. The space groups at both temperatures were determined by CBED to be the same. The following experiments were performed at 100 K.

Fig. 2.5.3.16(a) shows a CBED pattern taken with the [111] incidence at 80 kV, which clearly shows the first-order-Laue-zone reflections. The symmetry of the WP is seen to be $3m$ with the help of the enlarged insets. Possible diffraction groups are $3m$, $3m1_R$ and 6_Rmm_R from Table 2.5.3.3. Fig. 2.5.3.16(b), which is the central part of Fig. 2.5.3.16(a), shows projection symmetry $3m$, indicating that the projection diffraction group is $3m1_R$. Among the three groups $3m$, $3m1_R$ and 6_Rmm_R, diffraction groups for which the projection diffraction group is $3m1_R$ are $\bar{3}m$ and $3m1_R$. Possible point groups are found to be $3m$, $\bar{4}3m$ and $\bar{6}m2$ from Fig. 2.5.3.4. Fig. 2.5.3.16(c) shows a CBED pattern taken with the [100] incidence at 80 kV. The WP is seen to have symmetry $2mm$. Allowed diffraction groups are $2mm$, $2mm1_R$ and 4_Rmm_R. Fig. 2.5.3.16(d), which is the central part of Fig. 2.5.3.16(c), shows projection WP symmetry $4mm$, indicating that the projection diffraction group is $4mm1_R$. The diffraction group among the three groups $2mm$, $2mm1_R$ and 4_Rmm_R whose projection diffraction group is $4mm1_R$ is 4_Rmm_R. Possible point groups are found to be $\bar{4}3m$ and $\bar{4}2m$ from Fig. 2.5.3.4. Thus, the point group

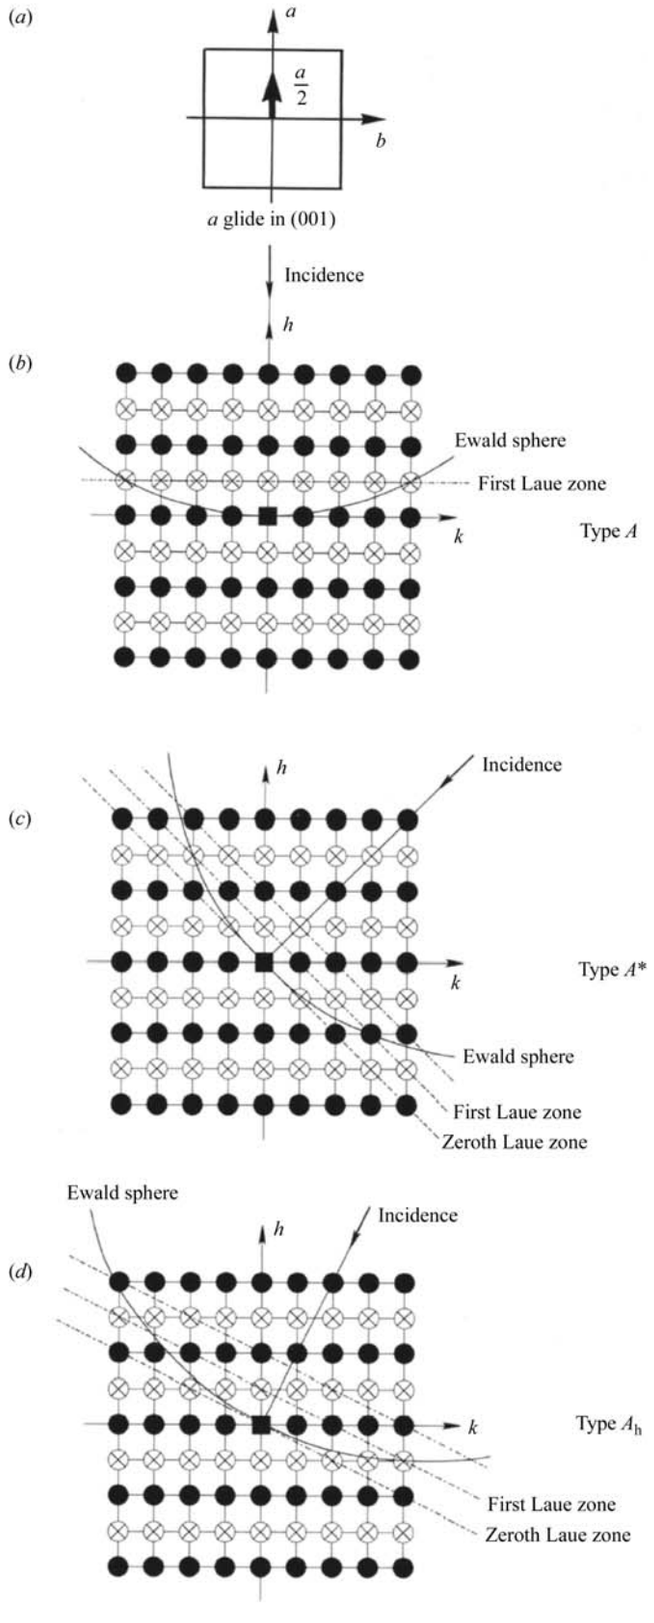

Fig. 2.5.3.13. Illustration of dynamical extinction lines appearing in HOLZ reflections due to glide planes. Black circles and circled crosses show kinematically allowed and kinematically forbidden reflections, respectively. (*a*) *a* glide in the (001) plane. (*b*) [100] incidence: dynamical extinction lines are formed in HOLZ reflections on both sides of the incident beam (type *A*). (*c*) [110] incidence: an extinction line is formed at a HOLZ reflection on one side of the incident beam because on the other side the Ewald sphere intersects an allowed HOLZ reflection (type *A**). (*d*) An incidence between [100] and [110]: an extinction line is formed at a HOLZ reflection on one side of the incident beam because on the other side the Ewald sphere does not intersect a HOLZ reflection (type A_h).

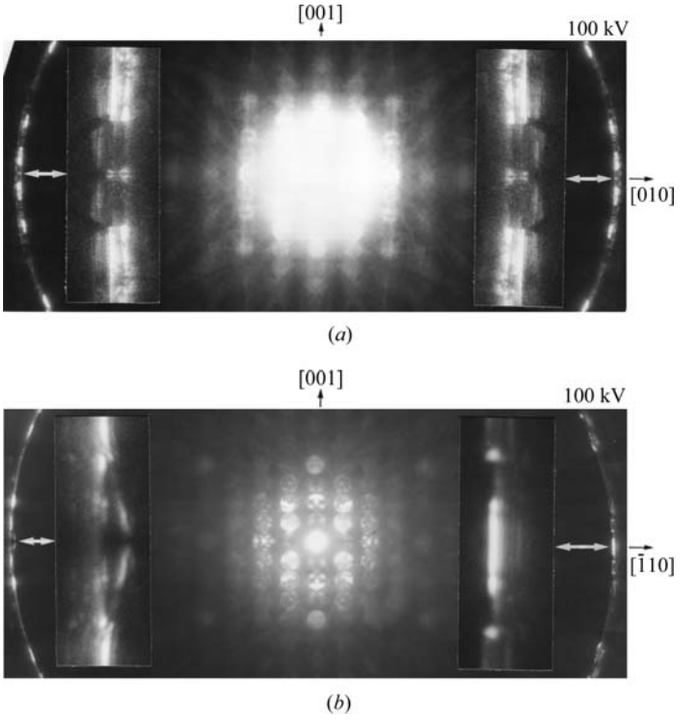

Fig. 2.5.3.14. HOLZ CBED pattern of FeS_2. (*a*) [100] incidence: type *A* dynamical extinction lines are seen clearly in the enlarged insets. (*b*) [110] incidence: a type *A** dynamical extinction line is seen clearly in the enlarged insets.

which satisfies the results obtained at the two crystal orientations is $\bar{4}3m$.

Fig. 2.5.3.16(*e*) shows an ordinary diffraction pattern taken with the [100] incidence at 80 kV. With the help of the lattice parameters and the camera length, the indices of the reflections are given as shown in the figure. The reflections $0kl$ ($k + l = 2n + 1$) are found to be kinematically forbidden. Thus, the lattice type is determined to be *I*.

The space groups having point group $\bar{4}3m$ and lattice type *I* are $I\bar{4}3m$ and $I\bar{4}3d$ from Table 2.5.3.9. Fig. 2.5.3.16(*d*) shows dynamical extinction lines A_2 in the 033 disc and equivalent discs (also broad lines A_2 in the 011 discs). Since the former space group does not give any dynamical extinction lines, the space group is determined to be $I\bar{4}3d$. For confirmation, a CBED pattern which contains the second-order-Laue-zone reflections was taken (Fig. 2.5.3.16*f*). Dynamical extinction lines *A* are seen in the 2,22,22 disc and the equivalent discs. This result also identifies the space group to be not $I\bar{4}3m$ but $I\bar{4}3d$ with the aid of Table 2.5.3.12.

2.5.3.4. Symmetry determination of incommensurate crystals

2.5.3.4.1. General remarks

Incommensurately modulated crystals do not have three-dimensional lattice periodicity. The crystals, however, recover lattice periodicity in a space higher than three dimensions. de Wolff (1974, 1977) showed that one-dimensional displacive and substitutionally modulated crystals can be described as a three-dimensional section of a (3 + 1)-dimensional periodic crystal. Janner & Janssen (1980*a*,*b*) developed a more general approach for describing a modulated crystal with *n* modulations as (3 + *n*)-dimensional periodic crystals ($n = 1, 2, \ldots$). Yamamoto (1982) derived a general structure-factor formula for *n*-dimensionally modulated crystals ($n = 1, 2, \ldots$), which holds for both displacive and substitutionally modulated crystals. Tables of the (3 + 1)-dimensional space groups for one-dimensional incommensurately modulated crystals were given by de Wolff *et al.* (1981), where the wavevector of the modulation was assumed to lie in the

WP symmetry is 3*m* (*b*). (*c*, *d*) [100] incidence at 80 kV: the WP symmetry is 2*mm* (*c*) and the projection WP symmetry is 4*mm* (*d*). Dynamical extinction lines A_2 and A_3 are seen (*d*). The point group is determined to be $\bar{4}3m$. (*e*) Spot diffraction pattern taken with the [100] incidence at 80 kV shows the absence of 0*kl* reflections. The lattice type is determined to be *I*. (*f*) [100] incidence at 100 kV: dynamical extinction lines *A* in HOLZ reflections confirm the existence of a glide plane. The space group is determined to be $I\bar{4}3d$.

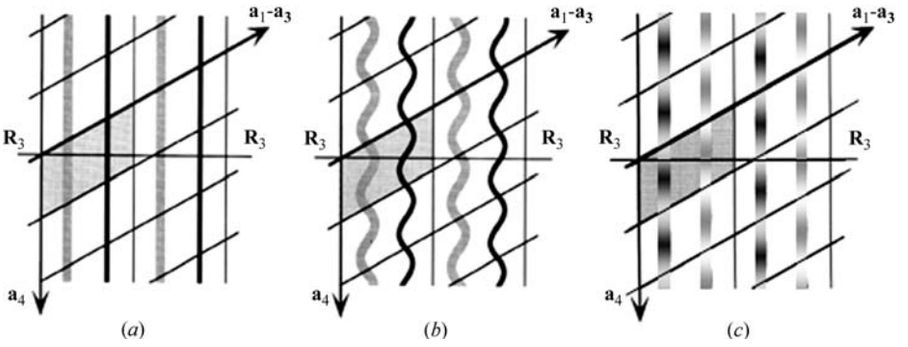

Fig. 2.5.3.17. The (3 + 1)-dimensional description of one-dimensionally modulated crystals. Atoms are shown as strings along the fourth direction $\mathbf{a}_4$. (*a*) No modulation, shown as straight strings. (*b*) Displacive modulation, shown as wavy strings. (*c*) Amplitude modulation with varying-density strings.

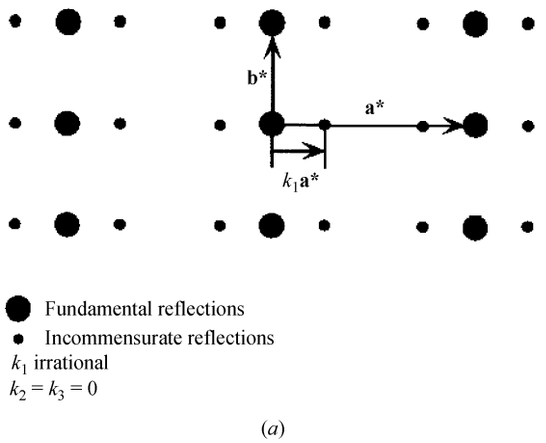
Tanaka (1993) clarified theoretically the interrelation between the symmetries of CBED patterns and the (3 + 1)-dimensional point-group symbols for incommensurately modulated crystals and verified experimentally the theoretical results for $Sr_2Nb_2O_7$ and Mo_8O_{23}. Terauchi *et al.* (1994) investigated dynamical extinction for the (3 + 1)-dimensional space groups. They clarified that approximate dynamical extinction lines appear in CBED discs of the reflections caused by incommensurate modulations when the amplitudes of the incommensurate modulation waves are small. They tabulated the dynamical extinction lines appearing in the CBED discs for all the (3 + 1)-dimensional space groups of the incommensurately modulated crystals. The tables were stored in the British Library Document Supply Centre as Supplementary Publication No. SUP 71810 (65 pp.). They showed an example of the dynamical extinction lines obtained from $Sr_2Nb_2O_7$. The point- and space-group determinations of the (3 + 1)-dimensional crystals are described compactly in the book by Tanaka *et al.* (1994, pp. 156–205).



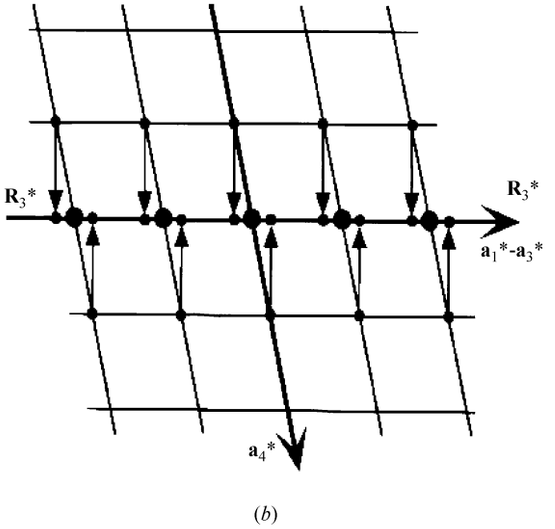


Fig. 2.5.3.18. (*a*) Schematic diffraction pattern from a modulated crystal. As an example, the wave number vector of modulation is assumed to be $k_1\mathbf{a}^*$, k_1 being an irrational number. Large and small spots denote fundamental and incommensurate reflections, respectively. (*b*) Incommensurate reflections are obtained by a projection of the Fourier transform of a (3 + 1)-dimensional periodic structure.

Fig. 2.5.3.17 illustrates (3 + 1)-dimensional descriptions of a crystal structure without modulation (*a*), a one-dimensional displacive modulated structure (*b*) and a one-dimensional substitutionally modulated structure (*c*). The arrows labelled $\mathbf{a}_1$–$\mathbf{a}_3$ (**a**, **b** and **c**) and $\mathbf{a}_4$ indicate the (3 + 1)-dimensional crystal axes. The horizontal line labelled $\mathbf{R}_3$ represents the three-dimensional space (external space). In the (3 + 1)-dimensional description, an atom is not located at a point as in the three-dimensional space, but extends as a string along the fourth direction $\mathbf{a}_4$ perpendicular to the three-dimensional space $\mathbf{R}_3$. The shaded parallelogram is a unit cell in the (3 + 1)-dimensional space. The unit cell contains two atom strings in this case. In the case of no modulations, the atoms are shown as straight strings, as shown in Fig. 2.5.3.17(*a*). For a displacive modulation, atoms are expressed by wavy strings periodic along the fourth direction $\mathbf{a}_4$ as shown in Fig. 2.5.3.17(*b*). The width of the atom strings indicates the spread of the atoms in $\mathbf{R}_3$. The atom positions of the modulated structure in $\mathbf{R}_3$ are given as a three-dimensional ($\mathbf{R}_3$) section of the atom strings in the (3 + 1)-dimensional space. A substitutional modulation, which is described by a modulation of the atom form factor, is expressed by atom strings with a density modulation along the direction $\mathbf{a}_4$ as shown in Fig. 2.5.3.17(*c*).

The diffraction vector **G** is written as

$$\mathbf{G} = h_1\mathbf{a}^* + h_2\mathbf{b}^* + h_3\mathbf{c}^* + h_4\mathbf{k},$$

where a set of $h_1h_2h_3h_4$ is a (3 + 1)-dimensional reflection index, and **a***, **b*** and **c*** are the reciprocal-lattice vectors of the real-lattice vectors **a**, **b** and **c** of the average structure. The modulation vector **k** is written as

$$\mathbf{k} = k_1\mathbf{a}^* + k_2\mathbf{b}^* + k_3\mathbf{c}^*,$$

where one coefficient k_i (i = 1–3) is an irrational number and the others are rational. Fig. 2.5.3.18(*a*) shows a diffraction pattern of a crystal with an incommensurate modulation wavevector $k_1\mathbf{a}^*$ (k_2 and k_3 = 0). Large and small black spots show the fundamental reflections and incommensurate reflections, respectively, only the first-order incommensurate reflections being shown. It

should be noted that the diffraction pattern of a modulated crystal is obtained by a projection of the Fourier transform of the (3 + 1)-dimensional periodic structure. Fig. 2.5.3.18(*b*) is assumed to be the Fourier transform of Fig. 2.5.3.17(*b*). Incommensurate reflections are obtained by a projection of the reciprocal-lattice points onto $\mathbf{R}_3^*$.

The displacive modulation is expressed by the atom displacement u_i^μ with x_4. The structure factor $F(h_1h_2h_3h_4)$ for the (3 + 1)-dimensional crystal with a displacive modulation is given by de Wolff (1974, 1977) as follows:

$$F(h_1h_2h_3h_4) = \sum_{\mu=1}^{N} f_\mu \exp[2\pi i(h_1\bar{x}_1^\mu + h_2\bar{x}_2^\mu + h_3\bar{x}_3^\mu)] \times \int_0^1 \exp\left\{2\pi i\left[\sum_{i=1}^{3}(h_i + h_4k_i)u_i^\mu + h_4\bar{x}_4^\mu\right]\right\} \mathrm{d}\bar{x}_4^\mu, \tag{2.5.3.6}$$

where

$$\bar{x}_4^\mu = (\bar{x}_1^\mu + n_1)k_1 + (\bar{x}_2^\mu + n_2)k_2 + (\bar{x}_3^\mu + n_3)k_3.$$

f_μ and $\bar{x}_i^\mu (i = 1\text{–}3)$ are, respectively, the atom form factor and the ith component of the position of the μth atom in the unit cell of the average structure. The symbol u_i^μ is the ith component of the displacement of the μth atom. Since the atom in the (3 + 1)-dimensional space is continuous along $\mathbf{a}_4$ and discrete along $\mathbf{R}_3$, the structure factor is expressed by summation in $\mathbf{R}_3$ and integration along $\mathbf{a}_4$ as seen in equation (2.5.3.6). The integration implies that the sum for the atoms with displacements is taken over the infinite number of unit cells of the average structure. That is, equation (2.5.3.6) is the structure factor for a unit cell with the lattice parameter of an infinite length in $\mathbf{R}_3$ along the direction of the modulation wavevector $\mathbf{k}$.

CBED patterns are obtained from a finite area of a specimen crystal. For the symmetry analysis of CBED patterns obtained from modulated structures, the effect of the finite size was considered by Terauchi & Tanaka (1993). The integration over a unit-cell length along $\mathbf{a}_4$ in equation (2.5.3.6) is rewritten in the following way with the summation over a finite number of three-dimensional sections of the atom strings:

$$F'(h_1h_2h_3h_4) = \sum_{\mu=1}^{N} f_\mu \exp[2\pi i(h_1\bar{x}_1^\mu + h_2\bar{x}_2^\mu + h_3\bar{x}_3^\mu)] \times \sum_{n_1}\sum_{n_2}\sum_{n_3} \exp\left\{2\pi i\left[\sum_{i=1}^{3}(h_i + h_4k_i)u_i^\mu + h_4\bar{x}_4^\mu\right]\right\}, \tag{2.5.3.7}$$

where $N_1 < n_1 \le N_1'$, $N_2 < n_2 \le N_2'$ and $N_3 < n_3 \le N_3'$, $N' = (N_1' - N_1)(N_2' - N_2)(N_3' - N_3)$ being the number of unit cells of the average structure included in a specimen volume from which CBED patterns are taken.

The substitutional modulation arises from a periodic variation of the site-occupation probability of the atoms. This modulation is expressed by a modulation of the atom form factor f_μ with x_4. The structure factor $F'(h_1h_2h_3h_4)$ for a finite-size crystal is written as

$$F'(h_1h_2h_3h_4) = \sum_{\mu=1}^{N} \exp[2\pi i\,(h_1x_1^\mu + h_2x_2^\mu + h_3x_3^\mu)] \times \sum_{n_1}\sum_{n_2}\sum_{n_3} f_\mu \exp(2\pi i h_4 x_4^\mu), \tag{2.5.3.8}$$

where $x_4^\mu = \sum_i (x_i^\mu + n_i)k_i$.

2.5.3.4.2. Point-group determination

The symmetries of the CBED patterns can be determined by examination of the symmetries of the structure factor $F'(h_1h_2h_3h_4)$ in equations (2.5.3.7) or (2.5.3.8). We consider a displacive modulated structure, which has a modulation wavevector $\mathbf{k} = k_3\mathbf{c}^*$ and belongs to (3 + 1)-dimensional space group $P^{P2/m}_{1\ \bar{1}}$. This space-group symbol implies the following.

(1) The modulation wavevector $\mathbf{k}$ exists inside the first Brillouin zone of the average structure (P).

(2) The average structure belongs to space group $P2/m$, the twofold rotation axis being parallel to the c axis.

(3) The symmetry subsymbol 1, which is written beneath symmetry symbol 2, indicates that the modulation wavevector $\mathbf{k}$ is transformed into itself by symmetry operation 2 of the average structure. The symmetry subsymbol beneath symmetry symbol m indicates that the wavevector $\mathbf{k}$ is transformed into $-\mathbf{k}$ by symmetry operation m. The modulated structure has a twofold rotation axis, which is common to the average structure, but does not have mirror symmetry, which is possessed by the average structure.

For the twofold rotation axis (symbol 2) of this space group, the structure factor $F'(h_1h_2h_3h_4)$ is written as

$$\begin{aligned} F'(h_1h_2h_3h_4) &= \sum_{\mu=1}^{N} f_\mu \exp[2\pi i(h_1\bar{x}_1^\mu + h_2\bar{x}_2^\mu + h_3\bar{x}_3^\mu)] \\ &\quad \times \sum_{n_3} \exp\{2\pi i[h_1u_1^\mu + h_2u_2^\mu + (h_3 + h_4k_3)u_3^\mu + h_4\bar{x}_4^\mu]\} \\ &\quad + \sum_{\mu=1}^{N} f_\mu \exp[2\pi i(-h_1\bar{x}_1^\mu - h_2\bar{x}_2^\mu + h_3\bar{x}_3^\mu)] \\ &\quad \times \sum_{n_3} \exp\{2\pi i[-h_1u_1^\mu - h_2u_2^\mu + (h_3 + h_4k_3)u_3^\mu + h_4\bar{x}_4^\mu]\}, \end{aligned} \tag{2.5.3.9}$$

where $x_4^\mu = (x_3^\mu + n_3)k_3$. It is found from equation (2.5.3.9) that two structure factors $F'(h_1h_2h_3h_4)$ and $F'(\bar{h}_1\bar{h}_2h_3h_4)$ are the same when reflections $h_1h_2h_3h_4$ and $\bar{h}_1\bar{h}_2h_3h_4$ are equivalent with respect to the twofold rotation axis of the average structure. Thus, not only fundamental reflections ($h_4 = 0$) from the average structure but also the satellite reflections ($h_4 \neq 0$) from the incommensurate structure show twofold rotation symmetry about the c^* axis.

For the mirror plane (symbol m), the structure factor is written in a similar manner to the case of the twofold rotation axis. It is found that $F'(h_1h_2h_3h_4)$ is not equal to $F'(h_1h_2\bar{h}_3\bar{h}_4)$ for the incommensurate reflections $h_4 \neq 0$. Hence, the incommensurate reflections do not show mirror symmetry with respect to the mirror plane of the average structure. For the fundamental reflections ($h_4 = 0$), $F'(h_1h_2h_3h_4)$ is equal to $F'(h_1h_2\bar{h}_3\bar{h}_4)$, indicating the existence of mirror symmetry. It should be noted that the mirror symmetry can be destroyed by the dynamical diffraction effect between the fundamental and incommensurate reflections. In most modulated structures, however, the amplitude of the modulation wave u_i^μ is not so large as to destroy the symmetry of the fundamental reflections. Thus, the fundamental

Table 2.5.3.13. *Wavevectors, point- and space-group symbols and CBED symmetries of one-dimensionally modulated crystals*

Wavevector transformation	Point-group symbol	Symmetry of incommensurate reflection	Space-group symbol	Dynamical extinction lines
$\mathbf{k} \rightarrow \mathbf{k}$	1	Same symmetry as average structure	1, s (1/2), t ($\pm$1/3), q ($\pm$1/4), h ($\pm$1/6)	Yes for s, q and h
$\mathbf{k} \rightarrow -\mathbf{k}$	$\bar{1}$	No symmetry	$\bar{1}$	No

reflections ought to show the symmetry of the average structure, while the incommensurate reflections lose the symmetry.

The problem of the finite size of the illuminated area is discussed using equations (2.5.3.7) and (2.5.3.8) in a paper by Terauchi & Tanaka (1993) and in the book by Tanaka *et al.* (1994, pp. 156–205). The results are as follows: Even if the size and position of an illuminated specimen area are changed, the intensity distribution in a CBED pattern changes but the symmetry of the pattern does not. To obtain the symmetries of incommensurate crystals, it is not necessary to take CBED patterns from an area whose diameter is larger than the period of the modulated structure. The symmetries of the modulated structure can appear when more than one unit cell of the average structure is illuminated for displacive modulations. For substitutional modulations, a specimen volume that produces the average atom form factor is needed, namely a volume of about 1 nm diameter area and 50 nm thick.

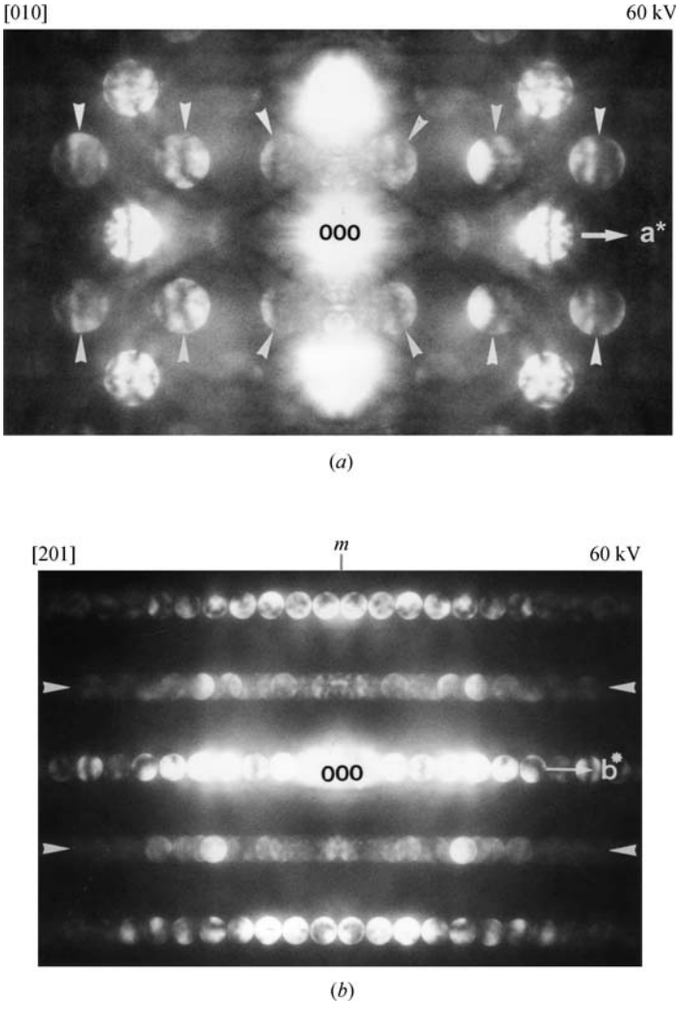

Fig. 2.5.3.19. CBED patterns of the incommensurate phase of $Sr_2Nb_2O_7$ taken at 60 kV. (*a*) [010] incidence: fundamental reflections show a mirror symmetry perpendicular to the a^* axis but incommensurate reflections do not [symmetry ($^m_1$)]. (*b*) [201] incidence: incommensurate reflections show mirror symmetry perpendicular to the b^* axis [symmetry ($^m_1$)]. The wave number vector of the modulation is $\mathbf{k} = (\frac{1}{2} - \delta)\mathbf{a}^*$.

Table 2.5.3.13 shows the point-group symmetries (third column) of the incommensurate reflections for the two point-group subsymbols. For symmetry subsymbol 1, both the fundamental and incommensurate reflections show the symmetries of the average structure. For symmetry subsymbol $\bar{1}$, the fundamental reflections show the symmetries of the average structure but the incommensurate reflections do not have any symmetry. These facts imply that the symmetries of the incommensurate reflections are determined by the point group of the average structure and the modulation wavevector **k**. In other words, observation of the symmetries of the incommensurate reflections is not necessary for the determination of the point groups, although it can ascertain the point groups of the modulated crystals.

An example of point-group determination is shown for the incommensurate phase of $Sr_2Nb_2O_7$. Many materials of the $A_2B_2O_7$ family undergo phase transformations from space group $Cmcm$ to $Cmc2_1$ and further to $P2_1$ with decreasing temperature. An incommensurate phase appears between the $Cmc2_1$ phase and the $P2_1$ phase. $Sr_2Nb_2O_7$ transforms at 488 K from the $Cmc2_1$ phase into the incommensurate phase with a modulation wavevector $\mathbf{k} = (\frac{1}{2} - \delta)\mathbf{a}^*$ (δ = 0.009–0.023) but does not transform into the $P2_1$ phase. The space group of $Sr_2Nb_2O_7$ was reported as $P^{C\,mc2_1}_{\bar{1}s\bar{1}}$ (Yamamoto, 1988). (Since the space-group notation $Cmc2_1$ is broadly accepted, the direction of the modulation is taken as the a axis.) The point group of the phase is $^{mm2}_{\bar{1}\,\bar{1}\,1}$. The modulation wavevector **k** is transformed to $-\mathbf{k}$ by the mirror symmetry operation perpendicular to the a axis ($^m_1$) and by the twofold rotation symmetry operation about the c axis ($^2_1$). The wavevector is transformed into itself by the mirror symmetry operation perpendicular to the b axis ($^m_1$).

Fig. 2.5.3.19(*a*) shows a CBED pattern of the incommensurate phase of $Sr_2Nb_2O_7$ taken with the [010] incidence at an accelerating voltage of 60 kV. The reflections indicated by arrowheads are the incommensurate reflections. Other reflections are the fundamental reflections. Since the pattern is produced by the interaction of the reflections in the zeroth-order Laue zone, symmetry operations ($^m_1$) and ($^2_1$) act the same. These symmetries are confirmed by the fact that the fundamental reflections show mirror symmetry perpendicular to the a^* axis (twofold rotation symmetry about the c^* axis) but the incommensurate reflections do not. Fig. 2.5.3.19(*b*) shows a CBED pattern of the incommensurate phase of $Sr_2Nb_2O_7$ taken with the [201] incidence at 60 kV. The reflections in the two rows indicated by arrowheads are the incommensurate reflections and the others are the fundamental reflections. Symmetry symbol ($^m_1$) implies that both the fundamental and incommensurate reflections display mirror symmetry perpendicular to the b^* axis. Fig. 2.5.3.19(*b*) exactly exhibits the symmetry.

2.5.3.4.3. Space-group determination

Table 2.5.3.13 shows the space-group symbols (fourth column) of the modulated crystals. When a glide (screw) component τ_4 between the modulation waves of two atom rows is 0, 1/2, $\pm$1/3, $\pm$1/4 or $\pm$1/6, symbol 1, s, t, q or h is given, respectively (de Wolff *et al.*, 1981). Such glide components are allowed for point-group symmetry 1 but are not for point-group symmetry $\bar{1}$. Dynamical

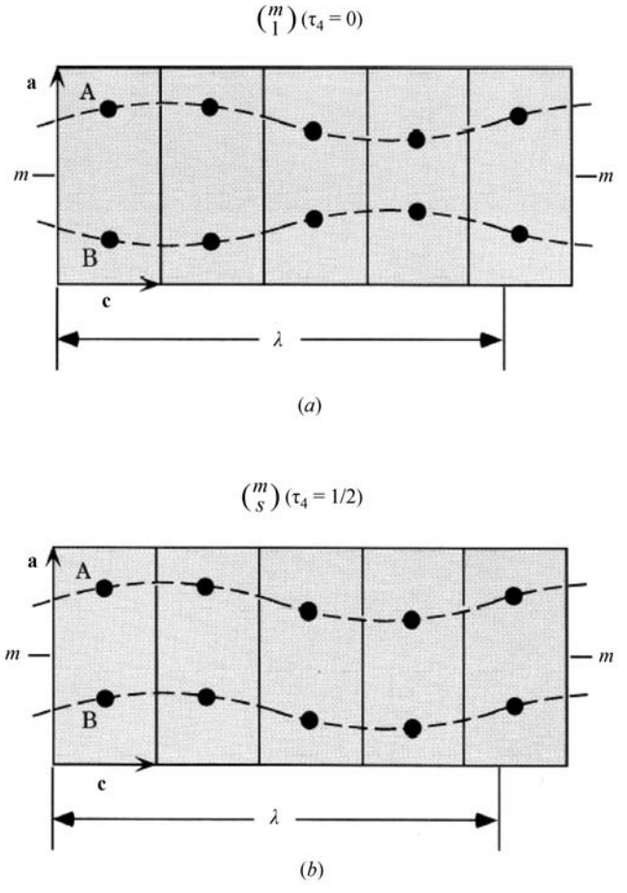

Fig. 2.5.3.20. (*a*) Mirror symmetry of modulation waves $\binom{m}{1}$ $\tau_4 = 0$. (*b*) Glide symmetry of modulation waves $\binom{m}{s}$ $\tau_4 = \frac{1}{2}$. The wave number vector of modulation is $k_3\mathbf{c}^*$.

extinction occurs for glide components *s*, *q* and *h* but does not for glide component *t*. When the average structure does not have a glide component, dynamical extinction due to a glide component τ_4 appears in odd-order incommensurate reflections. When the average structure has a glide component, dynamical extinction due to a glide component τ_4 appears in incommensurate reflections with $h_i + h_4 = 2n + 1$, where h_i and h_4 are the reflection indices for the average structure and incommensurate structure, respectively. Details are given in the paper by Terauchi *et al.* (1994).

Fig. 2.5.3.20(*a*) illustrates mirror symmetry $\binom{m}{1}$ between atom rows A and B, which is perpendicular to the *b* axis with no glide component ($\tau_4 = 0$). Here, the wave number vector of the modulation is assumed to be $\mathbf{k} = k_3\mathbf{c}^*$ following the treatment of de Wolff *et al.* (1981). Fig. 2.5.3.20(*b*) illustrates glide symmetry $\binom{m}{s}$ with a glide component $\tau_4 = \frac{1}{2}$. The structure factor $F(h_1h_2h_3h_4)$ is written for the glide plane $\binom{m}{s}$ of an infinite incommensurate crystal as

$$\begin{aligned}
&F(h_1h_2h_3h_4)\\
&= \sum_{\mu=1}^{N} f_\mu \exp[2\pi i(h_1\bar{x}_1^\mu + h_2\bar{x}_2^\mu + h_3\bar{x}_3^\mu)]\\
&\quad \times \int_0^1 \exp\{2\pi i[h_1u_1^\mu + h_2u_2^\mu + (h_3 + h_4k_3)u_3^\mu + h_4\bar{x}_4^\mu]\}\,\mathrm{d}\bar{x}_4^\mu\\
&\quad + \exp(h_4\pi i)\sum_{\mu=1}^{N} f_\mu \exp[2\pi i(h_1\bar{x}_1^\mu - h_2\bar{x}_2^\mu + h_3\bar{x}_3^\mu)]\\
&\quad \times \int_0^1 \exp\{2\pi i[h_1u_1^\mu - h_2u_2^\mu + (h_3 + h_4k_3)u_3^\mu + h_4\bar{x}_4^\mu]\}\,\mathrm{d}\bar{x}_4^\mu.
\end{aligned} \tag{2.5.3.10}$$

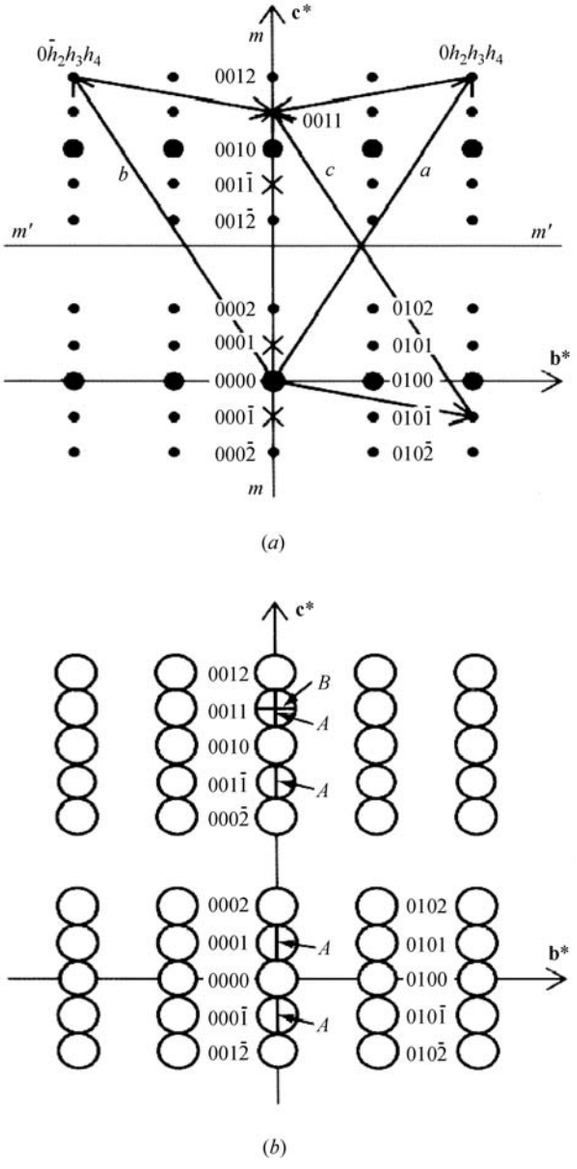

Fig. 2.5.3.21. (*a*) *Umweganregung* paths *a*, *b* and *c* to the 0011 forbidden reflection. (*b*) Expected dynamical extinction lines are shown, the 0011 reflection being excited. The wave number vector of modulation is $k_3\mathbf{c}^*$.

Thus, the following phase relations are obtained between the two structure factors:

$$\begin{aligned}
F(h_1h_2h_3h_4) &= F(h_1\bar{h}_2h_3h_4) \quad \text{for } h_4 \text{ even},\\
F(h_1h_2h_3h_4) &= -F(h_1\bar{h}_2h_3h_4) \quad \text{for } h_4 \text{ odd}.
\end{aligned} \tag{2.5.3.11}$$

These relations are analogous to the phase relations between the two structure factors for an ordinary three-dimensional crystal with a glide plane. The relations imply that dynamical extinction occurs for the glide planes and screw axes of the (3 + 1)-dimensional crystal with an infinite dimension along the direction of the incommensurate modulation wavevector **k**. Terauchi *et al.* (1994) showed that approximate dynamical extinction occurs for an incommensurate crystal of finite dimension.

Fig. 2.5.3.21(*a*) and (*b*) illustrate a spot diffraction pattern and a CBED pattern, respectively, expected from a modulated crystal with a (3 + 1)-dimensional space group $P^{P2mm}_{\bar{1}s\bar{1}}$ ($\mathbf{k} = k_3\mathbf{c}^*$) at the [100] incidence. The large and small spots in Fig. 2.5.3.21(*a*) designate the fundamental ($h_4 = 0$) and incommensurate reflections ($h_4 \neq 0$), respectively. The $00h_3h_4$ (h_4 = odd) reflections

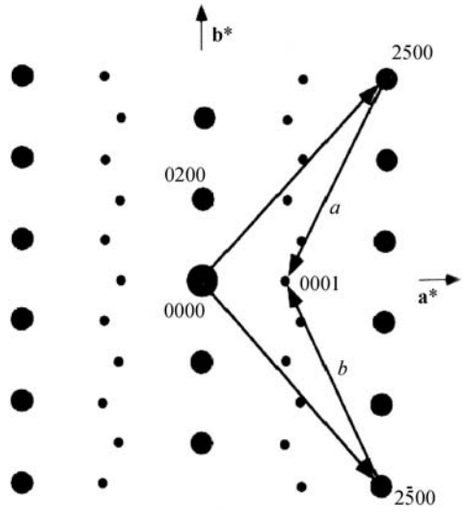

Fig. 2.5.3.22. Schematic diffraction pattern at the [001] incidence of $Sr_2Nb_2O_7$. *Umweganregung* paths *a* and *b via* fundamental reflections to the 0001 incommensurate reflection. Large and small spots denote fundamental and incommensurate reflections, respectively. The wave number vector of modulation is $\mathbf{k} = (\frac{1}{2} - \delta)\mathbf{a}^*$.

shown by crosses are kinematically forbidden by the glide plane (^m_s) perpendicular to the *b* axis. *Umweganregung* paths *a*, *b* and *c* in the ZOLZ to a kinematically forbidden reflection are drawn. The two paths *a* and *b* are geometrically equivalent with respect to the line *m*–*m* perpendicular to the *b* axis. Since every *Umweganregung* path to a kinematically forbidden reflection contains an odd number of $F(0h_{2,i}h_{3,i}h_{4,i})$ with odd $h_{4,i}$, the following equation is obtained.

$$F(0h_{2,1}h_{3,1}h_{4,1})F(0h_{2,2}h_{3,2}h_{4,2})\ldots F(0h_{2,n}h_{3,n}h_{4,n}) \quad \text{for path } a$$
$$= -F(0\bar{h}_{2,1}h_{3,1}h_{4,1})F(0\bar{h}_{2,2}h_{3,2}h_{4,2})\ldots F(0\bar{h}_{2,n}h_{3,n}h_{4,n})$$
$$\text{for path } b, \qquad (2.5.3.12)$$

where $\sum_{i=1}^{n} h_{2,i} = 0$, $\sum_{i=1}^{n} h_{3,i} = h_3$ and $\sum_{i=1}^{n} h_{4,i} = h_4$ (h_4 = odd).

When reflection $00h_3h_4$ (h_4 = odd) is exactly excited, the two paths *a* and *c* are symmetric with respect to the bisector m'–m' of the diffraction vector of the reflection and have the same excitation error. The waves passing through these paths have the same amplitude but different signs. Thus the following relation is obtained.

$$F(0h_{2,1}h_{3,1}h_{4,1})F(0h_{2,2}h_{3,2}h_{4,2})\ldots F(0h_{2,n}h_{3,n}h_{4,n}) \quad \text{for path } a$$
$$= -F(0\bar{h}_{2,n}h_{3,n}h_{4,n})F(0\bar{h}_{2,n-1}h_{3,n-1}h_{4,n-1})\ldots F(0\bar{h}_{2,1}h_{3,1}h_{4,1})$$
$$\text{for path } c, \qquad (2.5.3.13)$$

where $\sum_{i=1}^{n} h_{2,i} = 0$, $\sum_{i=1}^{n} h_{3,i} = h_3$ and $\sum_{i=1}^{n} h_{4,i} = h_4$ (h_4 = odd).

Therefore, dynamical extinction occurs in kinematically forbidden reflections of incommensurate crystals. Fig. 2.5.3.21(*b*) schematically shows the extinction lines in odd-order incommensurate reflections, where the 0011 reflection is exactly excited.

We consider the dynamical extinction from $Sr_2Nb_2O_7$ whose space group is $P^{Cmc2_1}_{\bar{1}\,s\,\bar{1}}$. The glide plane (^c_s) is perpendicular to the *b* axis with a glide vector $(\mathbf{c} + \mathbf{a}_4)/2$. The wave number vector of the modulation is $\mathbf{k} = (\frac{1}{2} - \delta)\mathbf{a}^*$. (Since space-group notation $Cmc2_1$ is broadly accepted, the direction of the modulation is taken as the *a* axis.) The reflections $h_10h_3h_4$ with $h_3 + h_4 = 2n + 1$ (n = integer) are kinematically forbidden. Fig. 2.5.3.22 shows a schematic diffraction pattern of $Sr_2Nb_2O_7$ at the [001] incidence. The large

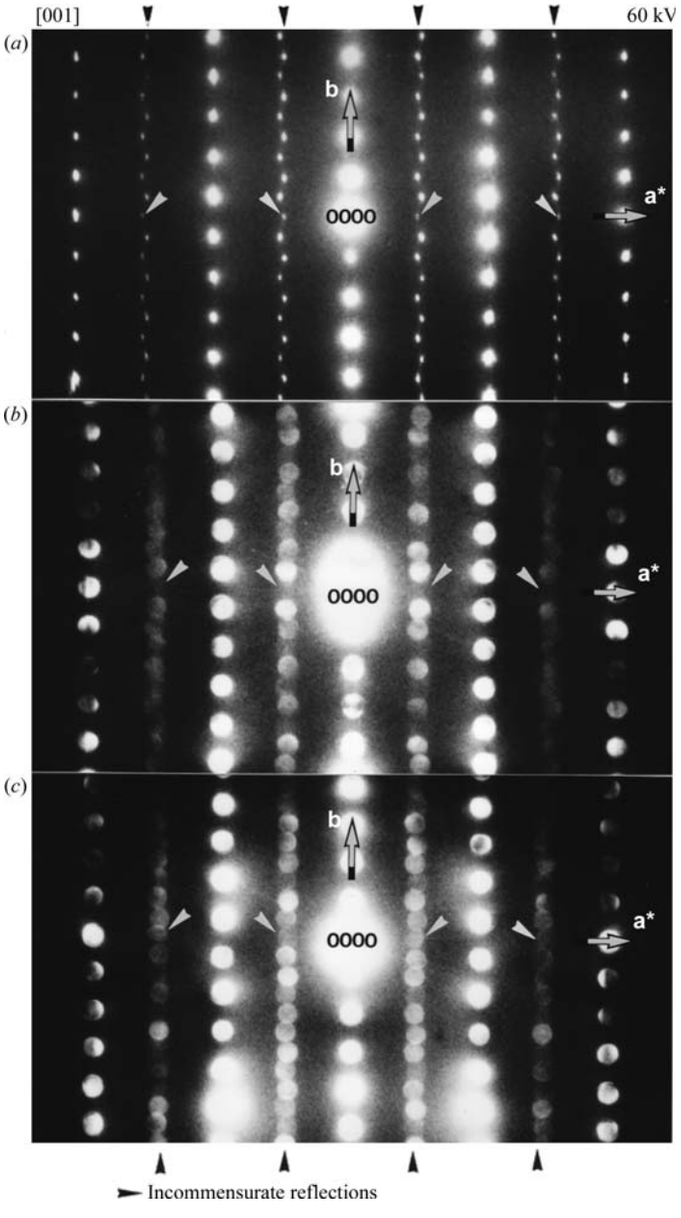

Fig. 2.5.3.23. Diffraction pattern of $Sr_2Nb_2O_7$ taken with [001] incidence at 60 kV. (*a*) Spot diffraction pattern. Kinematically forbidden 0001 and 200$\bar{1}$ incommensurate reflections exhibit definite intensity. (*b*) Zone-axis CBED pattern showing dynamical absence of 0001 and 200$\bar{1}$ incommensurate reflections. (*c*) CBED pattern taken at an incidence with a small tilt from the zone axis to the *b** direction. The kinematically forbidden incommensurate reflections have intensity due to incomplete cancellation of two waves through the *Umweganregung* paths. The wave number vector of modulation is $\mathbf{k} = (\frac{1}{2} - \delta)\mathbf{a}^*$.

and small spots indicate the fundamental (h_4 = 0) and incommensurate ($h_4 \neq 0$) reflections, respectively. *Umweganregung* paths *a* and *b* to the kinematically forbidden 0001 reflection *via* a fundamental reflection in the ZOLZ are drawn.

Fig. 2.5.3.23(*a*) shows a spot diffraction pattern of the incommensurate phase of $Sr_2Nb_2O_7$ taken with the [001] incidence at 60 kV. The incommensurate reflections in which dynamical extinction lines appear at this incidence are those with the indices $h_{1,\text{even}}00h_{4,\text{odd}}$ because $h_3 = 0$ and $h_1 + h_2 = 2n$ due to the lattice type *C* of the average structure.

The reflections in the four columns indicated by black arrowheads are incommensurate reflections. The reflections 0001, 000$\bar{1}$, 200$\bar{1}$ and $\bar{2}$001 designated by white arrowheads are kinematically forbidden but exhibit certain intensities, which are caused by multiple diffraction. Other reflections are fundamental reflections due to the average structure.

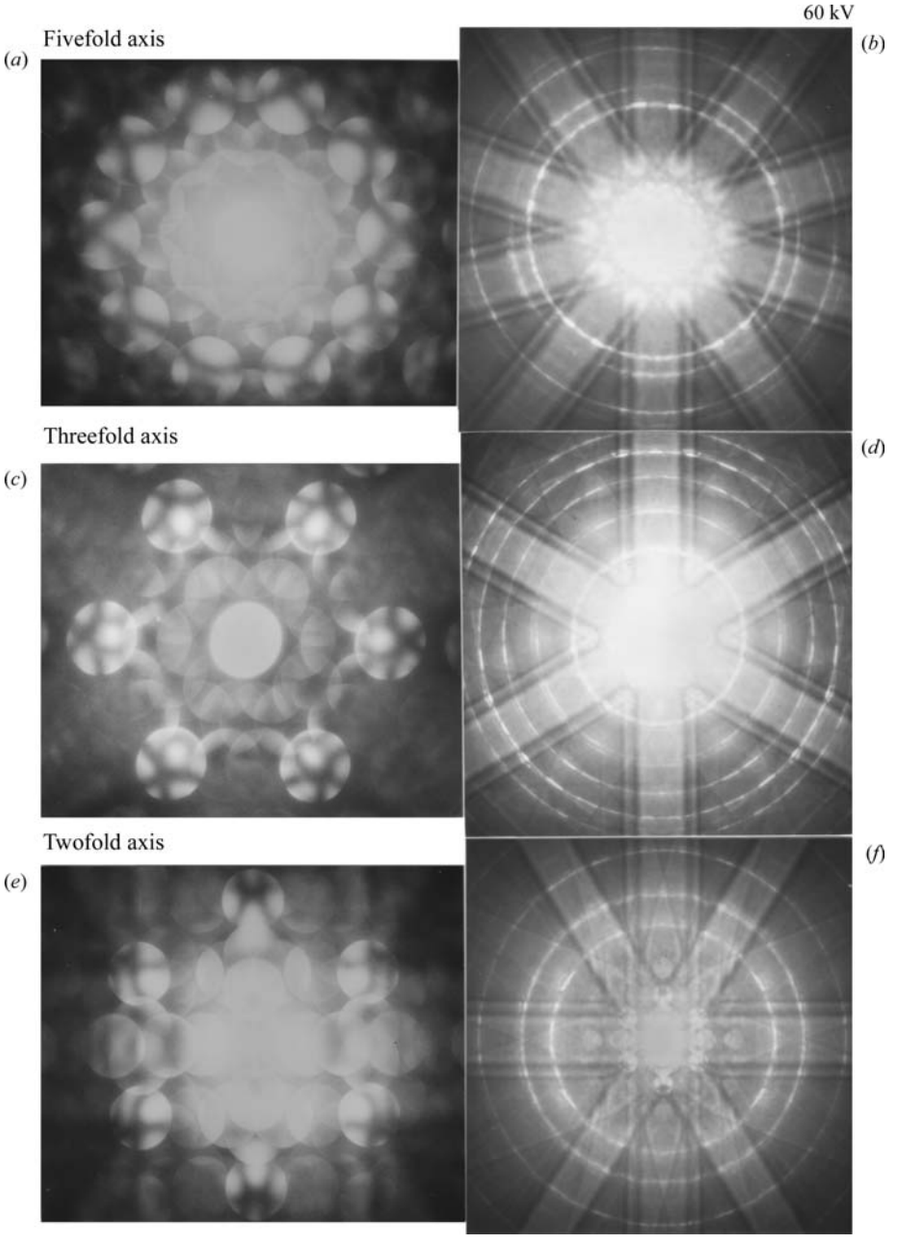

Fig. 2.5.3.24. Three pairs of ZOLZ [(*a*), (*c*) and (*e*)] and HOLZ [(*b*), (*d*) and (*f*)] CBED patterns taken at 60 kV from an area of $Al_{74}Mn_{20}Si_6$ about 3 nm in diameter and about 10 nm thick (Tanaka, Terauchi, Suzuki *et al.*, 1987). Symmetries are (*a*) 10*mm*, (*b*) 5*m*, (*c*) 6*mm*, (*d*) 3*m*, (*e*) 2*mm* and (*f*) 2*mm*.

Fig. 2.5.3.23(*b*) shows a CBED pattern corresponding to Fig. 2.5.3.23(*a*), taken from a specimen area 3 nm in diameter. The excitation errors of two *Umweganregung* paths *a* and *b* are the same at this electron incidence. The reflections 0001, $000\bar{1}$, $200\bar{1}$ and $\bar{2}001$ indicated by white arrowheads show no intensity. Dynamical extinction does not appear as a line in the present case because the width of the extinction line exceeds the disc size of the reflections. Fig. 2.5.3.23(*c*) shows a CBED pattern taken at an incidence slightly tilted toward the b^* axis from that for Fig. 2.5.3.23(*b*) or the [001] zone-axis incidence. The excitation errors are no longer the same for the two *Umweganregung* paths. Thus, it is seen that the kinematically forbidden reflections indicated by white arrowheads have intensities due to incomplete cancellation of waves coming through different paths, which is an additional proof of the dynamical extinction.

2.5.3.5. Symmetry determination of quasicrystals

2.5.3.5.1. Icosahedral quasicrystals

Penrose (1974) demonstrated that a two-dimensional plane can be tiled with thin and fat rhombi to give a pattern with local fivefold rotational symmetries but with no translational symmetry. Mackay (1982) extended the tiling to three dimensions using acute and obtuse rhombohedra, which also resulted in the acquisition of local fivefold rotational symmetries and in a lack of translational symmetry. The three-dimensional space-filling method was later completed by Ogawa (1985). These studies, however, remained a matter of design or geometrical amusement until Shechtman *et al.* (1984) discovered an icosahedral symmetry presumably with long-range structural order in an alloy of Al_6Mn (nominal composition) using electron diffraction. Since then, the term quasicrystalline order, a new class of structural order with no translational symmetry but long-range structural order, has been coined. Levine & Steinhardt (1984) showed that the quasilattice produces sharp diffraction patterns and succeeded in reproducing almost exactly the diffraction pattern obtained by Shechtman *et al*. (1984) using the Fourier transform of a quasi-periodic icosahedral lattice. When analysing X-ray and electron-diffraction data for a quasicrystal, the diffraction peaks can be successfully indexed by six independent vectors pointing to the vertices of an icosahedron. It was then found that the icosahedral quasicrystal can be described in terms of a regular crystal in six

Table 2.5.3.14. *Diffraction groups and CBED symmetries for two icosahedral point groups*

Point group	Diffraction group	BP	WP	DP	±DP

				m_2	2_Rm_2
				m_v	2_Rm_v
	(Projection) $10mm1_R$	$10mm$	$10mm$	2	21_R
				$2m_vm_2$	21_Rm_v

dimensions (*e.g.* Jarić, 1988). A quasicrystal is produced by the intersection of the six-dimensional crystal with an embedded three-dimensional hyperplane (the cut-and-projection technique).

Addition of several per cent of silicon to Al–Mn alloys caused a great increase in the degree of order of the quasicrystal. Bendersky & Kaufman (1986) prepared such a less-strained quasicrystalline $Al_{71}Mn_{23}Si_6$ alloy and determined its point group. They obtained fairly good zone-axis CBED patterns that showed symmetries of $10mm$, $6mm$ and $2mm$ in the ZOLZ discs and $5m$, $3m$ and $2mm$ in HOLZ rings. From these results, they identified the point group to be centrosymmetric $m\bar{3}\bar{5}$. Figs. 2.5.3.24(*a*)–(*f*) show three pairs of CBED patterns taken from an area about 100 nm thick and about 3 nm in diameter of an $Al_{74}Mn_{20}Si_6$ quasicrystal at an accelerating voltage of 60 kV (Tanaka, Terauchi & Sekii, 1987). This quasicrystal was found to have much better ordering than $Al_{71}Mn_{23}Si_6$. The fact that Kikuchi bands are clearly seen in the HOLZ patterns and the profiles of the bands are symmetric with respect to their centre indicates (Figs. 2.5.3.24*b*, *d* and *f*) that the quasicrystal has sufficiently good quality or highly ordered atomic arrangements to perform reliable symmetry determination. Each pair of CBED patterns consists of a ZOLZ pattern and a HOLZ pattern. The former is produced solely by the interaction of ZOLZ reflections, showing distinct symmetries in several discs.

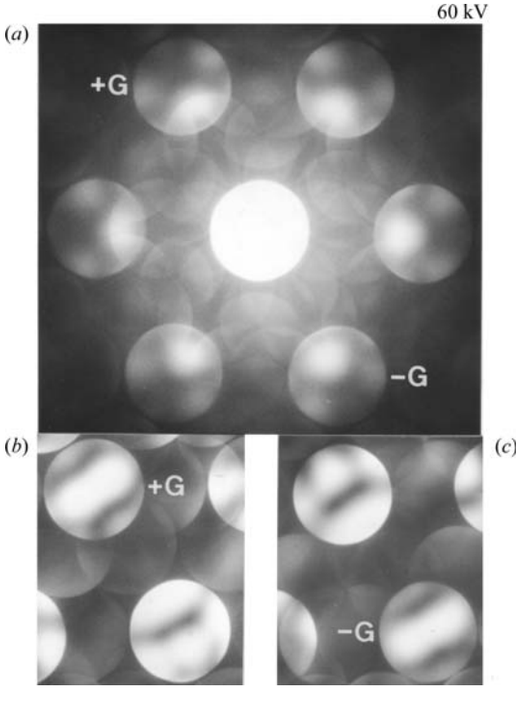

Fig. 2.5.3.25. CBED patterns of $Al_{74}Mn_{20}Si_6$ taken with an electron incidence along the threefold axis. (*a*) Zone-axis pattern showing symmetry $3m$. (*b*,*c*) ±DP showing translational symmetry or 2_R, indicating that the quasicrystal is centrosymmetric.

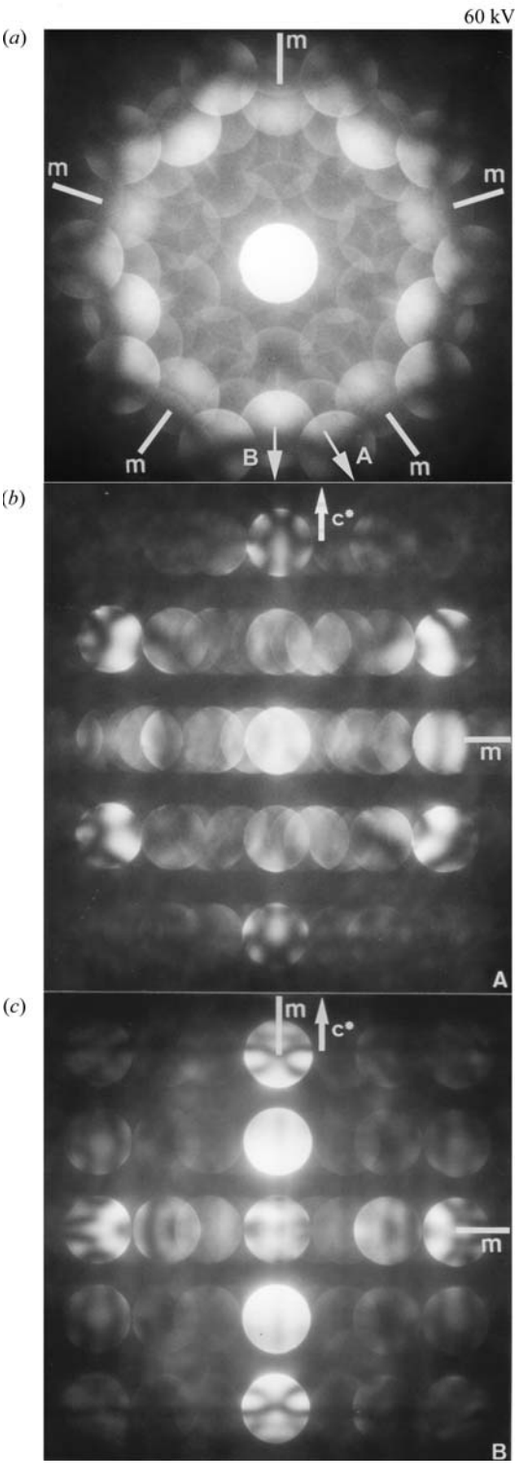

Fig. 2.5.3.26. CBED patterns of metastable $Al_{70}Ni_{15}Fe_{15}$ taken from a 3 nm diameter area. (*a*) Electron incidence along the decagonal axis: symmetry $5m$. (*b*) Electron incidence along direction A indicated in (*a*): symmetry m perpendicular to the decagonal axis. (*c*) Electron incidence along direction B indicated in (*a*): symmetry $2mm$. This alloy is found to be noncentrosymmetric.

The whole pattern of Fig. 2.5.3.24(*a*), formed by ZOLZ reflections, exhibits a tenfold rotation symmetry and two types of mirror symmetry, the resultant symmetry being expressed as

Table 2.5.3.15. *Pentagonal and decagonal point groups constructed by analogy with trigonal and hexagonal point groups*

This table is taken from Saito *et al.* (1992) with the permission of the Japan Society of Applied Physics.

Pentagonal	Decagonal
 5	 10
–	 $\bar{1}0$
 $\bar{5}$	 10/*m*
 5 2	 10 2 2
 5*m*	 10*mm*
–	 $\bar{1}0m2$
 $\bar{5}m$	 10/*mmm*

10*mm*. The whole pattern of Fig. 2.5.3.24(*b*), formed by HOLZ reflections, shows a fivefold rotation symmetry and a type of mirror plane, the resultant symmetry being 5*m*. Figs. 2.5.3.24(*c*) and (*d*) show symmetries 6*mm* and 3*m*, respectively. Figs. 2.5.3.24(*e*) and (*f*) show symmetry 2*mm*. There are two icosahedral point groups, 235 and $m\bar{3}\bar{5}$ (see Table 10.1.4.3 in *IT* A, 2005). The former is noncentrosymmetric with no mirror symmetry but the latter is centrosymmetric. Table 2.5.3.14 shows the diffraction groups expected from these point groups with the incident beam parallel to the fivefold or tenfold axis, and their symmetries appearing in the WP, BP, DP and ±DP. Projection diffraction groups and their symmetries, in which only the interaction between ZOLZ reflections is taken into account, are given in the second row of each pair. Diffraction groups obtained for the other incident-beam directions are omitted because they can be seen in Table 2.5.3.3. The whole-pattern symmetries observed for better-quality images of $Al_{74}Mn_{20}Si_6$ have confirmed the result of Bendersky & Kaufman (1986), *i.e.* the point group $m\bar{3}\bar{5}$. Fig. 2.5.3.25(*a*) shows a zone-axis CBED pattern taken at an electron incidence along the threefold axis. Figs. 2.5.3.25(*b*) and (*c*) show ±DPs taken when tilting the incident beam to excite a low-order strong reflection. The pattern of disc $+G$ agrees with that of disc $-G$ when the former is superposed on the latter with a translation of $-2G$. This symmetry 2_R directly proves that the quasicrystal is centrosymmetric, again confirming the point group as $m\bar{3}\bar{5}$. The lattice type was found to be primitive and no dynamical extinction was observed. Thus, the space group of the alloy was determined to be $Pm\bar{3}\bar{5}$.

Quasicrystals of Al–Mn alloys have been produced by the melt-quenching method and are thermodynamically metastable. Tsai *et al.* (1987) discovered a stable icosahedral phase in $Al_{65}Cu_{20}Fe_{15}$. This alloy has larger grains and is much better quality with less phason strain than $Al_{74}Mn_{20}Si_6$. The discovery of this alloy greatly accelerated the studies of icosahedral quasicrystals. It was found that the lattice type of this phase and of some other Al–Cu–TM (TM = transition metal) alloys is different from that of Al–Mn alloys. That is, Al–Cu–TM alloys display many additional spots in diffraction patterns of twofold rotation symmetry. The patterns were indexed either by all (six) even or all (six) odd, or by a face-centred (*F*) lattice. All the icosahedral quasicrystals known to date belong to the point group $m\bar{3}\bar{5}$; none with the noncentrosymmetric point group 235 have been discovered.

2.5.3.5.2. Decagonal quasicrystals

The first decagonal quasicrystal was found by Bendersky (1985) in an alloy of Al–Mn using the electron-diffraction technique. This phase has periodic order parallel to the tenfold axis, like ordinary crystals, but has quasiperiodic long-range structural order perpendicular to the tenfold axis. The diffraction peaks were indexed by one vector parallel to the tenfold axis and four independent vectors pointing to the vertices of a decagon. Thus, the decagonal quasicrystal is described in terms of a regular crystal in five dimensions.

Two space groups, $P10_5/m$ and $P10_5/mmc$, have been proposed for the alloy by Bendersky (1986) and by Yamamoto & Ishihara (1988), respectively. However, owing to the low quality of the specimens, CBED examination of the alloy could not determine whether the point group is 10/*m* or 10/*mmm*. Furthermore, identification of the space-group symmetry was not possible because observation of dynamical extinction caused by the screw axis and/or the glide plane was difficult. The Al–*M* (*M* = Mn, Fe, Ru, Pt, Pd, ...) quasicrystals found at an early stage were thermodynamically metastable. Subsequently, thermodynamically stable decagonal phases were discovered in the ternary alloys $Al_{65}Cu_{15}Co_{20}$ (Tsai *et al.*, 1989*a*), $Al_{65}Cu_{20}Co_{15}$ (He *et al.*, 1988) and $Al_{70}Ni_{15}Co_{15}$ (Tsai *et al.*, 1989*b*). However, space-group determination was still difficult due to their poor quasicrystallinity.

Tsai *et al.* (1989*c*) succeeded in producing a metastable but good-quality decagonal quasicrystal of $Al_{70}Ni_{15}Fe_{15}$. This alloy was found to be the first decagonal quasicrystal that could tolerate symmetry determination using CBED. The space group was determined to be $P\bar{1}0m2$ by Saito *et al.* (1992).

Fig. 2.5.3.26(*a*) shows a CBED pattern of $Al_{70}Ni_{15}Fe_{15}$ taken with an incidence parallel to the fivefold axis (*c* axis). The pattern clearly exhibits fivefold rotation symmetry and a type of mirror symmetry, the total symmetry being 5*m*. The slowly varying intensity distribution in the discs indicates that the pattern is formed by the interaction between ZOLZ reflections. Thus, the projection approximation should be applied to the analysis of the pattern. Patterns that were related to Fig. 2.5.3.26(*a*) by an inversion were observed when the illuminated specimen area was changed, indicating the existence of inversion domains. Table 2.5.3.15 shows possible pentagonal and decagonal point groups, which are constructed by analogy with the trigonal and hexagonal point groups (Saito *et al.*, 1992).

It can be seen that the point groups that satisfy the observed symmetry 5*m* in the projection approximation are 52, 5*m* and $\bar{1}0m2$. Point group 52 is a possibility because the horizontal

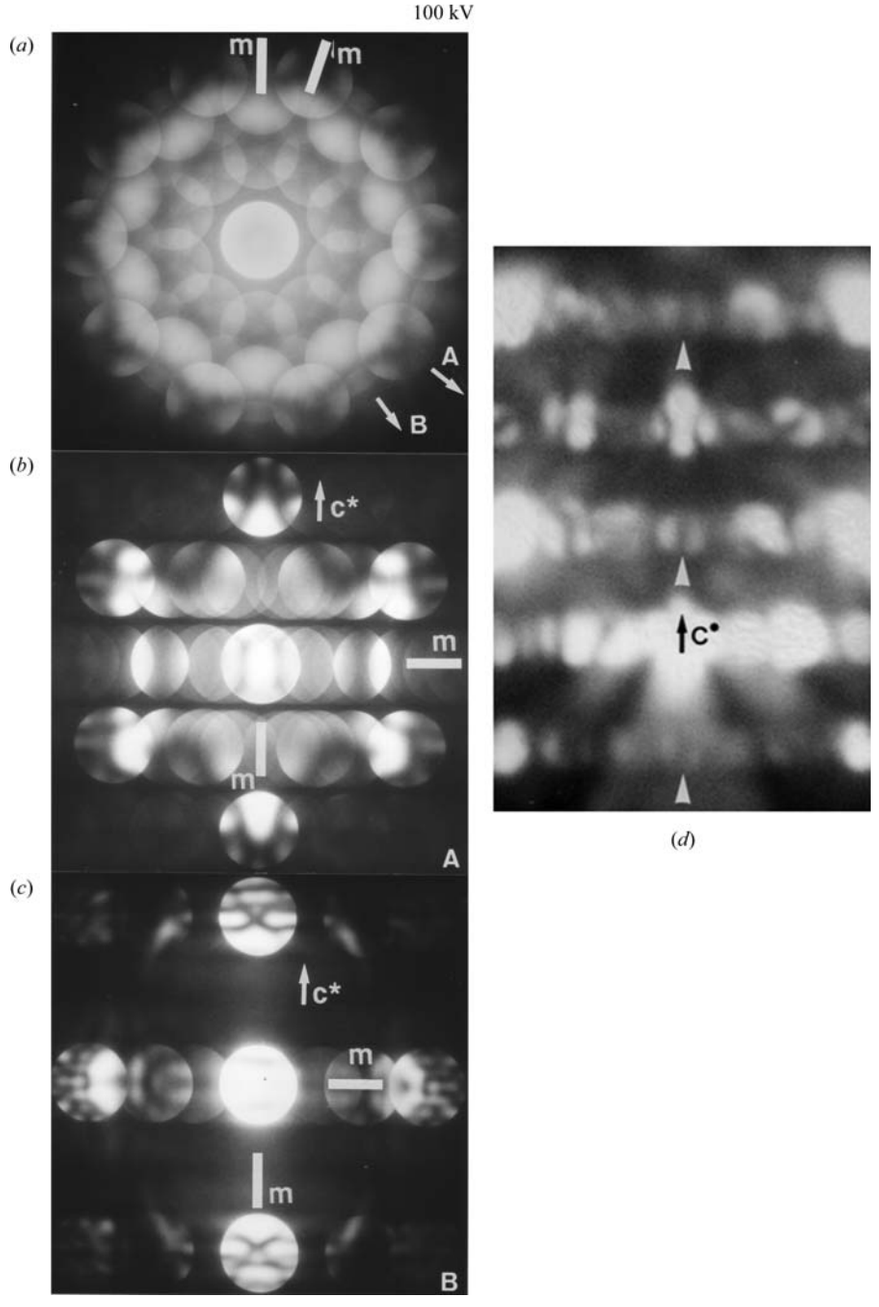

Fig. 2.5.3.27. CBED patterns of metastable $Al_{70}Ni_{20}Fe_{10}$ taken from a 3 nm diameter area. (*a*) Electron incidence along the decagonal axis: symmetry 10*mm*. (*b*) Electron incidence along direction A indicated in (*a*): symmetry 2*mm*. (*c*) Electron incidence along direction B indicated in (*a*): symmetry 2*mm*. (*d*) Reflections 00*l* (*l* = odd) show dynamical extinction lines. This alloy is determined to have the centrosymmetric space group $P10_5/mmc$.

twofold rotation axis is equivalent to the vertical mirror plane in the projection approximation. Figs. 2.5.3.26(*b*) and (*c*) were taken with beam incidences A and B, respectively, as denoted in Fig. 2.5.3.26(*a*). Mirror symmetry perpendicular to the *c* axis is seen in Fig. 2.5.3.26(*b*) and (*c*). Since the mirror symmetry requires a twofold rotation axis or a mirror plane perpendicular to the *c* axis, point groups 52 and $\overline{1}0m2$ remain as possibilities. Fig. 2.5.3.26(*c*) exhibits symmetry 2*mm*. Mirror symmetry parallel to the *c* axis requires the existence of a mirror plane parallel to the axis (a twofold rotation axis is not possible because the fivefold rotation axis already exists.). Since the mirror plane does not exist in point group 52 but does exist in $\overline{1}0m2$, the point group of the alloy is determined to be $\overline{1}0m2$. Examination of the ordinary diffraction patterns of the alloy revealed that the lattice type is primitive with a periodicity of 0.4 nm in the *c* direction and no dynamical extinction was observed. Thus, the space group of $Al_{70}Ni_{15}Fe_{15}$ was determined to be $P\overline{1}0m2$ (Saito *et al.*, 1992) by full use of the potential of CBED. This is the first quasicrystal with a noncentrosymmetric space group. High-resolution electron-microscope images revealed that the quasicrystal is composed of specific pentagonal atom clusters 2 nm in diameter (Tanaka *et al.*, 1993). Dark-field microscopy revealed the existence of inversion domains with an antiphase shift of *c*/2, the polarity being perpendicular to the *c* direction (Tsuda *et al.*, 1993).

Quasicrystals of $Al_{70}Ni_{10+x}Fe_{20-x}$ ($0 \leq x \leq 10$) were investigated by CBED and transmission electron microscopy (Tanaka *et al.*, 1993). The change in space group takes place at $x = 7.5$ upon a sudden decrease of the size of the inversion domains or a rapid mixing of the atom clusters with positive and negative polarities. As a result, the average structure becomes centrosymmetric. A CBED pattern of $Al_{70}Ni_{20}Fe_{10}$ taken at an incidence along the *c* axis shows tenfold rotation symmetry (Fig. 2.5.3.27*a*). CBED patterns taken at incidences A and B (shown in Fig. 2.5.3.27*a*) exhibit two mirror symmetries parallel and perpendicular to the *c* axis (Figs. 2.5.3.27*b* and *c*). Thus, the point group of this phase is

determined to be 10/*mmm*. Fig. 2.5.3.27(*d*) shows a CBED pattern taken by slightly tilting the incident beam to the *c** direction from incidence A. Dynamical extinction lines (arrowheads) are seen in the odd-order reflections along the *c** axis. This indicates the existence of a 10_5 screw axis and a *c*-glide plane. No other reflection absences were observed, implying the lattice type to be primitive. Therefore, the space group of $Al_{70}Ni_{20}Fe_{10}$ is determined to be centrosymmetric $P10_5/mmc$. It was found that the alloys with $0 \leq x \leq 7.5$ belong to the noncentrosymmetric space group $P\overline{1}0m2$ and those with $7.5 < x \leq 15$ belong to the centrosymmetric space group $P10_5/mmc$, keeping the specific polar structure of the basic clusters unchanged.

Another phase was found in the same alloys with $15 < x \leq 17$. This phase showed the same CBED symmetries as the phase with $7.5 < x \leq 15$. The space group of the phase was also determined to be $P10_5/mmc$. However, high-angle annular dark-field (HAADF) observations of the phase with $15 < x \leq 17$ showed that each atom cluster has only one mirror plane of symmetry (Saitoh *et al*., 1997, 1999). This implies that the structure of the specific cluster is changed from that of the phase with $7.5 < x \leq 15$. The clusters are still polar but take ten different orientations, producing centrosymmetric tenfold rotation symmetry on average, which was confirmed by HAADF observations (Saitoh, Tanaka & Tsai, 2001).

These three phases have been found for the similar alloys Al–*M*1–*M*2, where *M*1 = Ni and Cu, and *M*2 = Fe, Co, Rh and Ir (Tanaka *et al.*, 1996). Subsequently, decagonal quasicrystals were found in Al–Pd–Mn, Zn–Mg–RE (RE = Dy, Er, Ho, Lu, Tm and Y) and other alloy systems (Steurer, 2004). There are seven point groups in the decagonal system (Table 2.5.3.15). However, only two point groups, $\overline{1}0m2$ and 10/*mmm*, and two space groups, $P\overline{1}0m2$ and $P10_5/mmc$, are known reliably in real materials to date, though a few other point and space groups have been reported.

For further crystallographic aspects of quasicrystals, the reader is referred to the comprehensive reviews of Tsai (2003) and Steurer (2004), and to a review of more theoretical aspects by Yamamoto (1996).

2.5.4. Electron-diffraction structure analysis (EDSA)[2]

By B. K. Vainshtein and B. B. Zvyagin

2.5.4.1. Introduction

Electron-diffraction structure analysis (EDSA) (Vainshtein, 1964) based on electron diffraction (Pinsker, 1953) is used for the investigation of the atomic structure of matter together with X-ray and neutron diffraction analysis. The peculiarities of EDSA, as compared with X-ray structure analysis, are defined by a strong interaction of electrons with the substance and by a short wavelength λ. According to the Schrödinger equation (see Section 5.2.2) the electrons are scattered by the electrostatic field of an object. The values of the atomic scattering amplitudes, f_e, are three orders higher than those of X-rays, f_x, and neutrons, f_n. Therefore, a very small quantity of a substance is sufficient to obtain a diffraction pattern. EDSA is used for the investigation of very thin single-crystal films, of ~5–50 nm polycrystalline and textured films, and of deposits of finely grained materials and surface layers of bulk specimens. The structures of many ionic crystals, crystal hydrates and hydro-oxides, various inorganic, organic, semiconducting and metallo-organic compounds, of various minerals, especially layer silicates, and of biological structures have been investigated by means of EDSA; it has also been used in the study of polymers, amorphous solids and liquids.

Special areas of EDSA application are: determination of unit cells; establishing orientational and other geometrical relationships between related crystalline phases; phase analysis on the basis of d_{hkl} and I_{hkl} sets; analysis of the distribution of crystallite dimensions in a specimen and inner strains in crystallites as determined from line profiles; investigation of the surface structure of single crystals; structure analysis of crystals, including atomic position determination; precise determination of lattice potential distribution and chemical bonds between atoms; and investigation of crystals of biological origin in combination with electron microscopy (Vainshtein, 1964; Pinsker, 1953; Zvyagin, 1967; Pinsker *et al.*, 1981; Dorset, 1976; Zvyagin *et al.*, 1979).

There are different kinds of electron diffraction (ED) depending on the experimental conditions: high-energy (HEED) (above 30–200 kV), low-energy (LEED) (10–600 V), transmission (THEED) and reflection (RHEED). In electron-diffraction studies use is made of special apparatus – electron-diffraction cameras in which the lens system located between the electron source and the specimen forms the primary electron beam, and the diffracted beams reach the detector without aberration distortions. In this case, high-resolution electron diffraction (HRED) is obtained. ED patterns may also be observed in electron microscopes by a selected-area method (SAD). Other types of electron diffraction are: MBD (microbeam), HDD (high-dispersion), CBD (convergent-beam), SMBD (scanning-beam) and RMBD (rocking-beam) diffraction (see Sections 2.5.2 and 2.5.3). The recent development of electron diffractometry, based on direct intensity registration and measurement by scanning the diffraction pattern against a fixed detector (scintillator followed by photomultiplier), presents a new improved level of EDSA which provides higher precision and reliability of structural data (Avilov *et al*., 1999; Tsipursky & Drits, 1977; Zhukhlistov *et al*., 1997, 1998; Zvyagin *et al.*, 1996).

Electron-diffraction studies of the structure of molecules in vapours and gases is a large special field of research (Vilkov *et al*., 1978). See also *Stereochemical Applications of Gas-Phase Electron Diffraction* (1988).

2.5.4.2. The geometry of ED patterns

In HEED, the electron wavelength λ is about 0.05 Å or less. The Ewald sphere with radius λ^{-1} has a very small curvature and is approximated by a plane. The ED patterns are, therefore, considered as plane cross sections of the reciprocal lattice (RL) passing normal to the incident beam through the point 000, to scale $L\lambda$ (Fig. 2.5.4.1). The basic formula is

$$r = |\mathbf{h}|L\lambda, \text{ or } rd = L\lambda, \qquad (2.5.4.1)$$

where *r* is the distance from the pattern centre to the reflection, **h** is the reciprocal-space vector, *d* is the appropriate interplanar distance and *L* is the specimen-to-screen distance. The deviation of the Ewald sphere from a plane at distance *h* from the origin of the coordinates is $\delta_h = h^2\lambda/2$. Owing to the small values of λ and to the rapid decrease of f_e depending on $(\sin\theta)/\lambda$, the diffracted beams are concentrated in a small angular interval (≤ 0.1 rad).

Single-crystal ED patterns image one plane of the RL. They can be obtained from thin ideal crystalline plates, mosaic single-crystal films or, in the RHEED case, from the faces of bulk single crystals. Point ED patterns can be obtained more easily owing to the following factors: the small size of the crystals (increase in the dimension of RL nodes) and mosaicity – the small spread of crystallite orientations in a specimen (tangential tension of the RL nodes). The crystal system, the parameters of the unit cell and the Laue symmetry are determined from point ED patterns; the probable space group is found from extinctions. Point ED patterns may be used for intensity measurements if the kinematic

[2] Questions related to this section may be addressed to Dr D. L. Dorset (see list of contributing authors).

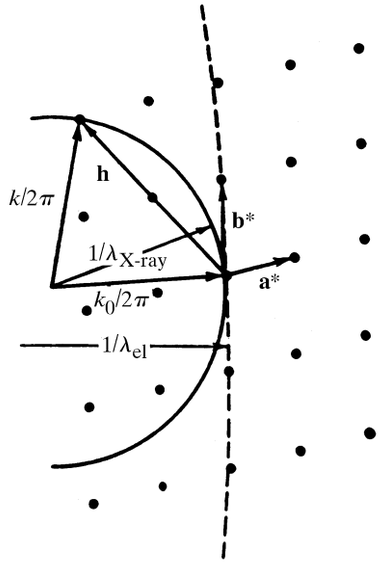

Fig. 2.5.4.1. Ewald spheres in reciprocal space. Dotted line: electrons, solid line: X-rays.

approximation holds true or if the contributions of the dynamic and secondary scattering are not too large.

The indexing of reflections and the unit-cell determination are carried out according to the formulae relating the RL to the DL (direct lattice) (Vainshtein, 1964; Pinsker, 1953; Zvyagin, 1967).

Under electron-diffraction conditions crystals usually show a tendency to lie down on the substrate plane on the most developed face. Let us take this as (001). The vectors **a** and **b** are then parallel, while vector $\mathbf{c}^*$ is normal to this plane, and the RL points are considered as being disposed along direct lines parallel to the axis c^* with constant hk and variable l.

The interpretation of the point patterns as respective RL planes is quite simple in the case of orthogonal lattices. If the lattice is triclinic or monoclinic the pattern of the crystal in the position with the face (001) normal to the incident beam does not have to contain $hk0$ reflections with nonzero h and k because, in general, the planes ab and a^*b^* do not coincide. However, the intersection traces of direct lines hk with the plane normal to them (plane ab) always form a net with periods

$$(a \sin\gamma)^{-1}, (b \sin\gamma)^{-1} \text{ and angle } \gamma' = \pi - \gamma \qquad (2.5.4.2a)$$

(Fig. 2.5.4.2). The points hkl along these directions hk are at distances

$$\eta = ha^* \cos\beta^* + kb^* \cos\alpha^* + lc^* \qquad (2.5.4.3)$$

from the ab plane.

By changing the crystal orientation it is possible to obtain an image of the a^*b^* plane containing $hk0$ reflections, or of other RL planes, with the exception of planes making a small angle with the axis c^*.

In the general case of an arbitrary crystal orientation, the pattern is considered as a plane section of the system of directions hk which makes an angle φ with the plane ab, intersecting it along a direction $[uv]$. It is described by two periods along directions $0h$, $0k$;

$$(a \sin\gamma \cos\psi_h)^{-1}, (b \sin\gamma \cos\psi_k)^{-1}, \qquad (2.5.4.2b)$$

with an angle γ'' between them satisfying the relation

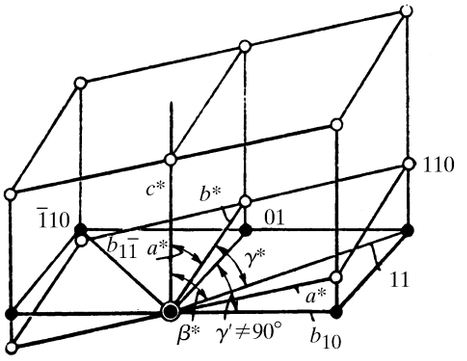

Fig. 2.5.4.2. Triclinic reciprocal lattice. Points: open circles, projection net: black circles.

$$\cos\gamma'' = \sin\psi_h \sin\psi_k - \cos\psi_h \cos\psi_k \cos\gamma, \qquad (2.5.4.2c)$$

and by a system of parallel directions

$$p_h h + p_k k = l; \quad l = 0, \pm1, \pm2, \ldots. \qquad (2.5.4.4)$$

The angles ψ_h, ψ_k are formed by directions $0h$, $0k$ in the plane of the pattern with the plane ab. The coefficients p_h, p_k depend on the unit-cell parameters, angle φ and direction $[uv]$. These relations are used for the indexing of reflections revealed near the integer positions hkl in the pattern and for unit-cell calculations (Vainshtein, 1964; Zvyagin, 1967; Zvyagin *et al.*, 1979).

In RED patterns obtained with an incident beam nearly parallel to the plane ab one can reveal all the RL planes passing through c^* which become normal to the beam at different azimuthal orientations of the crystal.

With the increase of the thickness of crystals (see below, Chapter 5.1) the scattering becomes dynamical and Kikuchi lines and bands appear. Kikuchi ED patterns are used for the estimation of the degree of perfection of the structure of the surface layers of single crystals for specimen orientation in HREM (*IT* C, 2004, Section 4.3.8). Patterns obtained with a convergent beam contain Kossel lines and are used for determining the symmetry of objects under investigation (see Section 2.5.3).

Texture ED patterns are a widely used kind of ED pattern (Pinsker, 1953; Vainshtein, 1964; Zvyagin, 1967). Textured specimens are prepared by substance precipitation on the substrate, from solutions and suspensions, or from gas phase in vacuum. The microcrystals are found to be oriented with a common (developed) face parallel to the substrate, but they have random azimuthal orientations. Correspondingly, the RL also takes random azimuthal orientations, having c^* as the common axis, *i.e.* it is a rotational body of the point RL of a single crystal. Thus, the ED patterns from textures bear a resemblance, from the viewpoint of their geometry, to X-ray rotation patterns, but they are less complicated, since they represent a plane cross section of reciprocal space.

If the crystallites are oriented by the plane (hkl), then the axis $[hkl]^*$ is the texture axis. For the sake of simplicity, let us assume that the basic plane is the plane (001) containing the axes a and b, so that the texture axis is $[001]^*$, *i.e.* the axis c^*. The matrices of appropriate transformations will define a transition to the general case (see *IT* A, 2005). The RL directions hk = constant, parallel to the texture axis, transform to cylindrical surfaces, the points with η_{hkl} = constant are in planes perpendicular to the texture axis, while any 'tilted' lines transform to cones or hyperboloids of rotation. Each point hkl transforms to a ring lying on these surfaces. In practice, owing to a certain spread of c^* axes of single crystals, the rings are blurred into small band sections of a

spherical surface with the centre at the point 000; the oblique cross section of such bands produces reflections in the form of arcs. The main interference curves for texture patterns are ellipses imaging oblique plane cross sections of the cylinders hk (Fig. 2.5.4.3).

At the normal electron-beam incidence (tilting angle $\varphi = 0^\circ$) the ED pattern represents a cross section of cylinders perpendicular to the axis c^*, *i.e.* a system of rings.

On tilting the specimen to an angle φ with respect to its normal position (usually $\varphi \simeq 60^\circ$) the patterns image an oblique cross section of the cylindrical RL, and are called oblique-texture (OT) ED patterns. The ellipses ($hk =$ constant) and layer lines ($l =$ constant) for orthogonal lattices are the main characteristic lines of ED patterns along which the reflections are arranged. The shortcoming of oblique-texture ED patterns is the absence of reflections lying inside the cone formed by rotation of the straight line coming from the point 000 at an angle $(90^\circ - \varphi)$ around the axis c^* and, in particular, of reflections $00l$. However, at $\varphi \lesssim 60$–70° the set of reflections is usually sufficient for structural determination.

For unit-cell determination and reflection indexing the values d (*i.e.* $|\mathbf{h}|$) are used, and the reflection positions defined by the ellipses hk to which they belong and the values η are considered. The periods a^*, b^* are obtained directly from h_{100} and h_{010} values. The period c^*, if it is normal to the plane a^*b^* (γ^* being arbitrary), is calculated as

$$c^* = \eta/l = (h_{hkl}^2 - h_{hk0}^2)^{1/2}/l. \qquad (2.5.4.5a)$$

For oblique-angled lattices

$$c^* = [(h_{l_1+l}^2 + h_{l_1-l}^2 - 2h_l^2)/2]^{1/2}/l. \qquad (2.5.4.5b)$$

In the general case of oblique-angled lattices the coaxial cylinders hk have radii

$$b_{hk} = (1/\sin\gamma)[(h^2/a^2) + (k^2/b^2) - (2hk\cos\gamma/ab)]^{1/2} \qquad (2.5.4.6)$$

and it is always possible to use the measured or calculated values b_{hk} in (2.5.4.5a) instead of h_{hk0}, since

$$\eta = (h_{hkl}^2 - b_{hk}^2)^{1/2}. \qquad (2.5.4.7)$$

In OT patterns the b_{hk} and η values are represented by the lengths of the small axes of the ellipses $B_{hk} = L\lambda b_{hk}$ and the distances of the reflections hkl from the line of small axes (equatorial line of the pattern)

$$D_{hkl} = L\lambda\eta/\sin\varphi = hp + ks + lq. \qquad (2.5.4.8)$$

Analysis of the B_{hk} values gives a, b, γ, while p, s and q are calculated from the D_{hkl} values. It is essential that the components of the normal projections c_n of the axis c on the plane ab measured in the units of a and b are

$$\begin{aligned} x_n &= (c/a)(\cos\beta - \cos\alpha\cos\gamma)/\sin^2\gamma \\ &= -p/q, \\ y_n &= (c/b)(\cos\alpha - \cos\beta\cos\gamma)/\sin^2\gamma \\ &= -s/q. \end{aligned} \qquad (2.5.4.9)$$

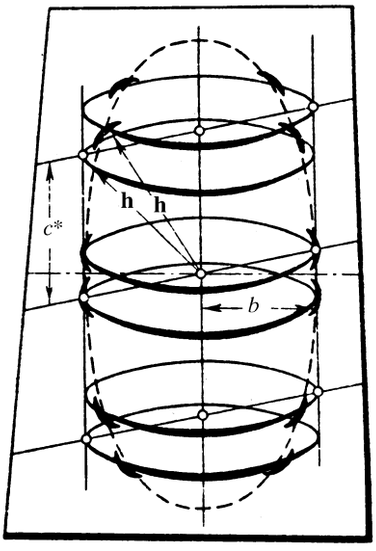

Fig. 2.5.4.3. Formation of ellipses on an electron-diffraction pattern from an oblique texture.

Obtaining x_n, y_n one can calculate

$$c_n = [(x_n a)^2 + (y_n b)^2 + 2x_n y_n ab\cos\gamma]^{1/2}.$$

Since

$$\begin{aligned} d_{001} &= L\lambda/q\sin\varphi, \\ c &= (c_n^2 + d_{001}^2)^{1/2}. \end{aligned} \qquad (2.5.4.10)$$

The α, β values are then defined by the relations

$$\begin{aligned} \cos\alpha &= (x_n a\cos\gamma + y_n b)/c, \\ \cos\beta &= (x_n a + y_n b\cos\gamma)/c. \end{aligned} \qquad (2.5.4.11)$$

Because of the small particle dimensions in textured specimens, the kinematic approximation is more reliable for OT patterns, enabling a more precise calculation of the structure amplitudes from the intensities of reflections.

Polycrystal ED patterns. In this case, the RL is a set of concentric spheres with radii h_{hkl}. The ED pattern, like an X-ray powder pattern, is a set of rings with radii

$$r_{hkl} = h_{hkl}L\lambda. \qquad (2.5.4.12)$$

2.5.4.3. Intensities of diffraction beams

The intensities of scattering by a crystal are determined by the scattering amplitudes of atoms in the crystal, given by (see also Section 5.2.1)

$$\begin{aligned} f_e^{abs}(s) &= 4\pi K\int \varphi(r)r^2\frac{\sin sr}{sr}\,dr; \\ K &= \frac{2\pi me}{h^2};\ f_e = K^{-1}f_e^{abs}, \end{aligned} \qquad (2.5.4.13)$$

where $\varphi(r)$ is the potential of an atom and $s = 4\pi(\sin\theta)/\lambda$. The absolute values of f_e^{abs} have the dimensionality of length L. In EDSA it is convenient to use f_e without K. The dimensionality of

f_e is [potential L^3]. With the expression of f_e in V Å^3 the value K^{-1} in (2.5.4.13) is 47.87 V Å^2.

The scattering atomic amplitudes $f_e(s)$ differ from the respective $f_x(s)$ X-ray values in the following: while $f_x(0) = Z$ (electron shell charge), the atomic amplitude at $s = 0$

$$f_e(0) = 4\pi \int \varphi(r) r^2 \, dr \qquad (2.5.4.14)$$

is the 'full potential' of the atom. On average, $f_e(0) \simeq Z^{1/3}$, but for small atomic numbers Z, owing to the peculiarities in the filling of the electron shells, $f_e(0)$ exhibits within periods of the periodic table of elements 'reverse motion', *i.e.* they decrease with Z increasing (Vainshtein, 1952, 1964). At large $(\sin\theta)/\lambda$, $f_e \simeq Z$. The atomic amplitudes and, consequently, the reflection intensities, are recorded, in practice, up to values of $(\sin\theta)/\lambda \simeq 0.8$–$1.2$ Å^{-1}, *i.e.* up to $d_{\min} \simeq 0.4$–0.6 Å.

The structure amplitude Φ_{hkl} of a crystal is determined by the Fourier integral of the unit-cell potential (see Chapter 1.2),

$$\Phi_{hkl} = \int_{\Omega} \varphi(\mathbf{r}) \exp\{2\pi i(\mathbf{r}\cdot\mathbf{h})\} \, dv_r, \qquad (2.5.4.15)$$

where Ω is the unit-cell volume. The potential of the unit cell can be expressed by the potentials of the atoms of which it is composed:

$$\varphi(\mathbf{r}) = \sum_{\text{cell},\, i} \varphi_{\text{at}\, i}(\mathbf{r} - \mathbf{r}_i). \qquad (2.5.4.16)$$

The thermal motion of atoms in a crystal is taken into account by the convolution of the potential of an atom at rest with the probability function $w(\mathbf{r})$ describing the thermal motion:

$$\varphi_{\text{at}} = \varphi_{\text{at}}(\mathbf{r}) * w(\mathbf{r}). \qquad (2.5.4.17)$$

Accordingly, the atomic temperature factor of the atom in a crystal is

$$f_{eT}[(\sin\theta)/\lambda] = f_e f_T = f_e[(\sin\theta)/\lambda] \exp\{-B[(\sin\theta)/\lambda]^2\}, \qquad (2.5.4.18)$$

where the Debye temperature factor is written for the case of isotropic thermal vibrations. Consequently, the structure amplitude is

$$\Phi_{hkl} = \sum_{\text{cell},\, i} f_{eT_i} \exp\{2\pi i(hx_i + ky_i + lz_i)\}. \qquad (2.5.4.19)$$

This general expression is transformed (see *IT* I, 1952) according to the space group of a given crystal.

To determine the structure amplitudes in EDSA experimentally, one has to use specimens satisfying the kinematic scattering condition, *i.e.* those consisting of extremely thin crystallites. The limit of the applicability of the kinematic approximation (Blackman, 1939; Vainshtein, 1964) can be estimated from the formula

$$A = \lambda \left| \frac{\langle \Phi_{\mathbf{h}} \rangle}{\Omega} \right| t \lesssim 1, \qquad (2.5.4.20)$$

where $\langle \Phi_{\mathbf{h}} \rangle$ is the averaged absolute value of $\Phi_{\mathbf{h}}$ (see also Section 2.5.2). Since $\langle \Phi_{\mathbf{h}} \rangle$ are proportional to $Z^{0.8}$, condition (2.5.4.20) is better fulfilled for crystals with light and medium atoms. Condition (2.5.4.20) is usually satisfied for textured and polycrystalline specimens. But for mosaic single crystals as well, the kinematic approximation limit is, in view of their real structure, substantially wider than estimated by (2.5.4.20) for ideal crystals. The fulfillment of the kinematic law for scattering can be, to a greater or lesser extent, estimated by comparing the decrease of experimental intensity $I_h[(\sin\theta)/\lambda]$ averaged over definite angular intervals, and sums $\sum f^2_{\text{obs}}[(\sin\theta)/\lambda]$ calculated for the same angular intervals.

For mosaic single-crystal films the integral intensity of reflection is

$$I_{\mathbf{h}} = j_0 S \lambda^2 \left| \frac{\Phi_{\mathbf{h}}}{\Omega} \right|^2 \frac{t d_{\mathbf{h}}}{\alpha} \simeq \Phi^2_{\mathbf{h}} d_{\mathbf{h}}; \qquad (2.5.4.21)$$

for textures

$$I_{\mathbf{h}} = j_0 S \lambda^2 \left| \frac{\Phi_{\mathbf{h}}}{\Omega} \right|^2 \frac{tL\lambda p}{2\pi R' \sin\varphi} \simeq \Phi^2_{\mathbf{h}} p / R'. \qquad (2.5.4.22)$$

Here j_0 is the incident electron-beam density, S is the irradiated specimen area, t is the thickness of the specimen, α is the average angular spread of mosaic blocks, R' is the horizontal coordinate of the reflection in the diffraction pattern and p is the multiplicity factor. In the case of polycrystalline specimens the local intensity in the maximum of the ring reflection

$$I_{\mathbf{h}} = j_0 S \lambda^2 \left| \frac{\Phi_{\mathbf{h}}}{\Omega} \right|^2 \frac{t d^2_{\mathbf{h}} p \Delta S}{4\pi L \lambda} \simeq \Phi^2_{\mathbf{h}} d^2_{\mathbf{h}} p \qquad (2.5.4.23)$$

is measured, where ΔS is the measured area of the ring.

The transition from kinematic to dynamic scattering occurs at critical thicknesses of crystals when $A \geq 1$ (2.5.4.20). Mosaic or polycrystalline specimens then result in an uneven contribution of various crystallites to the intensity of the reflections. It is possible to introduce corrections to the experimental structure amplitudes of the first strong reflections most influenced by dynamic scattering by applying in simple cases the two-wave approximation (Blackman, 1939) or by taking into account multibeam theories (Fujimoto, 1959; Cowley, 1981; Avilov *et al.* 1984; see also Chapter 5.2).

The application of kinematic scattering formulae to specimens of thin crystals (5–20 nm) or dynamic corrections to thicker specimens (20–50 nm) permits one to obtain reliability factors between the calculated Φ^{calc} and observed Φ^{obs} structure amplitudes of R = 5–15%, which is sufficient for structural determinations.

With the use of electron-diffractometry techniques, reliability factors as small as R = 2–3% have been reached and more detailed data on the distribution of the inner-crystalline potential field have been obtained, characterizing the state and bonds of atoms, including hydrogen (Zhukhlistov *et al.*, 1997, 1998; Avilov *et al.*, 1999).

The applicability of kinematics formulae becomes poorer in the case of structures with many heavy atoms for which the atomic amplitudes also contain an imaginary component (Shoemaker & Glauber, 1952). The experimental intensity measurement is made by a photo method or by direct recording (Avilov, 1979). In some cases the amplitudes Φ_{hkl} can be determined from dynamic scattering patterns – the bands of equal thickness from a wedge-shaped crystal (Cowley, 1981), or from rocking curves.

2.5.4.4. Structure analysis

The unit cell is defined on the basis of the geometric theory of electron-diffraction patterns, and the space group from extinc-

tions. It is also possible to use the method of converging beams (Section 2.5.3). The structural determination is based on experimental sets of values $|\Phi_{hkl}|^2$ or $|\Phi_{hkl}|$ (Vainshtein, 1964).

The trial-and-error method may be used for the simplest structures. The main method of determination is the construction of the Patterson functions

$$P(xyz) = \frac{1}{\Omega}\left[\Phi_{000}^2 + 2\sum_{hkl=-\infty}^{hkl=+\infty} |\Phi_{hkl}|^2 \cos 2\pi(hx + ky + lz)\right] \tag{2.5.4.24}$$

and their analysis on the basis of heavy-atom methods, superposition methods and so on (see Chapter 2.3). Direct methods are also used (Dorset *et al.*, 1979). Thus the phases of structure factors are calculated and assigned to the observed moduli

$$\Phi_{\mathbf{h}} = |\Phi_{\mathbf{h},\,\mathrm{obs}}| \exp\{i\alpha_{\mathrm{calc}}\}. \tag{2.5.4.25}$$

The distribution of the potential in the unit cell, and, thereby, the arrangement in it of atoms (peaks of the potential) are revealed by the construction of three-dimensional Fourier series of the potential (see also Chapter 1.3)

$$\varphi(xyz) = \frac{1}{\Omega}\sum_{\mathbf{h}} \Phi_{hkl} \exp\{-2\pi i(hx + ky + lz)\} \tag{2.5.4.26a}$$

or projections

$$\varphi'(xy) = \frac{1}{S}\sum_{\mathbf{h}} \Phi_{hk0} \exp\{-2\pi i(hx + ky)\}. \tag{2.5.4.26b}$$

The general formulae (2.5.4.26*a*) and (2.5.4.26*b*) transform, according to known rules, to the expressions for each space group (see *IT* I, 1952). If Φ_{hkl} are expressed in V Å^3 and the volume Ω or the cell area S in Å^3 and Å^2, respectively, then the potential φ is obtained directly in volts, while the projection of the potential φ' is in V Å. The amplitudes $|\Phi_{hkl}|$ are reduced to an absolute scale either according to a group of strong reflections

$$\sum|\Phi_{\mathbf{h}}|^{\mathrm{calc}} = \sum|\Phi_{\mathbf{h}}|^{\mathrm{obs}} \tag{2.5.4.27}$$

or using the Parseval equality

$$\sum_{\mathbf{h}=-\infty}^{+\infty} |\Phi_{\mathbf{h}}|^2 = \Omega^2\langle\varphi^2\rangle = \Omega\sum_{i(\mathrm{cell})} \frac{1}{2\pi^2}\int_0^{\infty} f_{eT_i}^2(s)\, s^2 \,\mathrm{d}s \tag{2.5.4.28}$$

or Wilson's statistical method

$$\langle\Phi^2[(\sin\theta)/\lambda]\rangle = \sum_i f_{eT_i}^2[(\sin\theta)/\lambda]. \tag{2.5.4.29}$$

The term Φ_{000} defines the mean inner potential of a crystal, and is calculated from $f_{\mathrm{e}}(0)$ [(2.5.4.13), (2.5.4.19)]

$$\langle\varphi_{\mathrm{cr}}\rangle = \Phi_{000}/\Omega = \frac{1}{\Omega}\sum f_{\mathrm{e}}(0). \tag{2.5.4.30}$$

The Fourier series of the potential in EDSA possess some peculiarities (Vainshtein, 1954, 1964) which make them different from the electron-density Fourier series in X-ray analysis. Owing to the peculiarities in the behaviour of the atomic amplitudes (2.5.4.13), which decrease more rapidly with increasing $(\sin\theta)/\lambda$ compared with f_{x}, the peaks of the atomic potential

$$\varphi_{\mathrm{at}}(r) = \frac{1}{2\pi^2}\int f_{eT}(s)\frac{\sin sr}{sr} s^2 \,\mathrm{d}s \tag{2.5.4.31}$$

are more 'blurred' and exhibit a larger half-width than the electron-density peaks $\rho_{\mathrm{at}}(r)$. On average, this half-width corresponds to the 'resolution' of an electron-diffraction pattern – about 0.5 Å or better. The potential in the maximum ('peak height') does not depend as strongly on the atomic number as in X-ray analysis:

$$\varphi(0) = \frac{1}{2\pi^2}\int f_{eT}(s)\, s^2 \,\mathrm{d}s \sim Z^{0.75}, \tag{2.5.4.32}$$

while in X-ray diffraction $\rho(0) \sim Z^{1.2}$. In such a way, in EDSA the light atoms are more easily revealed in the presence of heavy atoms than in X-ray diffraction, permitting, in particular, hydrogen atoms to be revealed directly without resorting to difference syntheses as in X-ray diffraction. Typical values of the atomic potential $\varphi(0)$ (which depend on thermal motion) in organic crystals are: H $\sim$ 35, C $\sim$ 165, O 215 V; in Al crystals 330 V, in Cu crystals 750 V.

The EDSA method may be used for crystal structure determination, depending on the types of electron-diffraction patterns, for crystals containing up to several tens of atoms in the unit cell. The accuracy in determination of atomic coordinates in EDSA is about 0.01–0.005 Å on average. The precision of EDSA makes it possible to determine accurately the potential distribution, to investigate atomic ionization, to obtain values for the potential between the atoms and, thereby, to obtain data on the nature of the chemical bond.

If the positions in the cell are occupied only partly, then the measurement of $\varphi_i(0)$ gives information on population percentage.

There is a relationship between the nuclear distribution, electron density and the potential as given by the Poisson equation

$$\nabla^2\varphi(\mathbf{r}) = -4\pi e[\rho_+(\mathbf{r}) - \rho_-(\mathbf{r})]. \tag{2.5.4.33}$$

This makes it possible to interrelate X-ray diffraction, EDSA and neutron-diffraction data. Thus for the atomic amplitudes

$$f_{\mathrm{e}}(s) = 4\pi Ke[Z - f_{\mathrm{x}}(s)]\, s^{-2}, \tag{2.5.4.34}$$

where Z is the nuclear charge and f_{x} the X-ray atomic scattering amplitude, and for structure amplitudes

$$\Phi_{hkl} = \pi Ke[Z_{hkl} - F_{hkl}]|\mathbf{h}|^{-2}, \tag{2.5.4.35}$$

where F_{hkl} is the X-ray structure amplitude of the electron density of a crystal and Z_{hkl} is the amplitude of scattering from charges of nuclei in the cell taking into account their thermal motion. The values Z_{hkl} can be calculated easily from neutron-diffraction data, since the charges of the nuclei are known and the experiment gives the parameters of their thermal motion.

In connection with the development of high-resolution electron-microscopy methods (HREM) it has been found possible to combine the data from direct observations with EDSA methods. However, EDSA permits one to determine the

atomic positions to a greater accuracy, since practically the whole of reciprocal space with 1.0–0.4 Å resolution is used and the three-dimensional arrangement of atoms is calculated. At the same time, in electron microscopy, owing to the peculiarities of electron optics and the necessity for an objective aperture, the image of the atoms in a crystal $\varphi'(\mathbf{x}) * A(\mathbf{x})$ is a convolution, with the aperture function blurring the image up to 1.5–2 Å resolution. In practice, in TEM one obtains only the images of the heaviest atoms of an object. However, the possibility of obtaining a direct image of a structure with all the defects in the atomic arrangement is the undoubted merit of TEM.

2.5.5. Image reconstruction[3]

By B. K. Vainshtein

2.5.5.1. Introduction

In many fields of physical measurements, instrumental and informative techniques, including electron microscopy and computational or analogue methods for processing and transforming signals from objects investigated, find a wide application in obtaining the most accurate structural data. The signal may be radiation from an object, or radiation transmitted through the object, or reflected by it, which is transformed and recorded by a detector.

The image is the two-dimensional signal $I(xy)$ on the observation plane recorded from the whole three-dimensional volume of the object, or from its surface, which provides information on its structure. In an object this information may change owing to transformation of the scattered wave inside an instrument. The real image $J(xy)$ is composed of $I(xy)$ and noise $N(xy)$ from signal disturbances:

$$J(xy) = I(xy) + N(xy). \tag{2.5.5.1}$$

Image-reconstruction methods are aimed at obtaining the most accurate information on the structure of the object; they are subdivided into two types (*Picture Processing and Digital Filtering*, 1975; Rozenfeld, 1969):

(*a*) Image restoration – separation of $I(xy)$ from the image by means of compensation of distortions introduced in it by an image-forming system as well as by an account of the available quantitative data reflecting its structure.

(*b*) Image enhancement – maximum exclusion from the observed image $J(xy)$ (2.5.5.1) of all its imperfections $N(xy)$ from both accidental distortions in objects and various 'noise' in signals and detector, and obtaining $I(xy)$ as the result.

These two methods may be used separately or in combination.

The image should be represented in the form convenient for perception and analysis, *e.g.* in digital form, in lines of equal density, in points of different density, in half-tones or colour form and using, if necessary, a change or reversal of contrast.

Reconstructed images may be used for the three-dimensional reconstruction of the spatial structure of an object, *e.g.* of the density distribution in it (see Section 2.5.6).

This section is connected with an application of the methods of image processing in transmission electron microscopy (TEM). In TEM (see Section 2.5.2), the source-emitted electrons are transmitted through an object and, with the aid of a system of lenses, form a two-dimensional image subject to processing.

Another possibility for obtaining information on the structure of an object is structural analysis with the aid of electron diffraction – EDSA. This method makes use of information in reciprocal space – observation and measurement of electron-diffraction patterns and calculation from them of a two-dimensional projection or three-dimensional structure of an object using the Fourier synthesis. To do this, one has to find the relative phases of the scattered beams.

The wavefunction of an electron-microscopic image is written as

$$\psi_\mathrm{I} = \mathscr{F}^{-1} T \mathscr{F} q \psi_0. \tag{2.5.5.2}$$

Here ψ_0 is the incident plane wave. When the wave is transmitted through an object, it interacts with the electrostatic potential $\varphi(\mathbf{r})$ [$\mathbf{r}(xyz)$ is the three-dimensional vector in the space of the object]; this process is described by the Schrödinger equation (Section 2.5.2.1). As a result, on the exit surface of an object the wave takes the form $q\psi_0(\mathbf{x})$ where q is the transmission function and $\mathbf{x}$ is the two-dimensional vector $\mathbf{x}(xy)$. The diffraction of the wave $q\psi_0$ is described by the two-dimensional Fourier operator:

$$\mathscr{F} q = Q(\mathbf{u}) = \int q(\mathbf{x}) \exp[2\pi i(\mathbf{x}\mathbf{u})]\, \mathrm{d}\mathbf{x}. \tag{2.5.5.3}$$

Here, we assume the initial wave amplitude to be equal to unity and the initial phase to be zero, so that $q\psi_0 = q$, which defines, in this case, the wavefunction in the back focal plane of an objective lens with the reciprocal-space coordinates $\mathbf{u}(u, v)$. The function Q is modified in reciprocal space by the lens transfer function $T(\mathbf{u})$. The scattered wave transformation into an image is described by the inverse Fourier operator $\mathscr{F}^{-1}TQ$.

The process of the diffraction $\mathscr{F} q\psi_0 = Q$, as seen from (2.5.5.1), is the same in both TEM and EDSA. Thus, in TEM under the lens actions $\mathscr{F}^{-1}TQ$ the image formation from a diffraction pattern takes place with an account of the phases, but these phases are modified by the objective-lens transfer function. In EDSA, on the other hand, there is no distorting action of the transfer function and the 'image' is obtained by computing the operation $\mathscr{F}^{-1}Q$.

The computation of projections, images and Fourier transformation is made by discretization of two-dimensional functions on a two-dimensional network of points – pixels in real space $\mathbf{x}(x_j, y_k)$ and in reciprocal space $\mathbf{u}(u_m, v_n)$.

2.5.5.2. Thin weak phase objects at optimal defocus

The intensity distribution $I(xy) \sim |\psi_1|^2$ of an electron wave in the image plane depends not only on the coherent and inelastic scattering, but also on the instrumental functions. The electron wave transmitted through an object interacts with the electrostatic potential $\varphi(\mathbf{r})$ which is produced by the nuclei charges and the electronic shells of the atoms. The scattering and absorption of electrons depend on the structure and thickness of a specimen, and the atomic numbers of the atoms of which it is composed. If an object with the three-dimensional distribution of potential $\varphi(\mathbf{r})$ is sufficiently thin, then the interaction of a plane electron wave ψ_0 with it can be described as the interaction with a two-dimensional distribution of potential projection $\varphi(\mathbf{x})$,

$$\varphi(\mathbf{x}) = \int_0^b \varphi(\mathbf{r})\, \mathrm{d}z, \tag{2.5.5.4}$$

where b is the specimen thickness. It should be noted that, unlike the three-dimensional function of potential $\varphi(\mathbf{r})$ with dimension $[M^{1/2}L^{3/2}T^{-1}]$, the two-dimensional function of potential projection $\varphi(\mathbf{x})$ has the potential-length dimension $[M^{1/2}L^{1/2}T^{-1}]$ which, formally, coincides with the charge dimension. The transmission function, in the general case, has the form

[3] Questions related to this section may be addressed to Dr P. A. Penczek (see list of contributing authors).

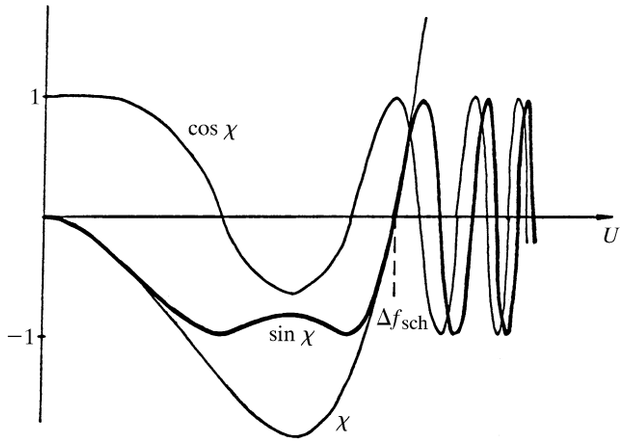

Fig. 2.5.5.1. The χ function and two components of the Scherzer phase function $\sin\chi(U)$ and $\cos\chi(U)$.

$q(\mathbf{x}) = \exp[-i\sigma\varphi(\mathbf{x})]$ (2.5.2.42), and for weak phase objects the approximation $[\sigma\varphi \ll 1]$

$$q(\mathbf{x}) = 1 - i\sigma\varphi(\mathbf{x}) \tag{2.5.5.5}$$

is valid.

In the back focal plane of the objective lens the wave has the form

$$Q(uv)\cdot T(U) \tag{2.5.5.6}$$

$$T = A(U)\exp(i\chi U) \tag{2.5.5.7a}$$

$$\chi(U) = \pi\Delta f\lambda U^2 + \frac{\pi}{2}C_s\lambda^3U^4, \tag{2.5.5.7b}$$

where $U = (u^2 + v^2)^{1/2}$; $\exp[i\chi(U)]$ is the Scherzer phase function (Scherzer, 1949) of an objective lens (Fig. 2.5.5.1), $A(U)$ is the aperture function, C_s the spherical aberration coefficient, and Δf the defocus value [(2.5.2.32)–(2.5.2.35)].

The bright-field image intensity (in object coordinates) is

$$I(xy) = |\psi_1(xy) * t(xy)|^2, \tag{2.5.5.8}$$

where $t = \mathscr{F}^{-1}[T]$. The phase function (2.5.5.7) depends on defocus, and for a weak phase object (Cowley, 1981)

$$I(xy) = 1 + 2\sigma\varphi(xy) * s(xy), \tag{2.5.5.9}$$

where $s = \mathscr{F}^{-1}[A(U)\sin\chi]$, which includes only an imaginary part of function (2.5.5.6). While selecting defocus in such a way that under the Scherzer defocus conditions [(2.5.2.44), (2.5.2.45)] $|\sin\chi| \simeq 1$, one could obtain

$$I(xy) = 1 + 2\sigma\varphi(xy) * a(xy). \tag{2.5.5.10}$$

In this very simple case the image reflects directly the structure of the object – the two-dimensional distribution of the projection of the potential convoluted with the spread function $a = \mathscr{F}^{-1}A$. In this case, no image restoration is necessary. Contrast reversal may be achieved by a change of defocus.

At high resolution, this method enables one to obtain an image of projections of the atomic structure of crystals and defects in the atomic arrangement – vacancies, replacements by foreign atoms, amorphous structures and so on; at resolution worse than atomic one obtains images of dislocations as continuous lines, inserted phases, inclusions *etc.* (Cowley, 1981). It is also possible to obtain images of thin biological crystals, individual molecules, biological macromolecules and their associations.

Image restoration. In the case just considered (2.5.5.10), the projection of potential $\varphi(xy)$, convoluted with the spread function, can be directly observed. In the general case (2.5.5.9), when the aperture becomes larger, the contribution to image formation is made by large values of spatial frequencies U, in which the function $\sin\chi$ oscillates, changing its sign. Naturally, this distorts the image just in the region of appropriate high resolution. However, if one knows the form of the function $\sin\chi$ (2.5.5.7), the true function $\varphi(xy)$ can be restored.

This could be carried out experimentally if one were to place in the back focal plane of an objective lens a zone plate transmitting only one-sign regions of $\sin\chi$ (Hoppe, 1971). In this case, the information on $\varphi(xy)$ is partly lost, but not distorted. To perform such a filtration in an electron microscope is a rather complicated task.

Another method is used (Erickson & Klug, 1971). It consists of a Fourier transformation $\mathscr{F}^{-1}$ of the measured intensity distribution TQ (2.5.5.6) and division of this transform, according to (2.5.5.7*a*,*b*), by the phase function $\sin\chi$. This gives

$$\frac{TQ}{\sin\chi} = Q(uv)A(U). \tag{2.5.5.11a}$$

Then, the new Fourier transformation $\mathscr{F}QA$ yields (in the weak-phase-object approximation) the true distribution

$$\varphi(xy) * a(xy). \tag{2.5.5.11b}$$

The function $\sin\chi$ depending on defocus Δf should be known to perform this procedure. The transfer function can also be found from an electron micrograph (Thon, 1966). It manifests itself in a circular image intensity modulation of an amorphous substrate or, if the specimen is crystalline, in the 'noise' component of the image. The analogue method (optical Fourier transformation for obtaining the image $\sin\chi$) can be used (optical diffraction, see below); digitization and Fourier transformation can also be applied (Hoppe *et al.*, 1973).

The thin crystalline specimen implies that in the back focal objective lens plane the discrete kinematic amplitudes Φ_{hk} are arranged and, by the above method, they are corrected and released from phase distortions introduced by the function $\sin\chi$ (see below) (Unwin & Henderson, 1975).

For the three-dimensional reconstruction (see Section 2.5.6) it is necessary to have the projections of potential of the specimen tilted at different angles α to the beam direction (normal beam incidence corresponds to $\alpha = 0$). In this case, the defocus Δf changes linearly with increase of the distance l of specimen points from the rotation axis $\Delta f_\alpha = \Delta f_0(1 + l\sin\alpha)$. Following the above procedure for passing on to reciprocal space and correction of $\sin\chi$, one can find $\varphi_\alpha(xy)$ (Henderson & Unwin, 1975).

2.5.5.3. An account of absorption

Elastic interaction of an incident wave with a weak phase object is defined on its exit surface by the distribution of potential projection $\varphi(xy)$; however, in the general case, the electron scattering amplitude is a complex one (Glauber & Schomaker, 1953). In such a way, the image itself has the phase and amplitude contrast. This may be taken into account if one considers not only the potential projection $\varphi(xy)$, but also the 'imaginary potential'

$\mu(xy)$ which describes phenomenologically the absorption in thin specimens. Then, instead of (2.5.5.5), the wave on the exit surface of a specimen can be written as

$$q(xy) = 1 - i\sigma\varphi(xy) - \mu(xy) \tag{2.5.5.12}$$

and in the back focal plane if $\Phi = \mathscr{F}\varphi$ and $M = \mathscr{F}\mu$

$$Q(uv) = \delta(uv) - i\sigma\Phi(uv) - M(uv). \tag{2.5.5.13}$$

Usually, μ is small, but it can, nevertheless, make a certain contribution to an image. In a sufficiently good linear approximation, it may be assumed that the real part $\cos\chi$ of the phase function (2.5.5.7*a*) affects $M(uv)$, while $\Phi(xy)$, as we know, is under the action of the imaginary part $\sin\chi$.

Thus, instead of (2.5.5.6), one can write

$$Q(\exp i\chi) = \delta(\mathbf{u}) - i\sigma\Phi(\mathbf{u})\sin\chi - M(\mathbf{u})\cos\chi, \tag{2.5.5.14}$$

and as the result, instead of (2.5.5.10),

$$\begin{aligned} I(xy) = 1 &+ 2\sigma\varphi(xy) * \mathscr{F}^{-1}(\sin\chi) * a(U) \\ &- 2\mu(xy) * \mathscr{F}^{-1}(\cos\chi) * a(U). \end{aligned} \tag{2.5.5.15}$$

The functions $\varphi(xy)$ and $\mu(xy)$ can be separated by object imaging using the through-focus series method. In this case, using the Fourier transformation, one passes from the intensity distribution (2.5.5.15) in real space to reciprocal space. Now, at two different defocus values Δf_1 and Δf_2 [(2.5.5.6), (2.5.5.7*a*,*b*)] the values $\Phi(\mathbf{u})$ and $M(\mathbf{u})$ can be found from the two linear equations (2.5.5.14). Using the inverse Fourier transformation, one can pass on again to real space which gives $\varphi(\mathbf{x})$ and $\mu(\mathbf{x})$ (Schiske, 1968). In practice, it is possible to use several through-focus series and to solve a set of equations by the least-squares method.

Another method for processing takes into account the simultaneous presence of noise $N(\mathbf{x})$ and transfer function zeros (Kirkland *et al.*, 1980). In this method the space frequencies corresponding to small values of the transfer function modulus are suppressed, while the regions where such a modulus is large are found to be reinforced.

2.5.5.4. Thick crystals

When the specimen thickness exceeds a certain critical value (~50–100 Å), the kinematic approximation does not hold true and the scattering is dynamic. This means that on the exit surface of a specimen the wave is not defined as yet by the projection of potential $\varphi(xy) = \int\varphi(\mathbf{r})\,\mathrm{d}z$ (2.5.5.3), but one has to take into account the interaction of the incident wave ψ_0 and of all the secondary waves arising in the whole volume of a specimen.

The dynamic scattering calculation can be made by various methods. One is the multislice (or phase-grating) method based on a recurrent application of formulae (2.5.5.3) for n thin layers Δz_i thick, and successive construction of the transmission functions q_i (2.5.5.4), phase functions $Q_i = \mathscr{F}q_i$, and propagation function $p_k = [k/2\pi i\Delta z]\exp[ik(x^2 + y^2)/2\Delta z]$ (Cowley & Moodie, 1957).

Another method – the scattering matrix method – is based on the solution of equations of the dynamic theory (Chapter 5.2). The emerging wave on the exit surface of a crystal is then found to diffract and experience the transfer function action [(2.5.5.6), (2.5.5.7*a*,*b*)].

The dynamic scattering in crystals may be interpreted using Bloch waves:

$$\Psi^j(\mathbf{r}) = \sum_H C_H^j \exp(-2\pi i\mathbf{k}_H^j \cdot \mathbf{r}). \tag{2.5.5.16}$$

It turns out that only a few (bound and valence Bloch waves) have strong excitation amplitudes. Depending on the thickness of a crystal, only one of these waves or their linear combinations (Kambe, 1982) emerges on the exit surface. An electron-microscopic image can be interpreted, at certain thicknesses, as an image of one of these waves [with a correction for the transfer function action (2.5.5.6), (2.5.5.7*a*,*b*)]; in this case, the identical images repeat with increasing thickness, while, at a certain thickness, the contrast reversal can be observed. Only the first Bloch wave which arises at small thickness, and also repeats with increasing thickness, corresponds to the projection of potential $\varphi(xy)$, *i.e.* the atom projection distribution in a thin crystal layer.

An image of other Bloch waves is defined by the function $\varphi(\mathbf{r})$, but their maxima or minima do not coincide, in the general case, with the atomic positions and cannot be interpreted as the projection of potential. It is difficult to reconstruct $\varphi(xy)$ from these images, especially when the crystal is not ideal and contains imperfections. In these cases one resorts to computer modelling of images at different thicknesses and defocus values, and to comparison with an experimentally observed pattern.

The imaging can be performed directly in an electron microscope not by a photo plate, but using fast-response detectors with digitized intensity output online. The computer contains the necessary algorithms for Fourier transformation, image calculation, transfer function computing, averaging, and correction for the observed and calculated data. This makes possible the interpretation of the pattern observed directly in experiment (Herrmann *et al.*, 1980).

2.5.5.5. Image enhancement

The real electron-microscope image is subdivided into two components:

$$J(xy) = I(xy) + N(xy). \tag{2.5.5.17}$$

The main of these, $I(xy)$, is a two-dimensional image of the 'ideal' object obtained in an electron microscope with instrumental functions inherent to it. However, in the process of object imaging and transfer of this information to the detector there are various sources of noise. In an electron microscope, these arise owing to emission-current and accelerating-voltage fluctuations, lens-supplying current (temporal fluctuations), or mechanical instabilities in a device, specimen or detector (spatial shifts). The two-dimensional detector (*e.g.* a photographic plate) has structural inhomogeneities affecting a response to the signal. In addition, the specimen is also unstable; during preparation or imaging it may change owing to chemical or some other transformations in its structure, thermal effects and so on. Biological specimens scatter electrons very weakly and their natural state is moist, while in the electron-microscope column they are under vacuum conditions. The methods of staining (negative or positive), *e.g.* of introducing into specimens substances containing heavy atoms, as well as the freeze-etching method, somewhat distort the structure of a specimen. Another source of structure perturbation is radiation damage, which can be eliminated at small radiation doses or by using the cryogenic technique. The structure of stained specimens is affected by stain graininess. We assume that all the deviations $\Delta I_k(xy)$ of a specimen image from the 'ideal' image $I_k(xy)$ are included in the noise term $N_k(xy)$. The substrate may also be inhomogeneous. All kinds of perturbations cannot be separated and they appear on an electron microscope image as the full noise content $N(xy)$.

The image enhancement involves maximum noise suppression $N(xy)$ and hence the most accurate separation of a useful signal $I(xy)$ from the real image $J(xy)$ (2.5.5.1). At the signal/noise ratio $I/N \simeq 1$ such a separation appears to be rather complicated. But in some cases the real image reflects the structure sufficiently well, *e.g.* during the atomic structure imaging of some crystals ($I/N > 10$). In other cases, especially of biological specimen imaging, the noise N distorts substantially the image, (I/N) ~ 5–10. Here one should use the methods of enhancement. This problem is usually solved by the methods of statistical processing of sets of images J_k ($k = 1, \ldots, n$). If one assumes that the informative signal $I_k(xy)$ is always the same, then the noise error $N(xy)$ may be reduced.

The image enhancement methods are subdivided into two classes:

(a) image averaging in real space xy;

(b) Fourier analysis and filtration in reciprocal space.

These methods can be used separately or in combination. The enhancement can be applied to both the original and the restored images; there are also methods of simultaneous restoration and enhancement.

The image can be enhanced by analogue (mainly optical and photographic) methods or by computational methods for processing digitized functions in real and reciprocal space.

The cases where the image has translational symmetry, rotational symmetry, and where the image is asymmetric will be considered.

Periodic images. An image of the crystal structure with atomic or molecular resolution may be brought to self-alignment by a shift by a and b periods in a structure projection. This can be performed photographically by printing the shifted image on the same photographic paper or, *vice versa*, by shifting the paper (McLachlan, 1958).

The Fourier filtration method for a periodic image I_p with noise N is based on the fact that in Fourier space the components $\mathscr{F}I_p$ and $\mathscr{F}N$ are separated. Let us carry out the Fourier transformation of the periodic signal I_p with the periods a, b and noise N:

$$\begin{aligned}\mathscr{F}J &= \mathscr{F}[I_p(xy) + N(xy)] \\ &= \textstyle\int I_p(xy) \exp[2\pi i(hx + ky)]\, \mathrm{d}x\, \mathrm{d}y + \mathscr{F}N \\ &= \textstyle\sum \Phi_{hk} \delta(\mathbf{u} - \mathbf{u}_{hk}) + \mathscr{F}N; \qquad (2.5.5.18) \\ \mathbf{u}_{hk} &= h\mathbf{a}^* + k\mathbf{b}^*.\end{aligned}$$

The left part of (2.5.5.18) represents the Fourier coefficients Φ_{hk} distributed discretely with periods a^* and b^* in the plane $\mathbf{u}(uv)$. This is the two-dimensional reciprocal lattice. The right-hand side of (2.5.5.18) is the Fourier transform $\mathscr{F}N$ distributed continuously in the plane. Thus these parts are separated. Let us 'cut out' from distribution (2.5.5.18) only Φ_{hk} values using the 'window' function $w(uv)$. The window should match each of the real peaks Φ_{hk} which, owing to the finite dimensions of the initial periodic image, are not points, as this is written in an idealized form in (2.5.5.18) with the aid of δ functions. In reality, the 'windows' may be squares of about $a^*/10$, $b^*/10$ in size, or a circle. Performing the Fourier transformation of product (2.5.5.18) without $\mathscr{F}N$, and set of windows $w(\mathbf{u}) = w(uv) * \sum_{h,k} \delta(\mathbf{u} - h\mathbf{a}^* - k\mathbf{b}^*)$, we obtain:

$$\begin{aligned}J(xy) &= \mathscr{F}^{-1}\{w(\mathbf{u}) \sum_{h,k} \Phi_{h,k} \delta(\mathbf{u} - \mathbf{u}_{h,k})\} \\ &= W(xy) * I_p(\mathbf{x}), \qquad (2.5.5.19)\end{aligned}$$

the periodic component without the background, $W(xy) = \mathscr{F}^{-1}w(\mathbf{u})$. The zero coefficient Φ_{00} in (2.5.5.19) should be decreased, since it is due, in part, to the noise. When the window w is sufficiently small, I_p in (2.5.5.19) represents the periodic distribution $\langle I \rangle$ (average over all the unit cells of the projection) included in I_p (2.5.5.18). Nevertheless, some error from noise in an image does exist, since with Φ_{hk} we also introduced into the inverse Fourier transformation the background transform values $\mathscr{F}^{-1}N_{hk}$ which are within the 'windows'.

This approach is realized by an analogue method [optical diffraction and filtering of electron micrographs in a laser beam (Klug & Berger, 1964)] and can also be carried out by computing.

As an example, Fig. 2.5.5.2(b) shows an electron micrograph of the periodic structure of a two-dimensional protein crystal, while Fig. 2.5.5.2(c) represents optical diffraction from this layer. In order to dissect the aperiodic component $\mathscr{F}N$ in a diffraction plane, according to the scheme in Fig. 2.5.5.2(a), one places a mask with windows covering reciprocal-lattice points. After such a filtration, only the I_p component makes a contribution during the image formation by means of a lens, while the component $\mathscr{F}N$ diffracted by the background is delayed. As a result, an optical pattern of the periodic structure is obtained (Fig. 2.5.5.2d).

Optical diffractometry also assists in determining the parameters of a two-dimensional lattice and its symmetry.

Using the same method, one can separate the superimposed images of two-dimensional structures with different periodicity and in different orientation, the images of the 'near' and 'far' sides of tubular periodic structures with monomolecular walls (Klug & DeRosier, 1966; Kiselev *et al.*, 1971), and so on.

Computer filtering involves measuring the image optical density J_{obs}, digitization, and Fourier transformation (Crowther & Amos, 1971). The sampling distance usually corresponds to one-third of the image resolution. When periodic weak phase objects are investigated, the transformation (2.5.5.18) yields the Fourier coefficients. If necessary, we can immediately make corrections in them using the microscope transfer function according to (2.5.5.6), (2.5.5.7a,b) and (2.5.5.11a), and thereby obtain the true kinematic amplitudes Φ_{hk}. The inverse transformation (2.5.5.16) gives a projection of the structure (Unwin & Henderson, 1975; Henderson & Unwin, 1975).

Sometimes, an observed image $J(\mathbf{x})$ is 'noised' by the $N(\mathbf{x})$ to a great extent. Then, one may combine data on real and reciprocal space to construct a sufficiently accurate image. In this case, the electron-diffraction pattern is measured and structure-factor moduli from diffraction reflection intensities $I_{hk,\,obs}$ are obtained:

$$|\Phi_{hk,\,obs}| \sim \sqrt{I_{hk,\,obs}}. \qquad (2.5.5.20)$$

At the same time, the structure factors

$$\Phi_{hk,\,calc} = |\Phi_{hk,\,calc}| \exp(i\alpha_{hk,\,calc}) \qquad (2.5.5.21)$$

are calculated from the processed structure projection image by means of the Fourier transformation. However, owing to poor image quality we take from these data only the values of phases α_{hk} since they are less sensitive to scattering density distortions than the moduli, and construct the Fourier synthesis

$$\begin{aligned}I(xy) = \sum_{hk} &|\Phi_{hk,\,obs}| \exp(i\alpha_{hk,\,calc}) \\ &\times \exp[2\pi i(hx + ky)]. \qquad (2.5.5.22)\end{aligned}$$

Here the possibilities of combining various methods open up, *e.g.* for obtaining the structure-factor moduli from X-ray

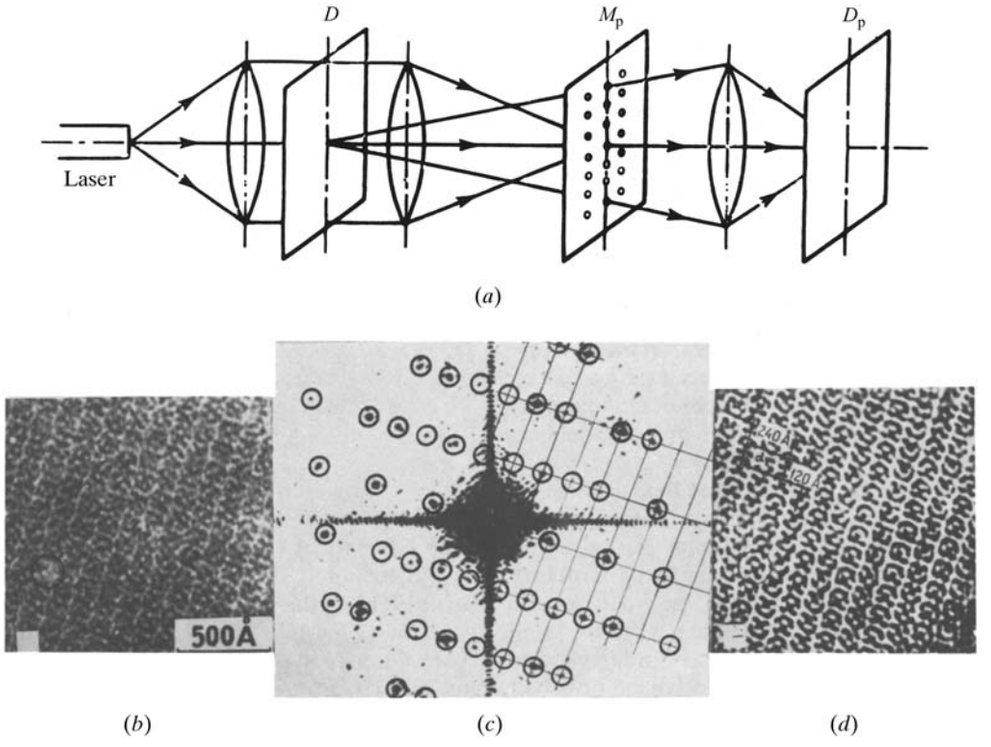

Fig. 2.5.5.2. (*a*) Diagram of an optical diffractometer. *D* is the object (an electron micrograph), M_p is the diffraction plane and a mask that transmits only Φ_{hk}, D_p is the plane of the (filtered) image; (*b*) an electron micrograph of a crystalline layer of the protein phosphorylase *b*; (*c*) its optical diffraction pattern (the circles correspond to the windows in the mask that transmits only the Φ_{hk} diffracted beams from the periodic component of the image); (*d*) the filtered image. Parts (*b*)–(*d*) are based on the article by Kiselev *et al.* (1971).

diffraction, and phases from electron microscopy, and so on (Gurskaya *et al.*, 1971).

Images with point symmetry. If a projection of an object (and consequently, the object itself) has a rotational *N*-fold axis of symmetry, the structure coincides with itself on rotation through the angle $2\pi/N$. If the image is rotated through arbitrary angles and is aligned photographically with the initial image, then the best density coincidence will take place at a rotation through $\alpha = (k2\pi/N)$ $(k = 1, \ldots, N)$ which defines *N*. The pattern averaging over all the rotations will give the enhanced structure image with an $(N)^{1/2}$ times reduced background (Markham *et al.*, 1963).

Rotational filtering can be performed on the basis of the Fourier expansion of an image in polar coordinates over the angles (Crowther & Amos, 1971).

$$I(r, \psi) = \sum_{n=-\infty}^{+\infty} g_n(r) \exp(in\varphi). \qquad (2.5.5.23)$$

The integral over the radius from azimuthal components g_n gives their power

$$p_n \sim \int_0^a |g_n|^2 r \, \mathrm{d}r, \qquad (2.5.5.24)$$

where *a* is the maximum radius of the particle. A set p_n forms a spectrum, the least common multiple *N* of strong peaks defining the *N*-fold symmetry. The two-dimensional reconstructed image of a particle with rotational symmetry is defined by the synthesis (2.5.5.24) with $n = 0, N, 2N, 3N$.

Asymmetric images. In this case, a set of images is processed by computational or analogue methods. The initial selection of images involves the fulfilment of the maximum similarity condition.

The averaging of *n* images in real space gives

$$I_{\text{enh}} = (1/n) \sum_{k=1}^{n} J_k(xy) = \langle I_k \rangle(xy) + (1/n) \sum N_k(xy). \qquad (2.5.5.25)$$

The signal/noise ratio on an average image is $(n)^{1/2}$ times enhanced.

The degree of similarity and accuracy of superposition of two images with an account both of translational and angular shifts is estimated by a cross-correlation function[4] of two selected images J_1 and J_2 (Frank, 1975, 1980).

$$\begin{aligned} k(\mathbf{x}') &= J_1 * J_2 = \int J_1(x) J_2(x + x') \, \mathrm{d}x \\ &= k_{I_1 I_2} + k_{I_1 N_2} + k_{I_2 N_1} + k_{N_1 N_2}. \end{aligned} \qquad (2.5.5.26)$$

The value $k(\mathbf{x}')$ is the measure of image similarity, the x' coordinate of the maximum indicates the shift of the images relative to each other. The first term of the resultant expression (2.5.5.26) is the cross-correlation function of noise-corrected images being compared, the second and third terms are approximately equal to zero, since the noise does not correlate with the signal; the last term is the autocorrelation function of the noise (Cramér, 1954; Frank, 1975, 1980).

The calculation of a correlation function is performed by means of Fourier transformation on the basis of the convolution theorem, since the Fourier transformation of the product of the Fourier transform of function J_1 and the conjugated Fourier transform function J_2 gives the cross-correlation function of the initial functions:

[4] At $I_j = I_k$ this is the autocorrelation function, an analogue of the Patterson function used in crystallography.

$$k = \mathscr{F}^{-1}[\mathscr{F}J_1 \cdot \mathscr{F}^* J_2]. \tag{2.5.5.27}$$

The probability density of samples for images has the form

$$p(J_1 J_2 \ldots J_n) = \frac{1}{(\sigma\sqrt{2\pi})^n} \times \exp\left[\frac{-1}{2\sigma^2}\sum^{n}\int [J_k(\mathbf{x}+\mathbf{x}_k) - J(\mathbf{x})]^2 \, \mathrm{d}x\right]. \tag{2.5.5.28}$$

Here J is the tentative image (as such, a certain 'best' image can first be selected, while at the repeated cycle an average image is obtained), $J_k(\mathbf{x})$ is the image investigated, σ is the standard deviation of the normal distribution of noises and x_k the relative shift of the image. This function is called a likelihood function; it has maxima relative to the parameters $J(x)$, x_k, σ. The average image and dispersion are

$$J(\mathbf{x}) = (1/n)\sum^{n}[J_k(\mathbf{x}-\mathbf{x}_k)],$$
$$\sigma^2 = (1/n)\sum^{n}[J_k(\mathbf{x}-\mathbf{x}_k) - J(\mathbf{x})]^2. \tag{2.5.5.29}$$

This method is called the maximum-likelihood method (Cramér, 1954; Kosykh *et al.*, 1983).

It is convenient to carry out the image alignment, in turn, with respect to translational and angular coordinates. If we start with an angular alignment we first use autocorrelation functions or power spectra, which have the maximum and the symmetry centre at the origin of the coordinates. The angular correlation maximum

$$f(\theta') = \int f_k(\theta - \theta') f_e(\theta) \, \mathrm{d}\theta \tag{2.5.5.30}$$

gives the mutual angle of rotation of two images.

Then we carry out the translational alignment of rotationally aligned images using the translational correlation function (2.5.5.26) (Langer *et al.*, 1970).

In the iteration alignment method, the images are first translationally aligned and then an angular shift is determined in image space in polar coordinates with the centre at the point of the best translational alignment. After the angular alignment the whole procedure may be repeated (Steinkilberg & Schramm, 1980).

The average image obtained may have false high-frequency components. They can be excluded by multiplying its Fourier components by some function and suppressing high-space frequencies, for instance by an 'artificial temperature factor' $\exp\{-B|\mathbf{u}|^2\}$.

For a set of similar images the Fourier filtration method can also be used (Ottensmeyer *et al.*, 1977). To do this, one should prepare from these images an artificial 'two-dimensional crystal', *i.e.* place them in the same orientation at the points of the two-dimensional lattice with periods a, b.

$$J = \sum_{k=1}^{n} J_k(\mathbf{x} - \mathbf{t}_p); \ \mathbf{t} = p_1\mathbf{a} + p_2\mathbf{b}. \tag{2.5.5.31}$$

The processing is then performed according to (2.5.5.18), (2.5.5.19); as a result one obtains $\langle I(xy)\rangle$ with reduced background. Some translational and angular errors in the arrangement of the images at the artificial lattice points act as an artificial temperature factor. The method can be realized by computing or by optical diffraction.

2.5.6. Three-dimensional reconstruction[5]

By B. K. Vainshtein and P. A. Penczek

2.5.6.1. The object and its projection

In electron microscopy (EM) and single-particle reconstruction, three-dimensional (3D) reconstruction methods are used for studying biological structures; that is, symmetric or asymmetric associations of biomacromolecules (muscles, spherical and rod-like viruses, bacteriophages, individual proteins and ribosomes) (Frank, 2006). The electron microscope is used to obtain parallel-beam two-dimensional (2D) projections $\varphi_2(\mathbf{x}, \boldsymbol{\tau})$ (ray transform) of frozen hydrated 3D macromolecules $\varphi_3(\mathbf{r})$ suspended in random orientations (Fig. 2.5.6.1). The function $\varphi_2(\mathbf{x}_\tau)$ is the 2D projection of the 3D molecular electron distribution $\varphi_3(\mathbf{r})$. One can also consider one-dimensional (1D) projections $\varphi_1(s, \boldsymbol{\tau})$ of multidimensional distributions; the set of these projections is called a Radon transform. For 2D distributions, ray and Radon transforms differ only in the notation. For ($d > 2$)-dimensional distributions the two are different: in a ray transform the integrals are calculated over straight lines and yield ($d - 1$)-dimensional projections, while in Radon transforms the integrals are calculated over ($d - 1$)-dimensional hyperplanes and yield 1D projections. In electron microscopy, Radon transforms are not directly measurable, but can be formed computationally and used in intermediate steps of the 3D reconstruction or in alignment procedures (Radermacher, 1994).

Within the linear weak-phase-object approximation of the image-formation process in the microscope [see equation (2.5.2.42) in Section 2.5.2 of this chapter], 2D projections represent line integrals of the potential of the particle under examination convoluted with the point-spread function of the microscope, s, so, using (2.5.2.43),

$$I(xy) = 1 + 2\sigma s(xy) * \varphi(xy) = 1 + 2\sigma s(xy) * \int \varphi_3(\mathbf{r}) \, \mathrm{d}z. \tag{2.5.6.1}$$

Since

$$\varphi_2(\mathbf{x}_\tau) = \int \varphi_3(\mathbf{r}) \, \mathrm{d}\tau, \quad \boldsymbol{\tau} \perp \mathbf{x}, \tag{2.5.6.2}$$

we have

$$I(xy) = 1 + 2\sigma s(\mathbf{x}_\tau) * \varphi_2(\mathbf{x}_\tau), \quad \boldsymbol{\tau} \perp \mathbf{x}. \tag{2.5.6.3}$$

If we omit constant terms, we obtain

$$I(xy) = s(\mathbf{x}_\tau) * \varphi_2(\mathbf{x}_\tau) = s(\mathbf{x}_\tau) * \int \varphi_3(\mathbf{r}) \, \mathrm{d}\tau, \quad \boldsymbol{\tau} \perp \mathbf{x}. \tag{2.5.6.4}$$

In this section, we will assume that all images were collected using the same defocus setting, so the point-spread function s is constant and does not depend on the projection direction $\boldsymbol{\tau}$. Thus, we will concern ourselves with the inversion of the projection problem

$$\varphi_2(\mathbf{x}_\tau) = \int \varphi_3(\mathbf{r}) \, \mathrm{d}\tau, \quad \boldsymbol{\tau} \perp \mathbf{x}. \tag{2.5.6.5}$$

[5] The original version of Section 2.5.6, written by the late B. K. Vainshtein, is here updated and expanded by P. A. Penczek.

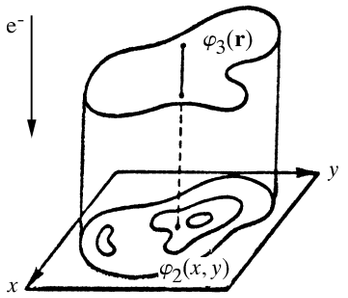

Fig. 2.5.6.1. A three-dimensional object φ_3 and its two-dimensional projection φ_2. The electron beam penetrates the specimen in the direction of the z axis.

The projection direction is defined by a unit vector $\boldsymbol{\tau}(\theta, \psi)$ and it is formed on the plane $\mathbf{x}$ perpendicular to $\boldsymbol{\tau}$. The set of various projections $\varphi_2(\mathbf{x}_{\tau_i}) = \varphi_{2_i}(\mathbf{x}_i)$ may be assigned by a discrete or continuous set of points on a unit sphere $|\tau| = 1$ (Fig. 2.5.6.2).

In Fourier space, the relation between an object and its projection is referred to as the central section theorem: the Fourier transformation of projection φ_2 of a 3D object φ_3 is the central (*i.e.*, passing though the origin of reciprocal space) 2D plane cross section of a 3D transform perpendicular to the projection vector (Bracewell, 1956; DeRosier & Klug, 1968; Crowther, Amos *et al.*, 1970). In Cartesian coordinates, a 3D Fourier transform is

$$\begin{aligned}\mathscr{F}[\varphi_3(\mathbf{r})] &= \Phi_3(u, v, w) \\ &= \iiint \varphi_3(x, y, z) \exp\{2\pi i(ux + vy + wz)\}\, \mathrm{d}x\, \mathrm{d}y\, \mathrm{d}z.\end{aligned} \tag{2.5.6.6}$$

The transform of projection $\varphi_2(x, y)$ along z is

$$\begin{aligned}\mathscr{F}[\varphi_2(x, y)] &= \Phi_3(u, v, 0) \\ &= \iiint \varphi_3(x, y, z) \exp\{2\pi i(ux + vy + 0z)\}\, \mathrm{d}x\, \mathrm{d}y\, \mathrm{d}z \\ &= \iiint \varphi_3(x, y, z)\, \mathrm{d}z \exp\{2\pi i(ux + vy)\}\, \mathrm{d}x\, \mathrm{d}y \\ &= \iint \varphi_2(x, y) \exp\{2\pi i(ux + vy)\}\, \mathrm{d}x\, \mathrm{d}y \\ &= \Phi_2(u, v).\end{aligned} \tag{2.5.6.7}$$

In the general case of projecting along the vector $\boldsymbol{\tau}$, the central section theorem is

$$\mathscr{F}[\varphi_2(\mathbf{x}_\tau)] = \Phi_3(\mathbf{u}_\tau), \quad \mathbf{u}_\tau \perp \boldsymbol{\tau}. \tag{2.5.6.8}$$

From this theorem it follows that the inversion of the 3D ray transform is possible if there is a continuous set of projections φ_τ corresponding to the motion of the vector $\boldsymbol{\tau}(\theta, \psi)$ over any continuous line connecting the opposite points on the unit sphere (Fig. 2.5.6.2) (Orlov's condition: Orlov, 1976). This result is evidenced by the fact that in this case the cross sections $\mathscr{F}[\varphi_2(\mathbf{x}_\tau)]$ that are perpendicular to $\boldsymbol{\tau}$ in Fourier space continuously cover the whole Fourier space, *i.e.*, they yield $\mathscr{F}[\varphi_3(\mathbf{r})]$ and thereby determine $\varphi_3(\mathbf{r}) = \mathscr{F}^{-1}[\Phi_3(\mathbf{u})]$.

In single-particle reconstruction, imaged objects are randomly and nonuniformly oriented on the substrate at different angles (Frank, 2006) and the distribution of their orientations is beyond our control; therefore, the practical impact of Orlov's condition is limited. In fact, it is more useful to determine *a posteriori*, *i.e.*, after the 3D reconstruction of the macromolecule is computed, how well the Fourier space was covered. This can be done by calculating the distribution of the 3D spectral signal-to-noise ratio (Penczek, 2002).

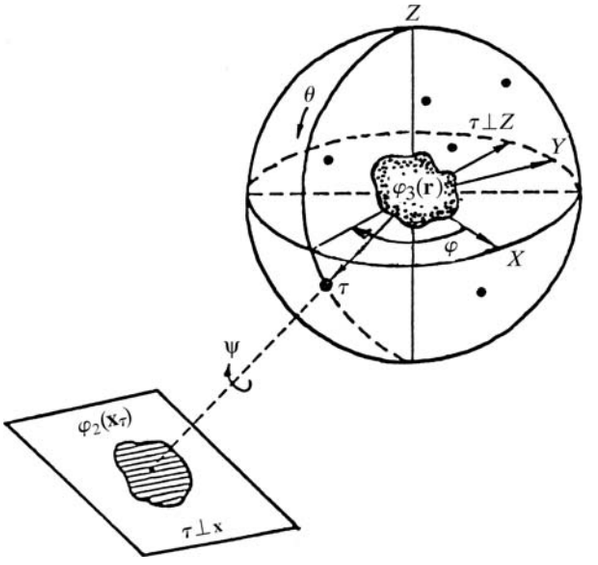

Fig. 2.5.6.2. The projection sphere and projection $\varphi_2(\mathbf{x}_\tau)$ of $\varphi_3(\mathbf{r})$ along $\boldsymbol{\tau}$ onto the plane $\boldsymbol{\tau} \perp \mathbf{x}$. The case $\boldsymbol{\tau} \perp Z$ represents orthoaxial projection. Points indicate an arbitrary distribution of projection directions $\boldsymbol{\tau}$.

2.5.6.2. 3D reconstruction in the general case

In the general case of the 3D reconstruction of $\varphi_3(\mathbf{r})$ from projections $\varphi_2(\mathbf{x}_\tau)$, the projection vector $\boldsymbol{\tau}$ occupies arbitrary positions on the projection sphere (Fig. 2.5.6.2). First, let us consider the case of a 2D function $\rho_2(\mathbf{x})$ and its ray transform $\varphi_1(x, \psi)$. We introduce an operation of backprojection b, which is stretching along $\boldsymbol{\tau}_\psi$ each 1D projection $\varphi_1(x_\psi)$ (Fig. 2.5.6.3). When the result is integrated over the full angular range of projections $\varphi_1(x, \psi)$, we obtain the projection synthesis defined as

$$b(x, y) = \int_0^\pi \varphi_1(x \cos\psi + y \sin\psi, \psi)\, \mathrm{d}\psi. \tag{2.5.6.9}$$

However, the backprojection operator is not the inverse of a 2D ray transform, as the resulting image b is blurred by the point-spread function $(x^2 + y^2)^{-1/2}$ (Vainshtein, 1971):

$$b(x, y) = \rho(x, y) * (x^2 + y^2)^{-1/2}. \tag{2.5.6.10}$$

By noting that the Fourier transform of $(x^2 + y^2)^{-1/2}$ is $(u^2 + v^2)^{-1/2}$ and by using the convolution theorem $\mathscr{F}[f * g] = \mathscr{F}[f]\mathscr{F}[g]$, we obtain the 'backprojection-filtering' inversion formula:

$$\begin{aligned}\rho(x, y) &= b(x, y) * (x^2 + y^2)^{1/2} = \mathscr{F}^{-1}\big[|\mathbf{u}|\mathscr{F}[b]\big] \\ &= \text{Filtration}_{|\mathbf{u}|}[\text{Backprojection}(\varphi_1)].\end{aligned} \tag{2.5.6.11}$$

The more commonly used 'filtered-backprojection' inversion is based on the 2D version of the central section theorem (2.5.6.8):

$$\mathscr{F}[\varphi_1(x_\psi)] = \Upsilon_2(\mathbf{u}_\psi) = \Upsilon_2(R, \Psi), \tag{2.5.6.12}$$

where $\mathscr{F}[\rho_2] = \Upsilon_2$. With this in mind, $\rho_2(\mathbf{x})$ can be related to its ray transform by evaluating the Fourier transform of ρ_2 in polar coordinates:

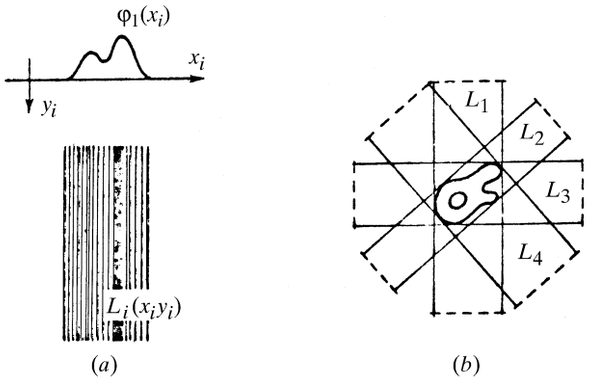

Fig. 2.5.6.3. (*a*) Formation of a backprojection function; (*b*) projection synthesis (2.5.6.9) is a superposition of these functions.

$$\begin{aligned}\rho_2(\mathbf{x}) &= \int \Upsilon_2(\mathbf{u}) \exp(-2\pi i \mathbf{u}\mathbf{x})\, \mathrm{d}\mathbf{u} \\ &= \int_0^{\pi} \int_{-\infty}^{\infty} \Upsilon_2(R, \Psi) \exp(-2\pi i \mathbf{x}\boldsymbol{\tau}) |R|\, \mathrm{d}R\, \mathrm{d}\Psi \\ &= \int_0^{\pi} \int_{-\infty}^{\infty} \mathscr{F}[\varphi_1(x_\psi)] \exp(-2\pi i \mathbf{x}\boldsymbol{\tau}) |R|\, \mathrm{d}R\, \mathrm{d}\Psi \\ &= \int_0^{\pi} \mathscr{F}^{-1}\big[|R| \mathscr{F}[\varphi_1(x_\psi)]\big]\, \mathrm{d}\Psi \\ &= \text{Backprojection}[\text{Filtration}_{|R|}(\varphi_1)]. \end{aligned} \tag{2.5.6.13}$$

In three dimensions, the backprojection stretches each 2D projection $\varphi_{2_i}[\mathbf{x}, \boldsymbol{\tau}(\theta, \psi)_i]$ along the projection direction $\boldsymbol{\tau}(\theta, \psi)_i$. A 3D synthesis is the integral over the hemisphere (Fig. 2.5.6.2)

$$b(\mathbf{r}) = \int_{\omega} \varphi_2(\mathbf{x}, \omega_{\boldsymbol{\tau}})\, \mathrm{d}\omega_{\boldsymbol{\tau}} = \varphi_3(\mathbf{r}) * (x^2 + y^2 + z^2)^{-1}. \tag{2.5.6.14}$$

Thus, in three dimensions the image b obtained using the backprojection operator is blurred by the point-spread function $1/(x^2 + y^2 + z^2)$ (Vainshtein, 1971). It is possible to derive inversion formulae analogous to (2.5.6.11) and (2.5.6.13).

The inversion formulae demonstrate that it is possible to invert the ray transform for continuous functions and for a uniform distribution of projections. In electron microscopy, the projections are never distributed uniformly in three dimensions. Indeed, a uniform distribution is not even desirable, as only certain subsets of projection directions are required for the successful inversion of a 3D ray transform, as follows from the central section theorem (2.5.6.8). In practice, we always deal with sampled data and with discrete, random and nonuniform distributions of projection directions. Therefore, the inversion formulae can be considered only as a starting point for the development of the numerical (and practical!) reconstruction algorithms. According to (2.5.6.10) and (2.5.6.14), a simple backprojection step results in reconstruction that corresponds to a convolution of the original function with a point-spread function that depends only on the distribution of projections, but not on the structure itself. Taking into account the linearity of the backprojection operation, one has to conclude that for any practically encountered distribution of projections it should be possible to derive the corresponding point-spread function and then, using either deconvolution or Fourier filtration (with a 'weighting function'), arrive at a good approximation of the structure. This observation forms the basis of the weighted backprojection algorithm (Section 2.5.6.5). Similarly, the central section theorem gives rise to direct Fourier inversion algorithms (Section 2.5.6.6). Nevertheless, since the data are discrete, the most straightforward methodology is to discretize and approach the reconstruction problem as an algebraic problem (Section 2.5.6.4).

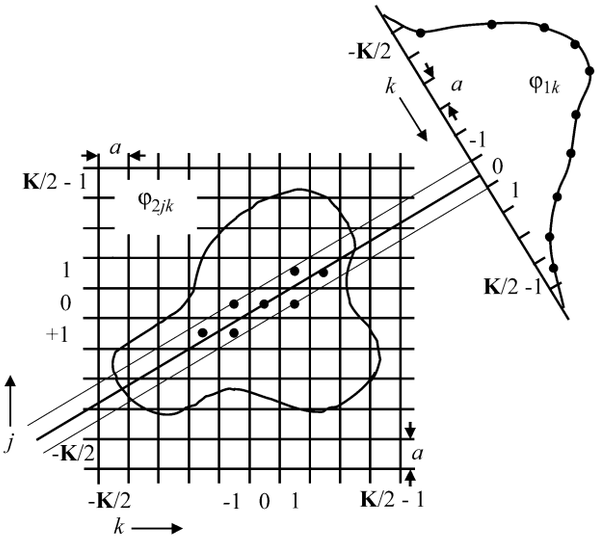

Fig. 2.5.6.4. Discretization in two dimensions ($d = 2$). The assumption is that the mass is located at the centre of the voxel.

2.5.6.3. Discretization and interpolation

In digital image processing, space is represented by a multidimensional discrete lattice. (It is sometimes expedient to use cylindrical or spherical coordinates, but these also have to be appropriately discretized.) The 2D projections $\varphi_2(\mathbf{x})$ are sampled on a Cartesian grid $\{\mathbf{k}a : \mathbf{k} \in \mathbf{Z}^d, (-\mathbf{K}/2) \leq \mathbf{k} \leq (\mathbf{K}/2)\}$, where d is the dimensionality of the grid ($d = 2$ for projections, $d = 3$ for the reconstructed object), $\mathbf{K} \in \mathbf{Z}_+^d$ is the size of the grid and a is the grid spacing (Fig. 2.5.6.4). In single-particle reconstruction, the units of a are usually ångstroms and we also assume that the data were appropriately sampled, *i.e.*, $a \leq (1/2u_{\max})$. Thus, the pixel size is less than or equal to the inverse of twice the maximum spatial frequency present in the data. Since the latter is not known in advance, a more practical rule is to select the pixel size at about one third of the expected resolution of the final structure, so that the adverse effects of interpolation are reduced.

The input electron microscopy data (projections of the macromolecule) are discretized on a 2D Cartesian grid, but each projection has a particular orientation in polar coordinates. Except for a few cases (projection directions parallel to the axes of the coordinate system of the 3D structure), an interpolation is required to relate measured samples to the voxel (volume pixel) values on the 3D Cartesian grid of the reconstructed structure (Fig. 2.5.6.4). The step of backprojection can be visualized as a set of rays with base a^{d-1} extended from projections and the ray values being added to the intersected voxels on the grid of the reconstructed structure (Figs. 2.5.6.3 and 2.5.6.4). One can select schemes that aim at approximation of the physical reality of the data collection, for example to weight the contributions by the areas of the voxels intersected by the ray or by the lengths of the lines that transverse the voxel (Huesman *et al.*, 1977). In order to reduce the time of calculations, in electron microscopy one usually assumes that all the mass is located at the centre of the voxel and the additional accuracy is achieved by application of tri- (or bi-)linear interpolation. The exception is the algebraic reconstruction technique with blobs algorithm (Marabini *et al.*, 1998), where the voxels are represented by smooth spherically symmetric volume elements [for example, the Keiser–Bessel function (2.5.6.44)].

In real space, both the projection and backprojection steps can be implemented in two different ways: as voxel driven or as ray driven (Laurette *et al.*, 2000). If we consider a projection, in the

voxel-driven approach the volume is scanned voxel by voxel. The nearest projection bin to the projection of each voxel is found, and the values in this bin and three neighbouring bins are increased by the corresponding voxel value multiplied by the weights calculated using bilinear interpolation. In the ray-driven approach, the volume is scanned along the projection rays. The value of the projection bin is increased by the values in the volume calculated in equidistant steps along the rays using trilinear interpolation. Because voxel- and ray-driven methods apply interpolation to projections or to voxels, respectively, the interpolation artifacts will be different in each case. Therefore, when calculating reconstructions using iterative algorithms that alternate between projection and backprojection steps, it is important to maintain consistency; that is, to use the same method for both steps. In either case, the computational complexity of each method is of the order of K^3, although the voxel-driven approach is faster due to the smaller number of neighbouring points used in the interpolation.

In the reconstruction methods based on the direct Fourier inversion of the 3D ray transform, the interpolation is performed in Fourier space. Unfortunately, it is difficult to design an accurate and fast interpolation scheme for the discrete Fourier space. Bilinear interpolation introduces local errors and when applied in real space it results in attenuation of high-frequency information. When applied in Fourier space, bilinear interpolation results in errors evenly spread over the whole frequency range, thus resulting in potentially severe nonlocal errors in real space. In order to eliminate this error it would be tempting to use interpolation based on Shannon's sampling theorem [Shannon, 1949; reprinted in *Proc. IEEE*, (1998), **86**, 447–457], which states that a properly sampled band-limited signal can be fully recovered from its discrete samples. For the signal represented by K^3 equispaced Fourier samples Φ_{3hkl}, the value of the Fourier transform Φ_3 at the arbitrary location (u, v, w) is given by (Crowther, Amos *et al.*, 1970)

$$\Phi_3(u, v, w) = \sum_{h=0}^{K-1} \sum_{k=0}^{K-1} \sum_{l=0}^{K-1} \Phi_{3hkl} w_h(u) w_k(v) w_l(w), \qquad (2.5.6.15)$$

where (Yuen & Fraser, 1979; Lanzavecchia & Bellon, 1994)

$$w_k(u) = \begin{cases} \dfrac{\sin\{K\pi[u-(k/K)]\}}{\sin\{\pi[u-(k/K)]\}}, & K \text{ odd}; \\ \dfrac{\sin\{K\pi[u-(k/K)]\}}{\tan\{\pi[u-(k/K)]\}}, & K \text{ even}. \end{cases} \qquad (2.5.6.16)$$

In cryo-EM, samples of Φ_3 are given at arbitrary 3D locations, as derived from Fourier transforms of 2D projection data (central section theorem) and one seeks to recover Φ_{3hkl} on the 3D Cartesian grid. Upon the inverse Fourier transform, it will yield the reconstructed object. The problem can be solved as an overdetermined system of linear equations (Crowther, DeRosier & Klug, 1970). Indeed, if we write Φ_3 and Φ_{3hkl} as 1D arrays $\mathbf{\Phi}_3$ and $\mathbf{\Phi}_{3(hkl)}$, respectively (the former has $K^2 \times$ [number of projections] elements, while the latter has K^3 elements), and we denote by $\mathbf{W}$ the appropriately dimensioned matrix of the interpolants, the least-squares solution is

$$\mathbf{\Phi}_{3(hkl)} = (\mathbf{W}^T\mathbf{W})^{-1}\mathbf{W}^T\mathbf{\Phi}_3. \qquad (2.5.6.17)$$

The above method is impractical because of the large size of the matrix $\mathbf{W}$. In some cases, when due to symmetries the projection data are distributed approximately evenly (as in the case of icosahedral structures), the problem can be solved to a good degree of accuracy by performing the interpolation (2.5.6.17) independently along each of the three frequency axes (Crowther, DeRosier & Klug, 1970). Thus, in this case the solution to the problem of interpolation in Fourier space becomes a solution to the reconstruction problem.

For a more general single-particle reconstruction application a moving Shannon window interpolation has been proposed (Lanzavecchia & Bellon, 1994, 1998). It is based on an attenuated version of the window function and in one dimension has the form

$$\Phi_1(u) = \sum_{k=m}^{m+n-1} \Phi_{1k} \frac{\sin\{\pi[u-(k/K)]\}}{\sin\{(\pi/2)[u-(k/K)]\}} \times (\cos\{(\pi/2)[u-(k/K)]\})^A, \qquad (2.5.6.18)$$

where n is the window size ($n \ll K$) and A is an integer that is even for K odd and *vice versa*. In multidimensional cases, a product of Φ's from (2.5.6.18) is used. In the case of interpolation between equispaced samples of Φ_{2hk}, excellent results have been reported for $n = 11$ (Lanzavecchia *et al.*, 1996). However, the application to the reconstruction problem, *i.e.*, to resampling of the nonuniformly distributed Fourier data onto a 3D Cartesian grid, does not yield satisfactory results. Although general conditions under which interpolation using (2.5.6.18) can be done are known (Clark *et al.*, 1985), they are not met in practice and the results are at best nonexact. In addition, the relatively large window size required ($n = 11$) results in impractical calculation times.

2.5.6.4. The algebraic and iterative methods

The algebraic methods have been derived based on the observation that when the projection equation (2.5.6.5) is discretized, it forms a set of linear equations. Thus, pixels from all available N projections are placed (in an arbitrary order) in a vector $\varphi_{2jk}^n, n = 1, \ldots, N \rightarrow \mathbf{f}$ and the voxels of the 3D object in a vector $\varphi_{3jkl} \rightarrow \mathbf{g}$ (in an order derived from the order of $\mathbf{f}$ by algebraic relations). Note we left the exact sizes of $\mathbf{f}$ and $\mathbf{g}$ undetermined, as the major advantage of algebraic methods is that we can include in the reconstruction only pixels located within an arbitrary support in two dimensions and this support can be different for each projection; similarly, the support of the object in three dimensions can be arbitrary. Thus, the number of elements in $\mathbf{f}$ and $\mathbf{g}$ are at most K^2N and K^3, respectively, with K^2 being the number of pixels within chosen support. In the algebraic formulation the operation of projection is defined by the *projection matrix* $\mathbf{P}$ whose elements $p_{\eta\xi}$ are the interpolation weights. Their values are determined by the interpolation scheme used, but for the bi- and trilinear interpolations $0 \leq p_{\eta\xi} \leq 1$. The algebraic version of (2.5.6.5) is

$$\mathbf{f} = \mathbf{P}\mathbf{g}. \qquad (2.5.6.19)$$

Matrix $\mathbf{P}$ is rectangular and since in single-particle reconstruction the number of projections exceeds the linear size of the object ($N \gg K$) the system of equations is overdetermined. It can be solved in a least-squares sense:

$$\tilde{\mathbf{g}} = (\mathbf{P}^T\mathbf{P})^{-1}\mathbf{P}^T\mathbf{f}, \qquad (2.5.6.20)$$

which yields a unique structure $\tilde{\mathbf{g}}$ that corresponds to the minimum of $|\mathbf{P}\mathbf{g} - \mathbf{f}|^2$. As in the case of direct inversion in Fourier space (2.5.6.17), the approach (2.5.6.20) is impractical because of the very large size of the projection matrix. Indeed, the size of $\mathbf{P}$ is $K^2N \times K^3$, which for a modest number of projections $N = 10\,000$ and image size $K^2 = 64^2 = 4096$ yields a matrix of size $\sim(4 \times 10^7) \times (2 \times 10^6)$! Nevertheless, in some cases

the projections of the structure are orthoaxial, the full 3D reconstruction reduces to a series of independent 2D reconstructions, and it becomes possible to solve (2.5.6.19) by using the singular value decomposition (SVD) of the matrix $\mathbf{P}$:

$$\mathbf{P} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T, \tag{2.5.6.21}$$

where $\mathbf{U}$ and $\mathbf{V}$ contain eigenvectors of matrices $\mathbf{P}\mathbf{P}^T$ and $\mathbf{P}^T\mathbf{P}$, respectively, and $\mathbf{\Sigma}$ is a diagonal matrix containing the first r nonnegative square roots of the eigenvalues of $\mathbf{P}\mathbf{P}^T$ (Golub & Van Loan, 1996). The solution is given by

$$\mathbf{g} = \mathbf{V}\mathbf{\Sigma}_l^{-1}\mathbf{U}^T\mathbf{f}, \tag{2.5.6.22}$$

where $\mathbf{\Sigma}_l^{-1}$ is the inverse of the matrix containing the $l \leq r$ largest elements of $\mathbf{\Sigma}$ with the remaining values set to zero. By selecting l appropriately we achieve a measure of regularization. The advantage of the approach is that for a given geometry the decomposition has to be calculated once; thus, the method becomes very efficient if the reconstruction has to be performed repeatedly for the same distribution of projections or if additional symmetries, such as helical, are taken into account (Holmes *et al.*, 2003).

In the general 3D case, a least-squares solution can be found using one of the iterative approaches that take advantage of the fact that the projection matrix is sparse. Indeed, if bilinear interpolation is used, a row of $\mathbf{P}$ will contain only about $4N$ nonzero elements (out of the total $\sim K^2N$). The main idea is that the matrix $\mathbf{P}$ is not explicitly calculated or stored; instead, its elements are calculated repeatedly during iterations as needed. In the simultaneous iterative reconstruction technique (SIRT) we find the minimum of

$$L(\mathbf{g}) = |\mathbf{P}\mathbf{g} - \mathbf{f}|^2 \tag{2.5.6.23}$$

by selecting the initial 3D structure $\mathbf{g}^0$ (usually set to zero) and by iteratively updating its current approximation $\mathbf{g}^{i+1}$ using the gradient of the objective function (2.5.6.23) $\nabla L(\mathbf{g})$,

$$\mathbf{g}^{i+1} = \mathbf{g}^i - \lambda^i\mathbf{P}^T(\mathbf{P}\mathbf{g}^i - \mathbf{f}) = \mathbf{g}^i - \lambda^i(\mathbf{P}^T\mathbf{P}\mathbf{g}^i - \mathbf{P}^T\mathbf{f}). \tag{2.5.6.24}$$

Setting the relaxation parameter $\lambda^i = \lambda = \text{constant}$ yields Richardson's algorithm (Gilbert, 1972). In single-particle reconstruction applications convergence (*i.e.*, a solution that is not dominated by the noise) is usually reached in ~100 iterations.

SIRT is extensively used in single-particle reconstruction (Frank *et al.*, 1996) because it yields superior results over a wide range of experimental conditions (Penczek *et al.*, 1992) and, when presented with angular gaps in the distribution of projections, produces the least disturbing artifacts. Note that strictly speaking, filtered backprojection and direct Fourier inversion algorithms are not applicable to data that do not cover the Fourier space fully. In addition, SIRT offers considerable flexibility in EM applications. First, it is possible to accelerate the convergence by adjusting relaxation parameters: setting $\lambda^i = \arg\min_{\lambda \geq 0} L(g^i - \lambda\nabla L(g^i))$ results in a steepest decent algorithm. Secondly, even faster convergence (in ~10 iterations) is achieved by solving (2.5.6.23) using the conjugate-gradient method, but this requires addition of a regularizing term to (2.5.6.23) in order to prevent excessive enhancement of noise. Such a term has the form $|\mathbf{B}\mathbf{g}|^2$, where matrix $\mathbf{B}$ is a discrete approximation of a Laplacian or higher-order derivatives. Thirdly, it is possible to take into account the underfocus settings of the microscope by including the contrast transfer function (CTF) of the microscope in (2.5.6.23) and by solving the problem for the structure $\mathbf{g}$ that in effect will be corrected for the CTF,

$$L(\mathbf{g}) = (1-\eta)\sum_\kappa |\mathbf{S}_\kappa\mathbf{P}_\kappa\mathbf{g} - \mathbf{f}_\kappa|^2 + \eta|\mathbf{B}\mathbf{g}|^2. \tag{2.5.6.25}$$

Here we assumed that the projection data were grouped according to the defocus settings indexed by κ and we introduced a Lagrange multiplier η whose value determines the smoothness of the solution $\mathbf{g}$ (Zhu *et al.*, 1997). $\mathbf{S}_\kappa$ represents the space-invariant point-spread function of the microscope for the κth defocus group; thus $\mathbf{S}_\kappa$ has a block-Toeplitz structure (Biemond *et al.*, 1990) and $\mathbf{S}_\kappa = \mathbf{S}_\kappa^T$. If we assume that there is no astigmatism (which means that the point-spread function is rotationally invariant), $\mathbf{S}_\kappa$ can be either applied to the projection of the structure or to the 3D structure itself. With these assumptions, (2.5.6.25) can be solved using the iterative scheme (Penczek *et al.*, 1997)

$$\mathbf{g}^{i+1} = \mathbf{g}^i - \lambda\big\{(1-\eta)\big[\sum_\kappa(\mathbf{S}_\kappa^T\mathbf{P}_\kappa^T\mathbf{P}_\kappa\mathbf{S}_\kappa\mathbf{g}^i) - \sum_\kappa(\mathbf{S}_\kappa^T\mathbf{P}_\kappa^T\mathbf{f}_\kappa)\big] + \eta\mathbf{B}^T\mathbf{B}\mathbf{g}^i\big\}. \tag{2.5.6.26}$$

The second sum can be precalculated and stored as a 3D volume in the computer memory. Thus, the input projections have to be read only once and are never accessed again during the course of the iterations, which eliminates the need to store them in the memory [as is also the case in (2.5.6.24)]. In addition, the product $\mathbf{B}^T\mathbf{B}$ is the 3D Laplacian, which can be applied efficiently without actually creating the matrix $\mathbf{B}^T\mathbf{B}$. Finally, because of the large size of the matrix $\mathbf{S}_\kappa$ it is more convenient to apply it in Fourier space and to modify the Fourier transform of the volume instead of using matrix multiplication or real-space convolution. Algorithms (2.5.6.24)–(2.5.6.26) are implemented in the *SPIDER* package (Frank *et al.*, 1996) and (2.5.6.24) in the *SPARX* package (Hohn *et al.*, 2007).

The algebraic reconstruction technique (ART) predates SIRT; in the context of tomographic reconstructions it was proposed by Gordon and co-workers (Gordon *et al.*, 1970) and later it was recognized as a version of Kaczmarz's method for iteratively solving (2.5.6.23) (Kaczmarz, 1993). We write (2.5.6.19) as a set of systems of equations, each relating single pixels f_n, $n = 1, \ldots, NK^2$ in projections with the 3D structure,

$$f_n = \mathbf{p}_n^T\mathbf{g}, \quad n = 1, \ldots, NK^2. \tag{2.5.6.27}$$

Note (2.5.6.27) and (2.5.6.19) are equivalent, as $\mathbf{f} = [f_1 f_2 \ldots f_N]^T$ and $\mathbf{P} = [\mathbf{p}_1\mathbf{p}_2 \ldots \mathbf{p}_N]^T$. With this notation and a relaxation parameter $0 < \mu < 2$, ART comprises the following steps:

(1) set $i = 0$ and the initial structure $\mathbf{g}^0$;

(2) for $n = 1, \ldots, NK^2$, set

$$\mathbf{g}^{iNK^2+n} = \mathbf{g}^{iNK^2+n-1} - \mu(\mathbf{p}_n^T\mathbf{g}^{iNK^2+n-1} - f_n)(\mathbf{p}_n/|\mathbf{p}_n|); \tag{2.5.6.28}$$

(3) set $i = i + 1$; go to step (2).

Although the mathematical forms of update equations in SIRT (2.5.6.24) and in ART (2.5.6.28) are very similar, there are profound differences between them. In SIRT, all voxels in the structure are corrected simultaneously after projections and backprojections of the current update of the structure are calculated. In ART, the projection/backprojection step (2.5.6.28) involves only correction with respect to an individual pixel in a single projection immediately followed by the update of the structure. This results in a much faster convergence of ART as compared to SIRT. Further acceleration can be achieved by

selecting the order in which pixels enter the correction step (2) in (2.5.6.28). It was observed that if a pixel is selected such that its projection direction is perpendicular to the projection direction of the previous pixel, the convergence is achieved faster (Hamaker & Solmon, 1978; Herman & Meyer, 1993). Interestingly, a random order works almost equally well (Natterer & Wübbeling, 2001).

In single-particle reconstruction, ART has been introduced in the form of 'ART with blobs' (Marabini *et al.*, 1998) and is available in the *Xmipp* package (Sorzano *et al.*, 2004). In this implementation, the reconstruction structure is represented by a linear combination of spherically symmetric, smooth, spatially limited basis functions, such as Kaiser–Bessel window functions (Lewitt, 1990, 1992; Matej & Lewitt, 1996). Introduction of blobs significantly reduces the number of iterations necessary to reach an acceptable solution (Marabini *et al.*, 1998).

The major advantage of iterative reconstruction methods is the ability to take advantage of *a priori* knowledge, *i.e.*, any information about the protein structure that was not initially included in the data processing, and introduce it into the reconstruction process in the form of constraints. Examples of such constraints include similarity to the experimental (measured) data, positivity of the protein mass density (only valid in conjunction with the CTF correction), bounded spatial support *etc*. Formally, the process of enforcing selected constraints is best described in the framework of the projections onto convex sets (POCS) theory (Sezan & Stark, 1982; Youla & Webb, 1982; Sezan, 1992) introduced into EM by Carazo and co-workers (Carazo & Carrascosa, 1986, 1987; Carazo, 1992).

2.5.6.5. Filtered backprojection

The method of filtered backprojection (FBP) is based on inversion formulae (2.5.6.11) (in two dimensions) or (2.5.6.14) (in three dimensions). It comprises the following steps: (i) a Fourier transform of each projection is computed; (ii) Fourier transforms of projections are multiplied by filters that account for a particular distribution of projections in Fourier space; (iii) the filtered projections are inversely Fourier transformed; (iv) real-space backprojection of processed projections yields the reconstruction. The method is particularly attractive due to the fact that the reconstruction calculated using simple real-space backprojection can be made efficient if the filter function is easy to compute.

In two dimensions with uniformly distributed projections the weighting function $c(|R|, \Psi)$ in Fourier space is the 'ramp function' $|R|$ [(2.5.6.13)]. In two dimensions with nonuniformly distributed projections, when the analytical form of the distribution of projections is not known, an appropriate approximation to $c(|R|, \Psi)$ has to be found. A good choice is to select weights such that the backprojection integral becomes approximated by a Riemann sum (Penczek *et al.*, 1996),

$$c(|R|, \Psi) = |R|\,\mathrm{d}R\,\mathrm{d}\Psi \rightarrow c(R_j, \Psi_i) = R_j \frac{1}{2\pi}\frac{\Psi_{i+1} - \Psi_{i-1}}{2} = R_j \frac{\Delta\Psi_i}{4\pi}. \quad (2.5.6.29)$$

For a given set of angles the weights $c(R_j, \Psi_i)$ are easily computed (Fig. 2.5.6.5).

In three dimensions, the weighting (2.5.6.29) is applicable in a single-axis tilt data-collection geometry, where the 3D reconstruction can be calculated as a series of independent 2D reconstructions. In the general 3D case, the analogue of weighting (2.5.6.29) cannot be used, as the data are given in the form of 2D projections and it is not immediately apparent what fraction of the 3D Fourier volume is occupied by Fourier pixels in projections. However, the analogue of weighting (2.5.6.29) can be used in the inversion of 3D Radon transforms or in a direction

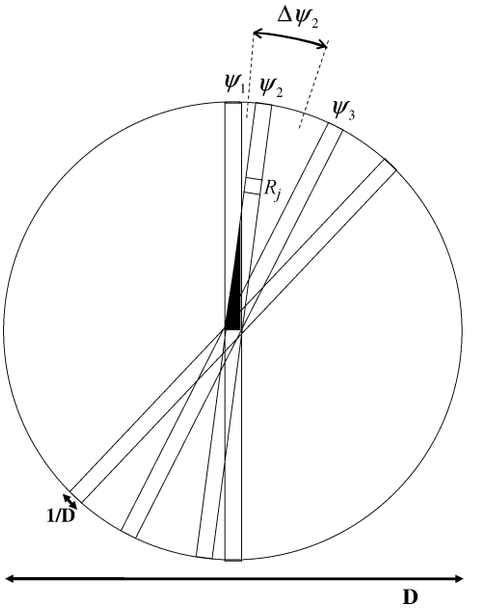

Fig. 2.5.6.5. Nonuniform distribution of projections. The projection weights for the reconstruction algorithms are chosen such that the backprojection integral becomes approximated by a Riemann sum and are equal to the angular length of an arc $\Delta\Psi_i$ (2.5.6.29). In Fourier space, projections of an object with real-space radius D form rectangles with width $1/D$. In the exact filter backprojection reconstruction method, the weights are derived based on the amount the overlap between projections (2.5.6.29).

inversion of 3D ray transforms that is based on an intermediate step of converting 2D projection data to 1D projection data, as described in Section 2.5.6.6.

In order to arrive at a workable solution, the weighting functions applicable to 2D projections are constructed based on an explicitly or implicitly formulated concept of the 'local density' of projections. This concept was introduced by Bracewell (Bracewell & Riddle, 1967), who suggested for a 2D case of nonuniformly distributed projections a heuristic weighting function,

$$c(R_j, \Psi_i) = \frac{R_j}{\sum_l \exp\left[-\text{constant}(|\Psi_i - \Psi_l| \bmod \pi)^2\right]}. \quad (2.5.6.30)$$

The weighting function (2.5.6.30) can be easily extended to three dimensions; however, it has a major disadvantage that for a uniform distribution of projections it does not approximate well the weighting function (2.5.6.29), which we consider optimal.

Radermacher *et al.* (1986) proposed a derivation of a general weighting function using a deconvolution kernel calculated for a given (nonuniform) distribution of projections and, in modification of (2.5.6.14), a finite length of backprojection (Fig. 2.5.6.3). Such a 'truncated' backprojection is

$$\hat{b}_i(\mathbf{r}) = \varphi_{2_i}(\mathbf{x}_\tau) * l(\mathbf{r}), \quad \boldsymbol{\tau} \perp \mathbf{x} \quad (2.5.6.31)$$

with projection directions $\boldsymbol{\tau}(\theta, \psi)_i$ and

$$l(\mathbf{r}) = \delta(\mathbf{x}_\tau) t(z_\tau), \qquad t(z_\tau) = \begin{cases} 1 & -(D/2) \le z \le (D/2), \\ 0 & \text{otherwise}, \end{cases} \quad (2.5.6.32)$$

where D is the diameter of the object or the length of the backprojection l. By taking the Fourier transform of (2.5.6.31) and using the central section theorem (2.5.6.8), we obtain a 3D Fourier transform of the backprojected projection,

$$\Phi_{3_i}(u, v, w) = \Phi_{2_i}(\mathbf{u}_\tau) D \operatorname{sinc}(D\pi w_\tau), \tag{2.5.6.33}$$

and the 3D reconstruction is obtained by the inverse Fourier transform of the sum of contributions given by (2.5.6.33),

$$\mathscr{F}[\hat{b}(\mathbf{r})] = \sum_i \Phi_{2_i}(\mathbf{u}_\tau) D \operatorname{sinc}(D\pi w_\tau). \tag{2.5.6.34}$$

z_τ and w_τ are variables in real and Fourier spaces, respectively, both extending in the direction of the projection direction $\boldsymbol{\tau}(\theta, \psi)_i$.

In this analysis, the transfer function of the backprojection algorithm is obtained by setting $\Phi_{2_i}(\mathbf{u}_\tau) = 1$, that is by finding the response of the algorithm to the input composed of delta functions in real space. This yields the inversion formula for a general weighted backprojection algorithm:

$$\varphi_3(\mathbf{r}) = \mathscr{F}[\hat{b}(\mathbf{r})] c(u, v, w), \tag{2.5.6.35}$$

with the weighting function given by

$$c(u, v, w) = \frac{1}{\sum_i D \operatorname{sinc}(D\pi w_\tau)}. \tag{2.5.6.36}$$

The general weighting function (2.5.6.36) is consistent with analytical solutions (2.5.6.11) and (2.5.6.14), as it can be shown that by assuming infinite support ($D \rightarrow \infty$) and continuous and uniform distribution of projection directions, in two dimensions one obtains $c(u, v) = (u^2 + v^2)^{-1/2}$ (Radermacher, 2000).

The derivation of (2.5.6.36) is based on the analysis of continuous functions and its direct application to discrete data results in reconstruction artifacts; therefore, Radermacher (1992) proposed attenuating the sinc functions in (2.5.6.36) by exponent functions with decay depending on the diameter of the structure D, or simply replacing the sinc functions by exponent functions. This, however, reduces the concept of the weighting function corresponding to the deconvolution to the concept of the weighting function representing the 'local density' of projections (2.5.6.30). The general weighted backprojection reconstruction is implemented in *SPIDER* (using exponent-based weighting functions) (Frank *et al.*, 1996), *Xmipp* (Sorzano *et al.*, 2004) and *SPARX* (Hohn *et al.*, 2007).

Harauz & van Heel (1986) proposed basing the calculation of the density of projections, thus the weighting function, on the overlap of Fourier transforms of projections in Fourier space. Although the concept is general, it can be easily approached in two dimensions. If the diameter of the object is D, the width of a Fourier transform of a projection is $2/D$ (Fig. 2.5.6.5), as follows from the central section theorem (2.5.6.8). Harauz and van Heel postulated that the weighting should be inversely proportional to the sum of geometrical overlaps between a given central section and the remaining central sections. For a pair of projections il, this overlap is

$$o_{il}(R) = T[DR \sin(\Psi_i - \Psi_l)], \tag{2.5.6.37}$$

where T represents the triangle function (selected by the authors because it can be calculated efficiently). Also, owing to the Friedel symmetry of central sections, the angles in (2.5.6.37) are restricted such that $0 \leq \Psi_i - \Psi_l \leq (\pi/2)$. In this formulation, the overlap is limited to the maximum frequency,

$$R_{il}^{\max} = \frac{2}{D \sin(\Psi_i - \Psi_l)}. \tag{2.5.6.38}$$

Thus, the overlap function becomes

$$o_{il}(R) = \begin{cases} 1 - (R/R_{il}^{\max}) & 0 \leq R < u_{il}^{\max} \\ 0 & R > u_{il}^{\max} \end{cases}. \tag{2.5.6.39}$$

In effect, the weighting function, called by the authors an 'exact filter', is

$$c(R, \Psi_i) = \frac{1}{1 + \sum_{l, l \neq i} o_{il}(R)}. \tag{2.5.6.40}$$

The weighting function (2.5.6.40) easily extends to three dimensions; however, the calculation of the overlap between central sections in three dimensions (represented by slabs) is more elaborate (Harauz & van Heel, 1986). The method is conceptually simple and computationally efficient. However, (2.5.6.40) does not approximate the correct weighting well for a uniform distribution of projections [*i.e.*, it should yield $c(R, \Psi_i) = R$]. This, as can be seen by integrating (2.5.6.39) over the whole angular range, is not the case. The exact filter backprojection reconstruction is implemented in the *IMAGIC* (van Heel *et al.*, 1996), *SPIDER* (Frank *et al.*, 1996) and *SPARX* (Hohn *et al.*, 2007) packages.

The 3D reconstruction methods based on filtered backprojection are commonly used in single-particle reconstruction. The reasons are: their versatility, ease of implementation, and – in comparison with iterative methods – good computational efficiency. Unlike in iterative methods, there are no parameters to adjust, although it has been noted that the results depend on the value of the diameter D of the structure in all three weighting functions [(2.5.6.30), (2.5.6.36) and (2.5.6.38)], so the performance of the reconstruction algorithm can be optimized for a particular data-collection geometry by changing the value of D (Paul *et al.*, 2004). However, because computation of the weighting function involves calculation of pairwise distances between projections, the computational complexity is proportional to the square of the number of projections and for large data sets these methods become inefficient. It also has to be noted that the weighting functions (2.5.6.30), (2.5.6.36) and (2.5.6.40) remain approximations of the correct weighting function (2.5.6.29).

2.5.6.6. Direct Fourier inversion

Direct Fourier methods are based on the central section theorem (2.5.6.8). A set of the 2D Fourier transforms of projections yields an approximation to Φ_3 on a nonuniform 3D grid, and a subsequent numerical 3D inverse Fourier transform gives an approximation to φ_3. If the 3D inverse Fourier transform could be realized by means of the 3D inverse fast Fourier transform (FFT), one would have a very fast reconstruction algorithm. Unfortunately, the preprocessing step yields Φ_3 on a nonuniform grid. In effect, the 3D inverse FFT is not applicable and an additional step of recovering samples of Φ_3 on a uniform grid from the available samples on a nonuniform grid is necessary.

One possibility is to resample the nonuniformly sampled version of Φ_3 onto a 3D Cartesian grid by some form of interpolation. For example, Grigorieff used a modified trilinear interpolation scheme in the *FREALIGN* package (Grigorieff, 1998). Simple interpolation methods have been found to give inaccurate results, although more sophisticated interpolation schemes can go a long way to improve the accuracy (Lanza-

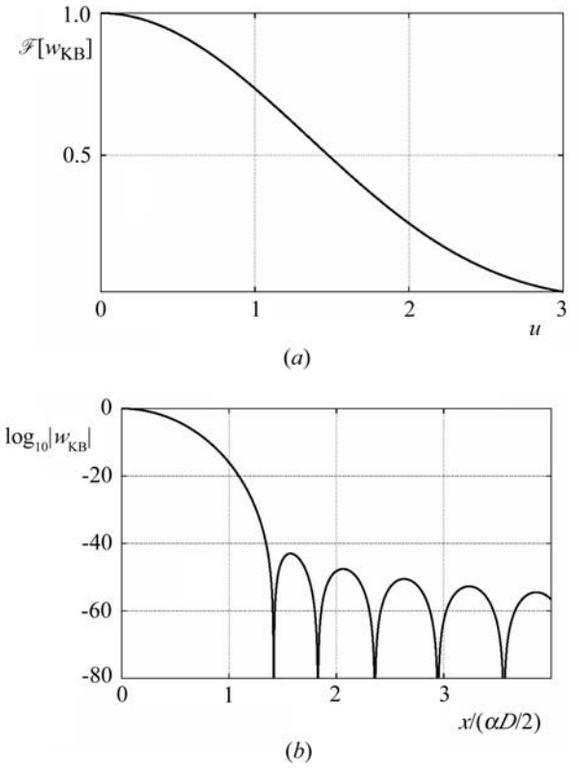

Fig. 2.5.6.6. Kaiser–Bessel window function used in the gridding reconstruction algorithm GDFR. (*a*) In Fourier space, the window function is effectively zero outside the support of six Fourier pixels. (*b*) In real space, the zeros of the window function are beyond the radius of the reconstructed object.

vecchia *et al.*, 1993). Unfortunately, the recommended window size makes them impractical for most applications.

The most accurate Fourier reconstruction methods are those that employ nonuniform Fourier transforms, particularly the 3D gridding method (O'Sullivan, 1985; Schomberg & Timmer, 1995). The gridding-based direct Fourier reconstruction algorithm (GDFR) (Penczek *et al.*, 2004) was developed specifically for single-particle reconstruction. It comprises three steps:

(1) The first step, known as 'gridding', involves calculating for the Fourier transform of each projection the convolution

$$\sum_i \mathscr{F}[w] * (c\mathscr{F}[\varphi_{2_i}]), \tag{2.5.6.41}$$

where c are 'gridding weights' designed to compensate for the nonuniform distribution of the grid points and $\mathscr{F}[w]$ is an appropriately chosen convolution kernel. After processing all projections, this step yields samples of $\mathscr{F}[w] * \mathscr{F}[\varphi_3]$ on a Cartesian grid.

(2) 3D inverse FFT is used to compute

$$w\varphi_3 = \mathscr{F}^{-1}\big[\mathscr{F}[w] * \mathscr{F}[\varphi_3]\big] \tag{2.5.6.42}$$

on a Cartesian grid.

(3) The weights are removed using division:

$$\varphi_3 = w\varphi_3/w. \tag{2.5.6.43}$$

The method involves a number of parameters. First, we need to decide the oversampling factor for the padding with zeros of input projections before FFTs are computed. In GDFR, the oversampling is set to two, although smaller factors can also yield good results. Second, we need a *window function* $\mathscr{F}[w]$ whose support in Fourier space is 'small'. In order to assure good computational efficiency of the convolution step (2.5.6.41), in GDFR this support was set to six Fourier voxels. In addition, in order to prevent division by zeros in (2.5.6.43), the *weighting function* $w = \mathscr{F}^{-1}[\mathscr{F}[w]]$ must be positive within the support of the reconstructed object. A recommendable window function is the separable, bell-shaped Kaiser–Bessel window (O'Sullivan, 1985; Jackson *et al.*, 1991; Schomberg & Timmer, 1995) (Fig. 2.5.6.6*a*):

$$\mathscr{F}[w_{KB}(\mathbf{u})] = \begin{cases} \displaystyle\prod_{v=1}^{d} \frac{I_0\{\pi D\alpha s_v[1-(u_v/s_v)^2]^{1/2}\}}{2s_v}, & \mathbf{u} \in [-\mathbf{s}, \mathbf{s}], \\ 0, & \mathbf{u} \notin [-\mathbf{s}, \mathbf{s}], \end{cases} \tag{2.5.6.44}$$

where I_0 is the zero-order modified Bessel function and $\alpha = 1.25$ is a parameter. The weighting function associated with $\mathscr{F}[w_{KB}]$ is

$$w_{KB}(\mathbf{x}) = \prod_{v=1}^{d} \frac{\sinh\Big[\pi D\alpha s_v\big(1-\{x_v/[\alpha(D/2)]^2\}\big)^{1/2}\Big]}{\pi D\alpha s_v\big(1-\{x_v/[\alpha(D/2)]^2\}\big)^{1/2}}. \tag{2.5.6.45}$$

Finally, the gridding weights c are chosen such that in discrete implementation of (2.5.6.41) and (2.5.6.42) we obtain a Riemann sum approximating the respective integral (Schomberg, 2002). The Voronoi diagram (Okabe *et al.*, 2000) of the sampling points provides a good partitioning of sampling space, so the gridding weights c are computed by constructing a Voronoi diagram of the grid points and by choosing the weights as the volumes of the Voronoi cells (Fig. 2.5.6.7*a*). In cryo-EM, the number of projections, thus the number of sampling points in Fourier space, is extremely large. Thus, although the calculation of the gridding weights *via* the 3D Voronoi diagram of the nonuniformly spaced grid points for $\mathscr{F}[\varphi_3]$ would lead to an accurate direct Fourier method, the method would be very slow and would require excessive computer memory. To circumvent this problem, in GDFR (Penczek *et al.*, 2004) the 2D reverse gridding method is used to compute the Fourier transform of each projection on a 2D polar grid. In this way, $\mathscr{F}[\varphi_3]$ is obtained on a 3D spherical grid, where the grid points are located both on centred spheres and on straight lines through the origin. Accordingly, it becomes possible to partition the sampled region into suitable sampling cells *via* the computation of a 2D Voronoi diagram on a unit sphere, rather than a 3D Voronoi diagram in Euclidean space (Fig. 2.5.6.7*b*). This significantly reduces the memory requirements and improves the computational efficiency of the method, particularly when a fast $O(n \log n)$ algorithm for computing the Voronoi diagram on the unit sphere is employed (Renka, 1997).

The gridding weights in GDFR correspond to the weighting functions in filtered backprojection algorithms. Moreover, setting the gridding weights to be equal to angular regions on the unit sphere directly corresponds to the equating of weighting function (2.5.6.29) in 2D filtered backprojection to the length of an arc on a unitary circle. Thus, both methods yield nearly optimum projection density functions.

The reversed gridding method is obtained by reversing the sequence of steps (1)–(3) of the gridding method:

(1) the input image is divided by the weighting function φ_2/w;

(2) the image is padded with zeros and 2D FFT is used to compute $\mathscr{F}[\varphi_2/w]$;

(3) gridding is used to compute $\mathscr{F}[w] * \mathscr{F}[\varphi_2/w]$ on an arbitrary nonuniform grid.

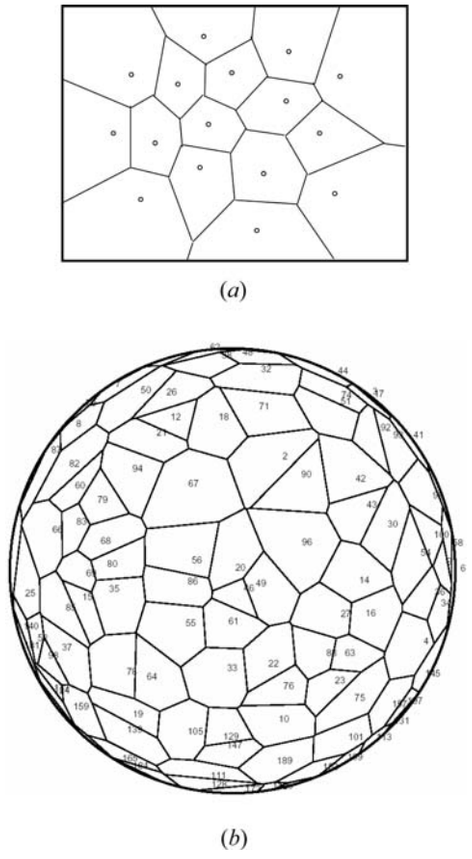

Fig. 2.5.6.7. Partitions of the sampling Fourier space using Voronoi diagrams in direct inversion algorithms. (*a*) Central section of a 3D Fourier volume with sampling points originating from 2D Fourier transforms of projections. Although 2D projections are sampled on a uniform (Cartesian) grid, the arbitrary rotations of projections in 3D space yields a nonuniform distribution of points in three dimensions. In effect, the 3D reconstruction by direct inversion using 3D FFT is not possible. (*b*) Voronoi diagram on a sphere in the GDFR algorithm. Using the reverse gridding method, the 2D Fourier transforms of projections are resampled onto 1D central lines using a constant angular step. In 3D Fourier space, they are located on central sections and their angular directions are evenly distributed on grand circles. However, since central sections have nonuniform distributions, the distribution of angular directions (sampling points on the unitary sphere) is also nonuniform and effectively random.

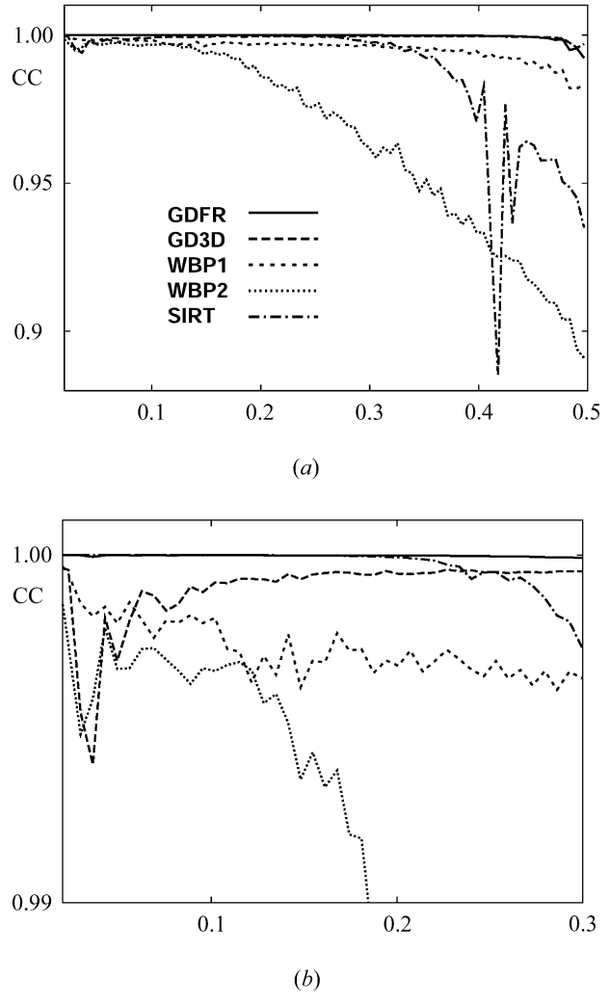

Fig. 2.5.6.8. (*a*) Plot of correlation coefficients (CCs) calculated between Fourier transforms of the reconstructed structure and the original phantom as a function of the magnitude of the spatial frequency using five reconstruction algorithms. GDFR: gridding direct Fourier reconstruction with Voronoi weights; GD3D: gridding reconstruction with simplified gridding weights; WBP1: general weighted backprojection with exponent-based weighting function; WBP2: exact filter weighted backprojection; SIRT: simultaneous iterative reconstruction algorithm. Noise-free projection data were computed in Fourier space using the reverse gridding method. (*b*) Rescaled version of the low-frequency range of (*a*). Note the different scales in (*a*) and (*b*). The horizontal axis is scaled in absolute frequency units with 0.5 equal to the Nyquist frequency.

Note the reverse gridding does not require explicit gridding weights, as in the third step they are constant (Penczek *et al.*, 2004).

In GDFR, the third step of the reversed gridding results in a set of 1D Fourier central lines $\mathcal{F}[\varphi_{1l}]$ calculated using a constant angular step. Clearly, upon inverse Fourier transform they amount to a Radon transform $\varphi_1(u, \psi)$ of the projection and, upon repeating the process for all available projections, they yield a Radon transform $\varphi_1(u, \boldsymbol{\theta})$ of a 3D object φ_3 (albeit non-uniformly sampled with respect to Eulerian angles). Thus GDFR, in addition to being a method of inverting a 3D ray transform, is also a highly accurate method of inverting a 3D Radon transform. GDFR is implemented in the *SPIDER* package (Frank *et al.*, 1996).

The results of a comparison of selected reconstruction algorithms are shown in Fig. 2.5.6.8. The tests were performed using simulated data with the projections of a phantom 3D structure calculated using the inverse gridding method (Penczek *et al.*, 2004). The GDFR yields a virtually perfect reconstruction that agrees with the phantom over the whole frequency range (with the exception of the highest frequencies, but these cannot be reproduced due to geometrical limitations). GD3D is also a gridding-based reconstruction algorithm, in which the gridding weights are calculated directly from contributions of the weighting function to the 3D Fourier pixels and are applied to the voxels in the 3D Fourier volume (Jackson *et al.*, 1991). This yields an approximation to the 'local density' of contributing projections. The simplified gridding weights in GD3D result in deterioration of the reconstruction in the low- and intermediate-frequency ranges. The general weighted backprojection with exponent-based weighting function (WBP1) performs quite well, although reproduction in the low-frequency range is inferior. Similar artifacts are present in the reconstruction using the exact filter weighted backprojection (WBP2), which, in addition, performs disappointingly at higher frequencies. This relatively poor performance is attributed to the nonoptimal weighting schemes used in both methods. It is also interesting to note that the backprojection step is identical in both algorithms; they only differ by the weighting function. The significant difference in their performance attests to the importance of good weighting schemes for high-quality 3D reconstructions from nonuniformly distributed projections. SIRT yields a reconstruction that in the low- and intermediate-frequency ranges matches in quality the reconstruction obtained with GDFR. However, there is a significant loss of quality at high frequencies. This is due to the

inferior linear interpolation scheme used in SIRT (this impediment is shared with WBP1 and WBP2). [The dip of the SIRT fidelity curve at a spatial frequency of 0.42 in Fig. 2.5.6.8(*a*) is due to an inconsistency between the interpolation methods used internally in SIRT to generate intermediate projections of the object to be reconstructed and the Fourier-space-based method used to generate the test data.] In terms of computational efficiency, gridding-based algorithms outperform weighted back-projection algorithms by a small factor while SIRT is approximately ten times slower (depending on the number of iterations used).

2.5.6.7. 3D reconstruction of symmetric objects

Many objects imaged by EM have symmetries; the two types that are often met are helical (phage tails, *F*-actin, microtubules, myosin thick filaments, and bacterial pili and flagella) and point-group symmetries (many macromolecular assemblies, virus capsids). If the object has helical symmetry, it is convenient to use cylindrical coordinates and a dedicated reconstruction algorithm; particularly for the initial analysis of the data that has to be done in Fourier space. Diffraction from such structures with c periodicity and scattering density $\varphi(r, \psi, z)$ is defined by the Fourier–Bessel transform:

$$\begin{aligned}\Phi(R, \Psi, Z) &= \sum_{-\infty}^{+\infty} \exp\Big[in\Big(\Psi + \frac{\pi}{2}\Big)\Big] \int_0^\infty \int_0^{2\pi} \int_0^l \varphi(r, \psi, z) \\ &\quad \times J_n(2\pi r R) \exp[-i(n\psi + 2\pi z Z)] r \, \mathrm{d}r \, \mathrm{d}\psi \, \mathrm{d}z \\ &= \sum_n G_n(R, Z) \exp\Big[in\Big(\Psi + \frac{\pi}{2}\Big)\Big]. \qquad (2.5.6.46)\end{aligned}$$

The inverse transform has the form

$$\rho(r, \psi, z) = \sum_n \int g_n(r, Z) \exp(in\psi) \exp(2\pi i z Z) \, \mathrm{d}Z, \qquad (2.5.6.47)$$

so that g_n and G_n are the mutual Bessel transforms

$$G_n(R, Z) = \int_0^\infty g_n(r, Z) J_n(2\pi r R) 2\pi r \, \mathrm{d}r \qquad (2.5.6.48)$$

and

$$g_n(r, Z) = \int_0^\infty G_n(R, Z) J_n(2\pi r R) 2\pi R \, \mathrm{d}R. \qquad (2.5.6.49)$$

Owing to helical symmetry, (2.5.6.48) and (2.5.6.49) contain only those of the Bessel functions that satisfy the selection rule (Cochran *et al.*, 1952)

$$l = mp + (nq/N), \qquad (2.5.6.50)$$

where N, q and p are the helix symmetry parameters, $m = 0, \pm 1, \pm 2, \ldots$. Each layer l is practically determined by the single function J_n with the lowest n; the contributions of other functions are neglected. Thus, the Fourier transform of one projection of a helical structure, with an account of symmetry and phases, gives the 3D transform (2.5.6.49). However, biological specimens tend to be flexible and disordered, and exact helical symmetry is rarely observed. A possible approach to dealing with flexibility is to computationally straighten filaments (Egelman, 1986), but this has the potential for introducing artifacts. Another difficulty with helical analysis is that the indexing of a pattern can be ambiguous and the wrong symmetry can be chosen (Egelman & Stasiak, 1988). Further complications exist when the filament does not have a precisely defined helical symmetry, such as *F*-actin, which has a random variable twist (Egelman *et al.*, 1982). To address these problems, Egelman developed a real-space refinement method for the reconstruction of helical filaments that is capable of determining the helical symmetry of an unknown structure (Egelman, 2000). In this approach, the Fourier–Bessel reconstruction algorithm is replaced by a general reconstruction algorithm discussed in Section 2.5.6.6 with the real-space projections supplied as input. Thus, the symmetry is not enforced within the reconstruction algorithm; instead, it is determined and imposed subsequently by real-space averaging.

The presence of point-group symmetry in the structure means that any projection yields as many symmetry-related (but differently oriented) copies of itself as the number of symmetry operations in the group. For example, for three dimensions, each projection enters the reconstruction process at six different projection directions, while for icosahedral symmetry (I) the number is sixty! This high multiplicity makes it possible to write a reconstruction program that explicitly takes into account the symmetry and can perform the task much faster than generic algorithms. Such programs are usually part of dedicated software packages that were specifically designed for the determination of icosahedral structures (Fuller *et al.*, 1996; Lawton & Prasad, 1996; Liang *et al.*, 2002). These icosahedral reconstruction programs are heavily indebted to a set of FORTRAN routines written by R. A. Crowther at the Medical Research Council Laboratory of Molecular Biology (MRC LMB) and perform the 3D reconstruction using the Fourier–Bessel transform strategy outlined above [(2.5.6.46)–(2.5.6.49)] (Crowther, Amos *et al.*, 1970; Crowther & Amos, 1972).

The general reconstruction methods (algebraic, filtered back-projection, direct Fourier inversion) easily accommodate symmetries in the data. In major single-particle reconstruction packages, reconstruction programs are implemented such that the point-group symmetry is a parameter of the program. The symmetry operation is internally taken into account during calculation of the weighting function and it is also applied to the set of Eulerian angles assigned to each projection so the multiple copies are implicitly created and processed. This approach results in an extended time of calculations, but it is entirely general. In direct Fourier inversion algorithms the numerical inaccuracy of the symmetrization performed in Fourier space will result in nonsymmetric artifacts in real space. Thus, in *SPIDER* (Frank *et al.*, 1996) an additional real-space symmetrization is performed after the reconstruction is completed. Finally, it has to be noted that although it might be tempting to calculate a 3D reconstruction without enforcement of symmetry and to symmetrize the resulting structure, this approach is incorrect. This fact can be seen from the way weighting functions are constructed: weighting functions calculated with symmetries taken into account are not equal to the weighting function calculated for a unique set of projections and subsequently symmetrized.

2.5.7. Single-particle reconstruction

By P. A. Penczek

2.5.7.1. Formation of projection images in single-particle reconstruction

Cryo-electron microscopy (cryo-EM) in combination with the single-particle approach is a new method of structure determination for large macromolecular assemblies. Currently, resolution in the range 10 to 30 Å can be reached routinely, although in a number of pilot studies it has been possible to obtain structures at 4 to 8 Å. Theoretically, electron microscopy can yield data

exceeding atomic resolution, but the difficulties in overcoming the very low signal-to-noise ratio (SNR) and low contrast in the data, combined with the adverse effects of the contrast transfer function (CTF) of the microscope, hamper progress in fulfilling the potential of the technique. However, in recent years, cryo-EM has proven its power in the structure determination of large macromolecular assemblies and machines which are too large and complex for the more traditional techniques of structural biology, *i.e.*, X-ray crystallography and NMR spectroscopy.

Single-particle reconstruction is based on the assumption that a protein exists in solution in multiple copies of the same basic structure. Unlike in crystallography, no ordering of the structure within a crystal grid is required; the enhancement of the SNR is achieved by bringing projection images of different (but structurally identical) proteins into register and averaging them. This is why the technique is sometimes called 'crystallography without crystals'.

Within the linear weak-phase-object approximation of the image formation process in the microscope [see equation (2.5.2.43) in Section 2.5.2], 2D projections represent line integrals of the Coulomb potential of the particle under examination convoluted with the point-spread function of the microscope, s, as introduced in Section 2.5.1. In addition, we have to consider the translation $\mathbf{t}$ of the projection in the plane of micrograph, suppression of high-frequency information by the envelope function E of the microscope, and two additive noises m^{B} and m^{S}. The first one is a coloured background noise, while the second is attributed to the residual scattering by the solvent or the supporting thin layer of carbon, if used, assumed to be white and affected by the transfer function of the microscope in the same way as the imaged protein. In order to have the image formation model correspond more closely to the physical reality of data collection, we write equation (2.5.6.4) from Section 2.5.6 such that the projection operation is always realized in the z direction of the coordinate system (corresponding to the direction of propagation of the electron beam), while the molecule is rotated arbitrarily by three Eulerian angles:

$$d_n(\mathbf{x}) = s_n(\mathbf{x}) * e_n(\mathbf{x}) * \left[\int f(\mathbf{T}_n\mathbf{r})\,\mathrm{d}z + m_n^{\mathrm{S}}(\mathbf{x})\right] + m_n^{\mathrm{B}}(\mathbf{x}), \quad n = 1, \ldots, N. \tag{2.5.7.1}$$

Here $f \in R^{n^3}$ represents the three-dimensional (3D) electron density of the imaged macromolecule and $d \in R^{n^2}$ is the nth observed two-dimensional (2D) projection image. The total number of projection images N depends on the structure determination project, and can vary from a few hundred to hundreds of thousands. Further, e is the inverse Fourier transform of the envelope function, $\mathbf{x} = [x \quad y]^T$ is a vector of coordinates in the plane of projections, $\mathbf{r} = [r_x \quad r_y \quad r_z \quad 1]^T$ is a vector of coordinates associated with nth macromolecule, $\mathbf{T}$ is the 4×4 transformation matrix given by

$$\mathbf{T}(\mathbf{R}, \mathbf{t}) = \begin{bmatrix} \mathbf{R} & \mathbf{t} \\ 0 & 1 \end{bmatrix}, \quad \begin{bmatrix} \mathbf{x} \\ z \\ 1 \end{bmatrix} = \mathbf{T}\mathbf{r}, \tag{2.5.7.2}$$

with $\mathbf{t} = [t_x \quad t_y \quad 1]^T$ being the shift vector of translation of the object (and its projection) in the xy plane (translation in z is irrelevant due to the projection operation) and $\mathbf{R}(\psi, \theta, \varphi)$ is the 3×3 rotation matrix specified by three Eulerian angles. As in Section 2.5.6, two of the angles define the direction of projection $\boldsymbol{\tau}(\theta, \varphi)$, while the third angle ψ results in rotation of the projection image in the plane of the formed image xy; changing this angle does not provide any additional information about the structure f. Both types of noise are assumed to be mutually uncorrelated and independent between projection images (*i.e.*, $\langle m_i^k m_j^l \rangle_{i \neq j} = 0$; k, l = S, B) and also uncorrelated with the signal ($\langle d_i m_i^k \rangle = 0$; k = S, B). Model (2.5.7.1) is semi-empirical in that, unlike in the standard model, we have two contributions to the noise. Although in principle amorphous ice should not be affected by the CTF, so the term m^{S} should be absorbed into m^{B}, in practice the buffer in which the protein is purified is not pure water and it is possible to observe CTF effects by imaging frozen buffer alone. Moreover, if a thin support carbon is used, it will be a source of very strong CTF-affected noise also included in m^{B}.

In Fourier space, (2.5.7.1) is written by taking advantage of the central section theorem [equation (2.5.6.8) of Section 2.5.6]: the Fourier transform of a projection is extracted as a Fourier plane uv of a rotated Fourier transform of a 3D object:

$$D_n(\mathbf{u}) = \mathrm{CTF}(\mathbf{u};\, \Delta f_n, q) E_n(\mathbf{u}) \Big\{ [F(\mathbf{T}\mathbf{v})]\big|_{u_z=0} + M_n^{\mathrm{S}}(\mathbf{u}) \Big\} + M_n^{\mathrm{B}}(\mathbf{u}). \tag{2.5.7.3}$$

The capital letters denote Fourier transforms of objects appearing in (2.5.7.1) while CTF (a Fourier transform of s) depends, among other parameters that are set very accurately (such as the accelerating voltage of the microscope), on the defocus setting Δf_n and the amplitude contrast ratio $0 \leq q < 1$ that reflects the presence of the amplitude contrast that is due to the removal of widely scattered electrons [the real term in (2.5.5.14)]. For the range of frequency considered, q is assumed to be constant and the CTF is written in terms of the phase perturbation function χ [given by equation (2.5.2.33)] as

$$\begin{aligned} \mathrm{CTF}(\mathbf{u};\, \Delta f) &= [1 + 2q(q-1)]^{-1/2} \big\{ (1-q) \sin[\chi(|\mathbf{u}|;\, \Delta f)] \\ &\quad - q \cos[\chi(|\mathbf{u}|;\, \Delta f)] \big\} \\ &= \sin\big\{ \chi(|\mathbf{u}|;\, \Delta f) - \arctan[q/(1-q)] \big\}, \end{aligned} \tag{2.5.7.4}$$

where for simplicity we assumed no astigmatism. Finally, the rotationally averaged power spectrum of the observed image, calculated as the expectation value of its squared Fourier intensities (2.5.7.3), is given by

$$P_d(u) = \mathrm{CTF}^2(u)\, E^2(u) \big[P_f(u) + P_{\mathrm{S}}(u) \big] + P_{\mathrm{B}}(u), \tag{2.5.7.5}$$

where $u = |\mathbf{u}|$ is the modulus of spatial frequency.

2.5.7.2. Structure determination in single-particle reconstruction

The goal of single-particle reconstruction is to determine the 3D electron-density map f of a biological macromolecule such that its projections agree in a least-squares sense with a large number of collected 2D electron-microscopy projection images, $d_n \in R^{n^2} (n = 1, 2, \ldots, N)$, of isolated (single) particles with random and unknown orientations. Thus, we seek a least-squares solution to the problem stated by (2.5.7.1) [or, equivalently, in Fourier space, to (2.5.7.3)]. This is formally written as a nonlinear optimization problem (Yang *et al.*, 2005),

$$\begin{aligned} &\min_{\psi_n, \theta_n, \varphi_n, t_{x_n}, t_{y_n}, f, \Delta f_n, q, \ldots} L(\psi_n, \theta_n, \varphi_n, t_{x_n}, t_{y_n}, f, \Delta f_n, q, \ldots) \\ &\quad \equiv \tfrac{1}{2} \sum_{n=1}^{N} \left\| s_n(\mathbf{x}) * e_n(\mathbf{x}) * \int f(\mathbf{T}_n\mathbf{r})\,\mathrm{d}z - d_n(\mathbf{x}) \right\|^2. \end{aligned} \tag{2.5.7.6}$$

The factor of $\frac{1}{2}$ is included merely for convenience. The objective function in (2.5.7.6) is clearly nonlinear due to the coupling

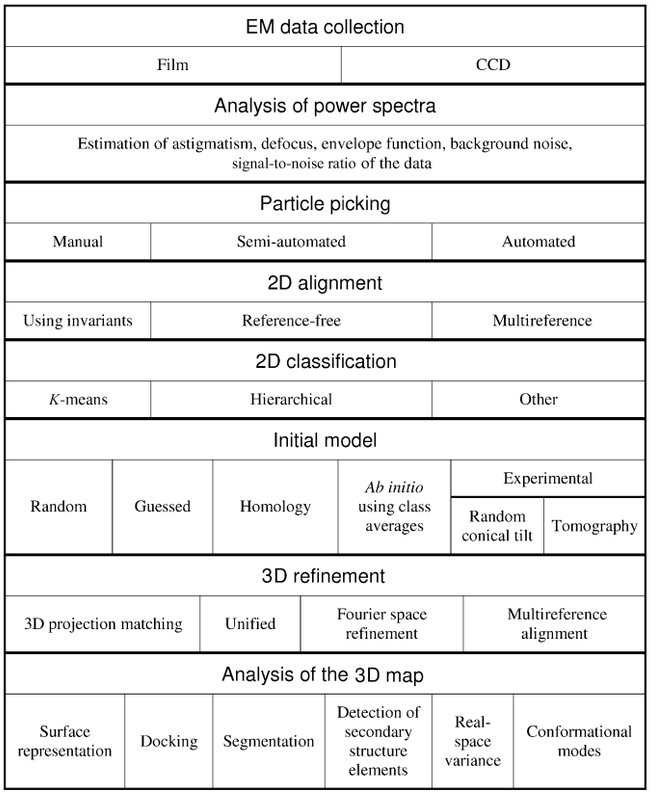

Fig. 2.5.7.1. Typical steps performed in a single-particle cryo-EM structure determination project.

between the orientation parameters $\psi_n, \theta_n, \varphi_n, t_{x_n}, t_{y_n}$ ($n = 1, 2, \ldots, N$) and the 3D density f.

The parameters in (2.5.7.6) to be determined can be separated into two groups. (1) The orientation parameters $\psi_n, \theta_n, \varphi_n, t_{x_n}, t_{y_n}$ that have to be determined entirely by solving (2.5.7.6) and for which there are no initial guesses, and the structure f itself, for which we may or may not have an initial guess. The number of parameters in this group is very large: $n^3 + 5m$. Note that in single-particle reconstruction, the number of projection data m is far greater than the linear size of the data in pixels, *i.e.*, $m \gg n$. (2) Various parameters which we will broadly call the parameters of the image formation model (2.5.7.1)–(2.5.7.4): the defocus settings of the microscope Δf_n, the amplitude contrast ratio q and, if analytical forms of the envelope function E, the power spectrum of the background noise M, or the structure F are adopted, the parameters of these equations. Some of the parameters in the second group are usually known very accurately or can be estimated from micrograph data before one attempts to solve (2.5.7.6) (see Section 2.5.7.4), but they can also be refined during the structure determination process [for the method for correcting the defocus settings, see Mouche *et al.* (2001)].

Owing to the very large number of parameters in (2.5.7.6) and the nonlinearities present, one almost never attempts to solve the problem directly. Instead, structure determination using the single-particle technique involves several steps. (i) The macromolecular complex is prepared with a purity of at least 90%. (ii) The sample is flash-frozen in liquid ethane. Alternatively, cryo-negative stain techniques or traditional negative stain methods can be used. (iii) Pictures of the macromolecular complexes are taken. (iv) Exhaustive analysis of 2D particle images aimed at increasing the SNR of the data and evaluation of the homogeneity of the sample is performed. (v) An initial low-resolution model of the structure is established using either experimental techniques or computational methods. (vi) The initial structure is refined in order to increase the resolution using an enlarged data set. Only in this step does one attempt to minimize (2.5.7.6) more or less directly. (vii) Visualization and interpretation of the resulting 3D electron-density map is the last step; it often involves docking of X-ray structures of molecules into EM density maps in order to reveal the arrangement of known molecules within the EM envelope (Fig. 2.5.7.1). As within the weak-phase-object approximation of the image formation in EM the relation between densities in collected images and the 3D electron density of the imaged macromolecule is linear [(2.5.7.1)], all data-processing methods employed in the structure determination project should be linear, so the densities in the cryo-EM 3D model can be interpreted in terms of the electron density of the protein.

In the actual single-particle project not all the steps have to be executed in the order outlined above. The technique has proved to be particularly useful in studies of functional complexes of proteins whose base state is known to a certain resolution or even of functional complexes whose atomic (X-ray crystallographic) structure is known. In these cases, steps (iv) and (v) can be omitted and the structure of the functional complex (for examples with ligands bound to it) can be relatively easily determined using the native structure as a starting point for step (vi).

In addition to difficulties with obtaining good cryo-EM data, the technique is computationally intensive. The reason is that in order to obtain a sufficient SNR in the 3D structure, processing of hundreds of thousands of EM projection images of the molecule might be necessary. For each, five orientation parameters have to be determined, and this is in addition to determination of the image-formation parameters required for the optimization of correlation searches. In effect, it is not unusual for single-particle projects to consume weeks of the computer time of multiprocessing clusters. This also explains why the knowledge of the base structure simplifies the work to a large degree: when it is known, initial values of the orientation parameters can be easily established, reducing not only the computational time, but also possibilities of errors in the structure-determination process.

2.5.7.3. Electron microscopy and data digitization

The electron microscope is a phase imaging system; *i.e.*, in order to create contrast in images, they have to be underfocused. Owing to the particular form of the CTF of the microscope [(2.5.7.4)], not only the amplitudes of the image in Fourier space are modified, but information in some ranges of spatial frequencies is set to zero and some phases have reversed sign. Therefore, in order to obtain possibly uniform coverage of Fourier space, the standard practice is to take pictures using different defocus settings and merge them computationally in order to fill gaps in Fourier space. The problem is compounded by the relation between underfocus and the envelope function of the microscope. Far-from-focus images have high contrast, but the envelope function has a relatively steep fall-off limiting the range of useful spatial frequencies. Conversely, close-to-focus images have little contrast, but the envelope function is decreasing, slowly extending useful information to high spatial frequencies. In effect, it is easier to process computationally far-from-focus data and to obtain accurate alignment of particles, but the results have severely limited resolution. Processing of close-to-focus data is challenging and results tend to be less accurate, but there is the potential to obtain high-resolution information.

The experimental techniques of initial structure determination (random conical tilt, tomography) require collection of tilt data. This is facilitated by dedicated microscope stages that can be rotated inside the microscope column yielding additional views of the same field. However, collection of high-quality tilt images is difficult. The quality of tilted images tends to be adversely affected by charging and drift effects. Moreover, as the stage is tilted the effective ice thickness increases (inversely proportionally to the cosine of the tilt angle, so at 60° the factor is two) and the contrast of the images decreases correspondingly. Finally,

the defocus in tilted micrographs varies depending on the position in the field, often forcing users to restrict the particle selection only to regions in the vicinity of the tilt axis. However, tilting establishes geometrical relations between different projections of the same particle, unambiguously allowing for robust determination of an initial 3D model and the handedness of the quaternary structure of the complex.

Electron microscope images can be either recorded on the film and subsequently converted to digital format, or they can be recorded using a charge-coupled device (CCD) camera in a digital format directly on a microscope. In either case, it is necessary to select the magnification of the microscope and the eventual pixel size of the digitized data before the data-collection session. High magnification can potentially yield high-resolution data, but at the same time it decreases the yield of particles. Lower magnification values can be used when images are recorded on film, which does not attenuate high spatial frequencies to the same extent as CCD cameras tend to do.

The pixel size has to be adjusted according to the expected resolution of the final structure. Although it is tempting to adopt a small pixel size (in the hope of achieving high resolution of the results), in most cases this is counterproductive, as it results in very large computer files that are difficult to handle and in excessively long data-processing times. Theoretically, the optimum pixel size is tied to the maximum frequency present in the data by Shannon's sampling theorem, which states that no information is lost if the signal is sampled at twice the maximum frequency present in the signal, and no additional information is gained by sampling using higher frequency. Thus, if the expected resolution is 12 Å, it should be sufficient to use a pixel size (on the specimen scale) of 6 Å. In practice, various image-processing operations performed during alignment of the data and 3D reconstruction of the complex significantly lower the range of useful frequencies. This is because in currently available single-particle reconstruction software packages rather unsophisticated interpolation schemes are employed, which were selected mainly for the speed of calculations. Therefore, it is advisable to oversample the data by a factor of 1.5 or even 3.0. For an expected resolution of 12 Å this corresponds to pixel sizes of 4 and 2 Å, respectively.

The windowed particles have to be normalized to adjust the image densities to a common framework of reference. The reason for this step is that microscopy conditions are never exactly the same and also within the same micrograph field the background densities can vary by a significant margin due to uneven ice thickness and other factors. A sensible approach to normalization is to assume that the statistical distribution of noise in areas surrounding particles should be the same (Boisset *et al.*, 1993). Hence a large portion of one of the micrographs from the processed set is selected and a reference histogram of its pixel values is generated. Next, assuming a linear transformation of pixel values, the two parameters of this transformation are found in such a way that the histogram of the transformed pixel values surrounding the particle optimally matches the reference histogram using χ^2 statistics as a discrepancy measure.

2.5.7.4. Assessment of the data quality and estimation of the image formation parameters

The initial assessment of the quality of the micrographs is usually performed during the data collection and in most cases before the micrographs are digitized. The micrographs are examined visually and those that have noticeable drift, astigmatisms, noticeable contamination or simply too low a number of particles to justify further analysis are simply discarded. After digitization of the accepted micrographs, the first step is estimation of the power spectrum, which will be examined for the presence of Thon rings (thus confirming that the micrograph is indeed usable) and astigmatism.

The method of averaged overlapping periodograms (Welch, 1967) is commonly used in EM to calculate the power spectrum. It is designed to improve the statistical properties of the estimate by taking advantage of the fact that when K identically distributed independent measurements are averaged, the variance of the average is decreased with respect to the individual variance by the ratio $1/K$. Thus, instead of calculating a periodogram (squared moduli of the discrete Fourier transform) of the entire micrograph field, one subdivides it into much smaller windows, calculates their periodograms and averages them. Typically, one would chose a window size of 512×512 pixels and an overlap of 50%, which will result in the reduction of the variance of the estimate to few percent with respect to the variance of the periodogram of the entire field (Fernandez *et al.*, 1997; Zhu *et al.*, 1997). Further reduction of the variance is achieved by rotational averaging of the 2D power-spectrum estimate. The resulting one-dimensional (1D) profile is finally used in the third step of our procedure.

For a set of micrographs the power spectra can be evaluated either visually or computationally in an automated fashion. Of main concern are the presence of Thon rings, the astigmatism and the extent to which Thon rings can be detected. Although in principle astigmatic data could be used in subsequent analysis (in fact, astigmatism could be considered advantageous, as particles from the same micrograph would contain complementary information in Fourier space), in practice they are discarded as currently there is no software that can process astigmatic data efficiently. The extent of Thon rings indicates the 'resolution' of the data, *i.e.*, the maximum frequency to which information in the data can be present.

A number of well established programs can assist the user in the calculation of power spectra and automated estimation of defocus and astigmatism (Huang *et al.*, 2003; Mindell & Grigorieff, 2003; Sander *et al.*, 2003; Mallick *et al.*, 2005). Given the analytical form of the CTF [(2.5.7.4)], the problem is solved by a robust fitting of the CTF parameters such that the analytical form of the CTF matches the power spectrum of the micrograph. Usually, the steps employed are: (1) robust estimation of the power spectrum; (2) calculation of the rotational average of the power spectrum; (3) subtraction from this rotational average of the slowly decreasing background [roughly corresponding to $P_{\rm B}$ in (2.5.7.5)]; (4) fitting of the defocus value Δf_n using known settings of the microscope (voltage, spherical aberration constant, ...) and usually assuming a constant and known value of the amplitude contrast ratio q (for cryo-EM data, q should be in the range 0.02–0.10); and (5) using the established defocus value Δf_n, analysis of the 2D power spectrum and fitting of the astigmatism amplitude and angle while refining the defocus. As long as the defocus value is not too small and there are at least two detectable zeros of the CTF, all available programs give very good and comparable results.

In some single-particle packages, the automated calculation of defocus is integrated with the estimation of additional characteristics of the image-formation parameters that are required for advanced application of a Wiener filter [(2.5.7.18)] (Saad *et al.*, 2001; Huang *et al.*, 2003), *i.e.*, the power spectra of two noise distributions $P_{\rm S}$ and $P_{\rm B}$ and the envelope function of the microscope E_n for each micrograph. A possible approach is to select slowly varying functions and fit their parameters to match the estimates of $P_{\rm S}$, $P_{\rm B}$ and P_d obtained from the data. Finally, it is necessary to have a description of the 1D rotationally averaged power spectrum of the complex P_f. One possibility is to carry out X-ray solution scattering experiments (Gabashvili *et al.*, 2000; Saad *et al.*, 2001) that yield a 1D power spectrum of the complex in solution. However, these experiments require large amounts of purified sample and the accuracy of the results in terms of the overall fall-off of the power spectrum can be disputed. For the purpose of cryo-EM, a simple approximation of the protein power spectrum by analytical functions is satisfactory.

2.5.7.5. 2D data analysis – particle picking

Depending on the properties of the imaged complex and the magnification used, a single micrograph can yield from a few to thousands of individual particle projections. The first step of the data processing is identification of particle projections in micrographs and their selection. The particles have to be windowed (boxed) using a window size exceeding the particle size by a 30–50% margin. Thus, for example, in order to determine the structure of a 550 kDa complex that has a diameter of ~120 Å to 12 Å resolution, it is appropriate to choose a pixel size of 3 Å and a window size of 60 pixels.

The selection of particles is a labour-intensive process; however, the quality of selected particle projections is a major factor in the subsequent steps of analysis and the inclusion of too many imperfect images may preclude successful determination of the 3D structure. There are three possible approaches: (1) manual selection; (2) semi-automated selection; (3) fully automated selection. In the early stages of analysis, particularly when little is known about the shape of the protein and the distribution of projection views, the manual approach is preferable. The researcher displays the micrograph on a computer screen (usually preprocessed by Fourier filtration and contrast-adjusted for better visibility of the protein) and interactively identifies locations of particle views. A trained and careful operator can yield much better results than automated approaches. The main risk is in inherent bias of a human operator – there is a tendency to focus on more familiar and more easily visible particle projections, omitting less frequently appearing orientations and in effect jeopardizing successful structure determination. In semi-automated approaches, an initial step in which putative particle projections in a micrograph are chosen is performed by a computer, all candidates are windowed and the user screens a gallery of possible particles instead of the full micrograph. Algorithms that perform the initial identification of particle views range from very simple (for example a band-pass filtration of a micrograph with subsequent selection of peaks that are no closer to each other than half of the expected particle size) to sophisticated nonlinear noise-suppression methods [for details on various algorithms see the Special Issue of the *Journal of Structural Biology* (Zhu *et al.*, 2004)]. Since the human operator will be responsible for the ultimate decision, preference is given to the faster method. In most cases, semi-automated methods are implemented within a framework of a user-friendly graphical user interface that can greatly facilitate the work. Fully automated methods are currently actively under development but, curiously, even for proteins whose high-resolution structure is known, the success rate cannot match that of a human operator (Zhu *et al.*, 2004).

The automated procedures can be divided into three groups: (1) those that rely on *ad hoc* steps of denoising and contrast enhancement followed by the search for regions of known size that emerge above the background level (Adiga *et al.*, 2004); (2) those that extract orientation-independent statistical features from regions of the micrograph that may contain particles and proceed with classification (Lata *et al.*, 1995; Hall & Patwardhan, 2004); and (3) those that employ templates, *i.e.*, either class averages of particles selected from micrographs or projections of a known 3D structure of the complex (Huang & Penczek, 2004; Sigworth, 2004).

The advantage of the first two approaches is that they do not require template images, *i.e.*, since they are based on a very broadly defined description of particles (general size, shape or abstract features derived from examples of typical particles), they are applicable in cases when no 3D structure of the complex is available. Methods from the second category usually require a training session for the algorithm to construct a set of weights for the predefined features. The methods that take advantage of the availability of templates vary greatly in complexity from straightforward cross-correlation with a generic shape (a Gaussian function, a low-passed circle) (Frank & Wagenknecht, 1984) to matched filters with large number of templates and parameters derived from the image-formation model of the micrograph (CTF and envelope functions) (Huang & Penczek, 2004; Sigworth, 2004). The motivation is clear: given an ideal object and image-formation parameters, it should be only a matter of sheer computer power and user's patience to have all particles matching the template selected. In practice, the problem is much more challenging and the success rate of template-based methods does not necessarily exceed the success rate of carefully tuned *ad hoc* methods.

One of the difficulties with the application of correlation techniques to the particle-picking problem is the unevenness of micrographs, which is caused by uneven illumination by the electron beam and, to a much larger degree, by the uneven thickness of the ice layer and, when used, the supporting carbon. A possible remedy is to calculate a 'locally normalized' cross-correlation function, in which the total variance of the micrograph is replaced by the local variance of the micrograph calculated within a window of n pixels centred on the current location l. This method has a fast implementation in Fourier space (van Heel, 1982; Roseman, 2003). A faster method is to just apply a high-pass filtration of the micrograph using a high-pass Gaussian Fourier filter with a half-width $(1/np)$ Å^{-1}, where p is the pixel size. This simple step will all but eliminate the unevenness of the micrograph background.

The main difficulty with the correlation technique is the computational complexity of the problem arising from the very large number of templates that have to be considered. The particles in the micrograph are projections of a 3D object with arbitrary in-plane rotations. In effect, to perform an exhaustive search, it is necessary to sample quasi-uniformly three Eulerian angles [equation (2.5.7.17) with $\Delta\psi = \delta\theta$]. For example, a very crude angular step of $\delta\theta = 10^\circ$ results in ~13 000 2D templates! A reduction in the number of templates can be achieved either using clustering techniques (Huang & Penczek, 2004; Wong *et al.*, 2004) or by exploring the eigenstructure of the whole set of templates (Sigworth, 2004).

2.5.7.6. 2D alignment of EM images

Alignment of pairs of 2D images is a fundamental step in single-particle reconstruction. It is aimed at bringing into register various particle projections by determining three orientation parameters (rotation angles and x and y translations) and is employed in 2D alignment of large sets of 2D noisy data and in 3D structure-refinement algorithms. The computational efficiency and numerical accuracy of this step are deciding factors in achieving high-quality structural results in an acceptable time.

All 2D alignment methods considered are aimed at finding transformation parameters such that the least-squares discrepancy between two images f and g is minimized,

$$\int \left|f(\mathbf{x}) - g(\mathbf{T}\mathbf{x})\right|^2 \mathrm{d}\mathbf{x} \rightarrow \min, \tag{2.5.7.7}$$

where $\mathbf{x} = [x \quad y \quad 1]^T$ is a vector containing the coordinates. $\mathbf{T}$ is the transformation matrix given by

$$\mathbf{T}(\alpha, x, y) = \begin{bmatrix} \cos\alpha & -\sin\alpha & t_x \\ \sin\alpha & \cos\alpha & t_y \\ 0 & 0 & 1 \end{bmatrix}, \tag{2.5.7.8}$$

and is dependent on three transformation parameters: rotation angle α and two translations t_x and t_y . It has to be noted that a minimum of (2.5.7.7) can be found rapidly using the fast Fourier

transform (FFT) algorithm if only the *xy* translation is sought (2D FFT), or if only the rotation angle is needed (1D FFT).

2D alignment methods can be divided into three classes: (1) those that employ exhaustive searches in order to find three orientation parameters; (2) those that perform exhaustive searches by using either simplifications (separate searches for translation and rotation parameters) (Penczek *et al.*, 1992) or by taking advantage of invariant image representations (Schatz & van Heel, 1990; Frank *et al.*, 1992 and the following discussion; Schatz & van Heel, 1992; Marabini & Carazo, 1996); or finally (3) those that are aimed at improvement of previously determined parameters and employ local searches.

In practice, as the windowed particles are approximately centred, the search for translation parameters can be restricted to relatively small values. A very efficient algorithm that takes advantage of the geometry is based on resampling to polar coordinates of the area of the image that roughly corresponds to the particle size. The resampling is done around centres placed on pixels located within a distance from the image centre that corresponds to a preset maximum translation (Joyeux & Penczek, 2002) (Fig. 2.5.7.2). For each translation, a 1D rotational cross-correlation function in polar coordinates is calculated. Overall, the alignment method based on resampling to polar coordinates comprises the following steps: (1) the image is resampled to polar coordinates; (2) 1D FFTs of various lengths are calculated, appropriately weighted and padded with zeros to equalize their lengths; (3) complex multiplications with 1D Fourier transforms of the similarly processed referenced image are calculated; (4) the inverse 1D FFT is calculated and the position of the maximum is found. The last step yields the rotation angle. Steps (1)–(4) are repeated with the image that is being aligned shifted to account for translations. In addition, the rotation angle for one of the images being mirrored is efficiently calculated in parallel with step (3) by repeating the multiplication with the 1D Fourier transforms of the reference image complex conjugated. This additional check is a necessity in the analysis of single-particle data sets, as usually one can expect on average half of the images to be mirrored versions of the other half in the data set. Overall, the method is very accurate, because only data under the circular mask enter the calculation.

For a set of N images containing the same object in various orientations and corrupted by an additive noise, the problem of alignment would be relatively simple. For proteins that have strong preferred orientation and particularly when a staining technique is used for grid preparation, this is certainly the case. In the procedure called *reference-based alignment*, one of the images that appears 'typical' is selected and used as a reference to align the remaining images. After all available images are aligned their average is calculated and used as a reference in a repeated alignment of all images. The process is iterated until the orientations of the images stabilize (Frank *et al.*, 1982).

More formally, Frank *et al.* (1988) proposed the definition of a set of N images f_k , $k = 1, \ldots, N$, aligned if a set of transformations $\mathbf{T}_k$, $k = 1, \ldots, N$, (rotation angles and translations) is found such that all pairs of images are mutually brought into register, so the expression

$$L_1(\{f\}, \{\mathbf{T}\}) = \sum_{k=1}^{N-1} \sum_{l=k+1}^{N} \left\| f_k(\mathbf{T}_k\mathbf{x}) - f_l(\mathbf{T}_l\mathbf{x}) \right\|^2 = \sum_{k=1}^{N-1} \sum_{l=k+1}^{N} \left(\left\| f_k(\mathbf{T}_k\mathbf{x}) \right\|^2 + \left\| f_l(\mathbf{T}_l\mathbf{x}) \right\|^2 - 2 f_k(\mathbf{T}_k\mathbf{x}) f_l(\mathbf{T}_l\mathbf{x}) \right) \quad (2.5.7.9)$$

is minimized. Although there is no simple way to minimize L_1, the interesting observation is that there is no requirement of the images to represent the same particle, not even a similar one. This leads to the conclusion that if the minimum of L_1 could be found, a set of diverse images could be aligned; moreover, upon alignment similar images would have similar orientation and subsequent classification of such an aligned data set would reveal subsets of similar images.

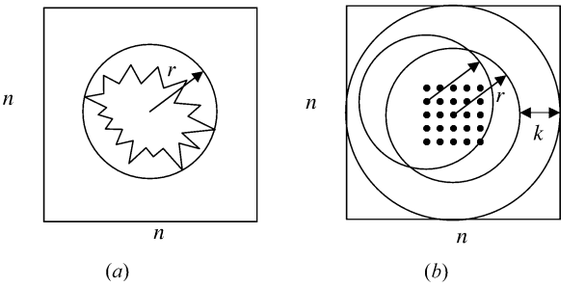

Fig. 2.5.7.2. The geometrical constraints of the 2D alignment problem. (*a*) The reference 2D particle is placed within a square image frame $n \times n$ pixels and its size is such that it can be bounded by a circle with a radius r no larger than $0.9n$. (*b*) The particle projection, the size of which is bounded by the same radius as the reference view, can be located within a circle centred on discrete locations within the image frame, such that the maximum translation is $k = (n/2) - r$. The number of possible translations is $(2k + 1)^2$. Reprinted from Joyeux & Penczek (2002) with permission from Elsevier.

A practical method of minimizing, called a *reference-free alignment*, was proposed by Penczek *et al.* (1992) by showing that minimization of L_1 is equivalent to maximization of

$$L_2(\{f\}, \{\mathbf{T}\}) = \sum_{k=1}^{N-1} \left\| f_k(\mathbf{T}_k\mathbf{x}) - \langle f \rangle_k \right\|^2, \quad (2.5.7.10)$$

where

$$\langle f \rangle_k = \frac{1}{N-1} \sum_{l=1, l\neq k}^{N} f_l(\mathbf{T}_l\mathbf{x}) \quad (2.5.7.11)$$

is the partial average of the set of images calculated with the exclusion of the kth image. The method is based on the observation that given a set of approximately aligned images, it should be possible to minimize L_2 by sequentially correcting alignments of individual images using the cross-correlation function between each image and the average of the remaining ones. On each step, depending whether the orientation of the image changes or not, (2.5.7.10) will decrease or remain constant.

The outcome of the reference-free alignment algorithm is an aligned set of N images, so all particles that have similar shapes will have similar orientations. Thus, it is natural (and because of the alignment possible) to divide the data set into classes of images that have similar shapes and orientations, *i.e.*, to cluster them. A number of well known clustering algorithms have been adopted for EM applications (Frank, 1990). The general purpose of clustering is to organize objects (in the case of EM, images) into classes whose members are similar to each other, while dissimilar to objects from other classes.

Reference-free alignment with subsequent clustering works well as long as all particles share the same overall shape (*i.e.*, the very low frequency component), as is the case for ribosomes. However, some molecules yield projections that have quite different shapes, as for example is the case for barrel-like proteins GroEL (Roseman *et al.*, 1996) with rectangular views and circular end views or flat and rectangular hemocyanin (Boisset *et al.*, 1995). In this case, the reference-free alignment tends to be unstable, as (2.5.7.10) has multiple local minima, which in practice means that the global average of the whole data set can vary significantly depending on the initiation of the procedure. In general, reference-free alignment is an 'alignment first, classifi-

cation second' approach. It is possible to reverse this order by using invariants with the supporting rationale that once approximately homogeneous classes of images were found, it should be easy to align them subsequently as within each class they will share the same motif.

A practical approach to reference-free alignment known as *alignment by classification* (Dube *et al.*, 1993) is based on the observation that for a very large data set and centred particles one can expect that although the in-plane rotation is arbitrary, there is a high chance that at least some of the similar images will be in the same rotational orientation. Therefore, in this approach the images are first (approximately) centred, then subjected to classification, and subsequently aligned.

In its simplest form, the *multireference alignment* belongs to the class of *supervised classification* methods: given a set of templates (*i.e.*, reference images; these can be selected unprocessed particle projections, or class averages that resulted from preceding analysis, or projections of a previously determined EM structure, or projections of an X-ray crystallographic structure), each of the images from the available data sets is compared (using a selected discrepancy measure) with all templates and assigned to the class represented by the most similar one. Equally often multireference alignment is understood as a form of *unsupervised classification*, more precisely *K*-means classification, even if the description is not formalized in terms of the latter. Given a number of initial 2D templates, the images are compared with all templates and assigned to the most similar one. New templates are calculated by averaging images assigned to their predecessors and the whole procedure is repeated until a stable solution is reached.

2.5.7.7. Initial determination of 3D structure using tilt experiments

The 2D analysis of projection images provides insight into the behaviour of the protein on the grid in terms of the structural consistency and the number and shape of projection images. In order to obtain 3D information, it is necessary to find geometrical relations between different observed 2D images. The most robust and historically the earliest approach is based on tilt experiments. By tilting the stage in the microscope and acquiring additional pictures of the same area of the grid it is possible to collect projection images of the same molecule with some of the required Eulerian angles determined accurately by the setting of the goniometer of the microscope.

In random conical tilt (RCT) reconstruction (Radermacher *et al.*, 1987), two micrographs of the same specimen area are collected: the first one is recorded at a tilt angle of ~50° while the second one is recorded at 0° (Fig. 2.5.7.3). If particles have preferred orientation on the support carbon film (or within the amorphous ice layer, if no carbon support is used), the projections of particles in the tilted micrographs form a conical tilt series. Since in-plane rotations of particles are random, the azimuthal angles of the projections of tilted particles are also randomly distributed; hence the name of the method. The untilted image is required for two reasons: (i) the particle projections from the untilted image are classified, thus a subset corresponding to possibly identical images can be selected ensuring that the projections originated from similar and similarly oriented structures; and (ii) the in-plane rotation angle found during alignment corresponds to the azimuthal angles in three dimensions (one of the three Eulerian angles needed). The second Eulerian angle, the tilt, is either taken from the microscope setting of the goniometer or calculated based on geometrical relations between tilted and untilted micrographs. The third Eulerian angle corresponds to the angle of the tilt axis of the microscope stage and is also calculated using the geometrical relations between two micrographs. In addition, it is necessary to centre the particle projections selected from tilted micrographs; although various correlation-based schemes have been proposed,

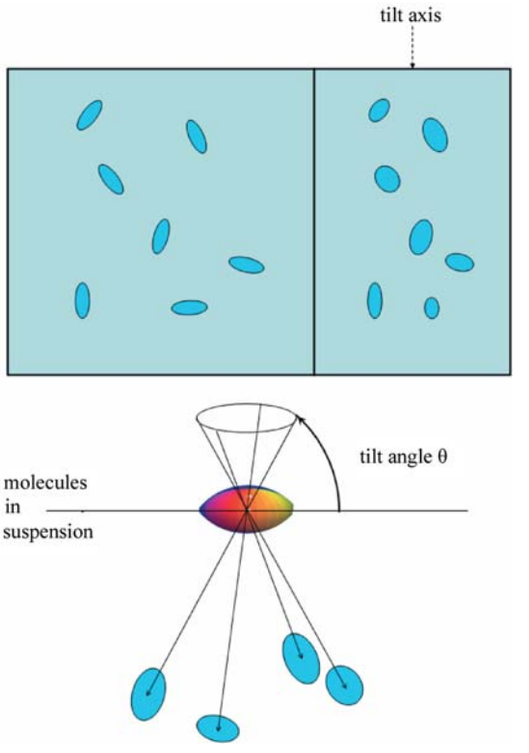

Fig. 2.5.7.3. Principle of random conical tilt reconstruction. A tilt pair of images of the same grid area is collected. By aligning the particle images in the untilted micrograph (left), the Eulerian angles of their counterparts in the tilted micrograph (right) are established. The particle images from the tilted micrograph are used for 3D reconstruction of the molecule (bottom). The set of projections form a cone in Fourier space; information within the cone remains undetermined.

the problem is difficult as the tilt data tend to be very noisy and have very low contrast.

Given three Eulerian angles and centred tilted projections, a 3D reconstruction is calculated. There are numerous advantages of the RCT method. (i) Assuming the sign of the tilt angle is read correctly (it can be confirmed by analysing the defocus gradient in the tilted micrographs), the method yields a correct hand of the structure. (ii) With the exception of the in-plane rotation of untilted projections, which can be found relatively easily using alignment procedures, the remaining parameters are determined by the experimental settings. Even if they are not extremely accurate, the possibility of a gross error is eliminated, which positively distinguishes the method from the *ab initio* computational approaches that use only untilted data. (iii) The computational analysis is entirely done using the untilted data, which have high contrast. (iv) The RCT method is often the only method of obtaining 3D information if the molecule has strongly preferential orientation and only one view is observed in untilted micrographs. The main disadvantage is that the conical projection series leaves a significant portion of the Fourier space undetermined. This follows from the central section theorem [equation (2.5.6.8) of Section 2.5.6]: as the tilt angle is less than 90°, the undetermined region can be thought to form a cone in three dimensions and is referred to as the missing cone. The problem can be overcome if the molecule has more than one preferred orientation. Subsets of particles that have similar untilted appearance (as determined by clustering) are processed independently and for each a separate 3D structure is calculated. If the preferred orientations are sufficiently different, *i.e.*, the orientations of the original particles in three dimensions are sufficiently different in terms of their angles with respect to the z axis, the 3D structures can be aligned and merged, all but eliminating the problem of the missing cone and yielding a robust, if resolution-limited, initial model of the molecule (Penczek *et al.*,

1994). It should be noted that RCT by itself almost never results in a high-resolution 3D model of the molecule. This is due to a variety of reasons, the main ones being the already mentioned poor quality of high-tilt data and difficulties with the collection of large numbers of high-quality tilted micrographs (they are often marred by drift).

In cases when the molecule does not have well defined preferred orientations, it is possible to use electron tomography to obtain the initial model. In this method, a single-axis tilt series of projection images of the same specimen area is collected using an angular step of ~2° and a maximum tilt angle not exceeding 60° (Crowther, DeRosier & Klug, 1970). The single-axis tilt data-collection geometry yields worse coverage of the Fourier space than the RCT method, leaving missing wedges uncovered (Penczek & Frank, 2006). This results in severe artifacts in real space, which make smaller objects virtually unrecognizable. The situation can be largely rectified using so-called double-axis tomography, in which a second single-axis tilt series of data are collected after rotating the specimen grid in-plane by 90° (Penczek *et al.*, 1995). This reduces the undetermined region to a missing pyramid and makes the resolution almost isotropic in the *xy* plane.

The tomographic projection data have to be aligned. This is done using either correlation techniques that enforce pairwise alignment of images (Frank & Mcewen, 1992) or by taking advantage of fiducial markers and enforcing their consistency with respect to a 3D model (Lawrence, 1992; Penczek *et al.*, 1995). In the application to single-particle work, it is possible to use locations of protein in the micrographs as markers. After the 3D reconstruction is calculated, regions collecting individual molecules are windowed from the volume and all molecules are aligned in three dimensions (Walz *et al.*, 1997). While generally robust, the procedure is labour- and computer-intensive. Unlike RCT, where only two exposures of the same field are required, electron tomography may require over one hundred images, raising serious concerns about radiation damage. Moreover, most of the data have to be collected at high tilt angle, thus are of lower quality. Particularly troublesome is alignment of 3D molecules deteriorated by the missing wedge/pyramid artifacts, with the directions of artifacts different for each object. However, when successful, electron tomography yields a very good initial model of the molecule, free from missing-Fourier-space-related artifacts and with defined handedness.

2.5.7.8. Ab initio 3D structure determination using computational methods

The experiment-based methods of initial 3D structure determination (RCT and electron tomography) are quite powerful, but rather challenging to employ in practice. Particularly frustrating is the fact that a large volume of difficult-to-record tilt data have to be collected, even though they cannot be used for subsequent high-resolution work. Therefore, whenever possible, preference is given to computational methods in which 3D geometrical relations between particle projections are established using various mathematical approaches using only untilted data.

The most straightforward approach and historically the earliest is based on the central section theorem [equation (2.5.6.8) of Section 2.5.6]: because Fourier transforms of 2D projections of a 3D object are the central section of the 3D Fourier transform of this object, it is a straightforward consequence that Fourier transforms of any two projections intersect along a line, henceforth called a *common line*. (Two trivial exceptions are the case of projections in the same direction, in which their Fourier transforms coincide with possible differences in in-plane rotation, and the case of projections in opposite directions, in which they are mirror versions of each other.) This fact was originally used by Crowther, DeRosier & Klug (1970) to solve the structure of viruses with icosahedral (60-fold) symmetry. In this case, the Fourier transform of each projection intersects itself (or rather the symmetry-related copies of itself) 37 times with the exception of degenerate cases of projections in directions of one of three symmetry axes, in which cases the number of common lines is less. Thus, it is possible to find the orientation of a single projection with respect to the chosen system of symmetry axes.

For asymmetric objects a set of three projections that do not intersect along the same line (which would correspond to the single-axis tilt geometry) uniquely determine their respective orientations (with the exception of the overall rotation, which remains arbitrary, and the handedness of the solution, which remains undetermined). Indeed, three projections span three common lines, and each common line yields two angles: for each of the intersecting sections it is the angle between the *x* axis in the system of coordinates of this section and the common line in the plane of this section. Thus, we have a total of six angles. At the same time, by arbitrarily setting the orientation of the first projection in 3D space to three Eulerian angles equal to zero (or the corresponding rotation matrix $\mathbf{R}_1 = \mathbf{I}$), we need to determine two rotation matrices $\mathbf{R}_2$ and $\mathbf{R}_3$ (or two sets of three Eulerian angles) for the remaining two projections, respectively. So, given six in-plane angles we have to find a solution for six Eulerian angles. Let the angle of the common line between the *i*th and *j*th projection in the plane of the *i*th projection be α_{ij} and the corresponding unit vector in the plane of *i*th projection be

$$\mathbf{n}_{ij} = [\cos\alpha_{ij} \quad -\sin\alpha_{ij} \quad 0]^T, \quad i, j = 1, 2, 3, \quad i \neq j, \tag{2.5.7.12}$$

where we added the third coordinate for convenience. The orientations of unit vectors $\mathbf{n}_{ij}$ in 3D space have to be related by rotation matrices; for example, vector $\mathbf{n}_{21}$ (the direction of the common line between the first and second projection in the plane of the second projection) should coincide with vector $\mathbf{n}_{12}$ (the direction of the same common line, but in the plane of the first projection) upon rotation by (unknown) matrix $\mathbf{R}_2$. All possible relations are

$$\begin{aligned} \mathbf{R}_2\mathbf{n}_{21} &= \mathbf{n}_{12} \\ \mathbf{R}_2\mathbf{n}_{23} &= \mathbf{R}_3\mathbf{n}_{32} \\ \mathbf{R}_3\mathbf{n}_{31} &= \mathbf{n}_{13}. \end{aligned} \tag{2.5.7.13}$$

Equations (2.5.7.13) have two solutions corresponding to two different hands of the molecule [for details see Farrow & Ottensmeyer (1992)].

The common-lines method works very well in the absence of noise. However, even a modest amount of noise can yield quite erroneous results or no results at all. The reason is that the solution of (2.5.7.13) is highly nonlinear with respect to the six given angles α_{ij} and small errors in the location of peaks in cross-correlation functions can lead to quite large discrepancies from the correct solution. The main difficulty with the application of the common-lines method is that the analytical solution in the form of (2.5.7.13) exists only for three projections (Goncharov *et al.*, 1987).

As a working approach to *ab initio* structure determination, the common-lines method has been implemented under the name of *angular reconstitution* in *IMAGIC* (van Heel, 1987*a*; van Heel *et al.*, 1996). In order to reduce sensitivity to noise, the method is applied not to individual projection images, but to class averages resulting from the multireference alignment of input data (van Heel *et al.*, 2000). In order to overcome the problem of the lack of solution for the larger than three number of projections, the user has to begin with selection of three judiciously chosen class averages, obtain the solution using (2.5.7.13) and subsequently include (angle) additional class averages using a brute-force approach, in which the Eulerian angles of the new projection are

calculated using a similarity measure based on common lines with the already-angled set serving as a reference.

Some of the disadvantages of the angular reconstitution were addressed in the common-lines-based method for determining orientations for $N > 3$ particle projections simultaneously (Penczek *et al.*, 1996). In this method, the problem is formulated in terms of minimization of the variance of the 3D structure, as expressed in terms of common-lines discrepancy between N projections. In a sense, the design of the method is the exact opposite of the 'standard' common-lines approach: instead of trying to the determine the Eulerian angles (rotation matrices $\mathbf{R}_i$) based on angles α_{ij} of common lines in the planes of the projections, one assumes that rotation matrices $\mathbf{R}_i$ are known, finds the set of angles α_{ij} of common lines and computes the overall discrepancy along these lines. For a pair of projections i and j, the in-plane angles of common lines are found by solving the system of equations

$$\mathbf{R}_i \mathbf{n}_{ij} = \mathbf{R}_j \mathbf{n}_{ji} \tag{2.5.7.14}$$

for α_{ij} and α_{ji}. The discrepancy minimized in the method is the variance of the 3D structure that, by analogy to the 2D case (2.5.7.10) and (2.5.7.11) is

$$L_{\rm cl}(\{F\}, \{\mathbf{R}\}) = \sum_{m=0}^{M} \sum_{k=1}^{N} \left\| F_k(u_m, \alpha; \mathbf{R}_k) - \langle F \rangle_k \right\|^2 u_m^2 \Delta u \Delta \Omega_{kl},$$
$$\langle F \rangle_k = \frac{1}{N-1} \sum_{l=1, l\neq k}^{N} F_l(u_m, \alpha; \mathbf{R}_l), \tag{2.5.7.15}$$

where $L_{\rm cl}$ is written in Fourier 3D polar coordinates and $F_k(u_m, \alpha; \mathbf{R}_k)$ is the Fourier transform of the kth projection in 2D polar coordinates (u_m, α) with the orientation in 3D Fourier space given by the rotation matrix $\mathbf{R}_k$. All Fourier planes F_k are considered to have zero thickness, so all discrepancies are calculated only along common lines and the 'partial average' $\langle F \rangle_k$ is in fact an arrangement of $N-1$ Fourier planes in 3D space. An approximation to $u_m^2 \Delta u \Delta \Omega_{kl}$ is calculated by equating the values of $\Delta \Omega_{kl}$ to the areas of the Voronoi diagram cells constructed on a unit sphere for points of intersection of common lines with this unit sphere (see Section 2.5.6.6). Generally the method performs very well, particularly if the projection images cover 3D angular space evenly.

Some macromolecules, particularly those that have an elongated barrel-like shape, will have a strongly preferential orientation with respect to the direction of electron beam showing only what are often called 'side views', *i.e.*, projections perpendicular to rotation along one axis corresponding to single-axis tilt data-collection geometry. These orthoaxial projections form single-axis tilt reconstruction geometry. In this case, Fourier transforms of all projections share only one common line, the line coinciding with the rotation axis, and clearly the common-lines-based method is not applicable to the *ab initio* structure determination. To cope with this situation, a method termed *Sidewinder* was developed (Pullan *et al.*, 2006). It is based on the observation that a Fourier transform of a finite object with a diameter D can be considered to have a nonzero thickness $1/D$ (Fig. 2.5.6.5). Thus, if the angle between two central sections of the 3D Fourier transform of this object, as derived from 2D Fourier transforms of its projections, is not too large, then these two sections will share information in Fourier space that is proportional to the amount of overlap of the two 'slabs' in Fourier space. Using this observation, the general idea employed in *Sidewinder* is to calculate pairwise cross-correlation coefficients (CCCs) between class averages of side views and to use this information to deduce the values of the azimuthal Eulerian angles using the Monte Carlo minimization method (Fishman, 1995).

For structures that have reasonably high symmetry and for those for which it is possible to collect high-quality EM data, it is sometimes possible to determine the initial structure using the 3D projection alignment method, which will be described in the next section. However, the approach is extremely computationally intensive and it is virtually impossible to try the method repeatedly to verify that the approach converges to more-or-less the same 3D structure, as is recommended for other *ab initio* methods described in this section. When the method is successful it is quite powerful, as an intermediate resolution structure can be obtained without going through intermediate and quite laborious steps of analysis of the data. A word of caution is warranted: with the direct method, unless there is external evidence that the obtained structure is correct, it is possible to obtain a self-consistent but entirely incorrect model of the molecule.

In the absence of reliable objective measures of the correctness of the structure, one can apply common sense in order to spot definitely improbable 3D maps. Given the mass of the complex it is possible to calculate the corresponding volume, and thus the threshold at which the map should be examined (Section 2.5.7.11). If at this threshold the mass density is discontinuous or there are pieces of mass surrounding the structures, the map is most likely to be incorrect. Similarly, strong directional artifacts appearing as streaks permeating the structure indicate that either the collected projection images are dominated by one or two views of the structure or that the angular assignment is incorrect. In addition, the 3D map should be centred in the window box; although the centring is not strictly speaking a mathematical requirement for a successful reconstruction, all single-particle structure-determination software packages take advantage of the fact that for centred objects orientation searches are easier to perform. So, if the map is not centred it is a clear indication of the failure of the procedure. Finally, for symmetric structures there should be no large pieces of mass on the symmetry axes.

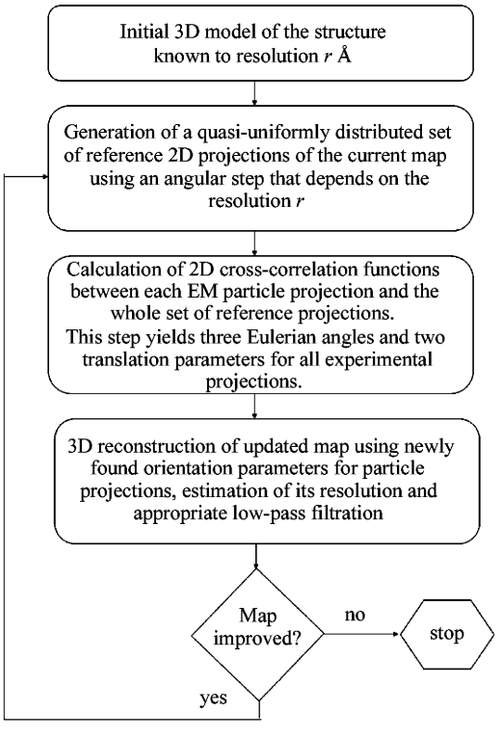
2.5.7.9. Refinement of a 3D structure

Given an initial low-resolution model of the 3D structure and the data set of 2D projection images of the complex that have Fourier-space information extending beyond the resolution of the model, it is possible to refine the structure such that the full extent of the resolution information in the data will be utilized. In some cases, it is also possible to use as an initial structure in the refinement procedure a structure of a homologous protein, thus avoiding the process of *ab initio* structure determination altogether. The goal of the refinement is to find such orientation parameters for each of the particle projections for which (2.5.7.6) is minimized. There exist various implementations of the structure-refinement strategy and they can be roughly divided into those that perform exhaustive searches for all five orientation parameters (two translations and three Eulerian angles per 2D projection image) and those that perform local searches, usually by employing gradient information. Finally, the strategies may differ in how the correction for the CTF is implemented.

The original 3D projection-matching strategy (Penczek *et al.*, 1994) is based on the observation that given an ideal structure f and the necessary parameters of the CTF and image-formation model, it is straightforward to find five orientation parameters for each projection image. One begins with the determination of the sufficient angular step: assuming the structure is properly sampled at the Nyquist frequency and has a real-space radius of r voxels, the angular step is given by

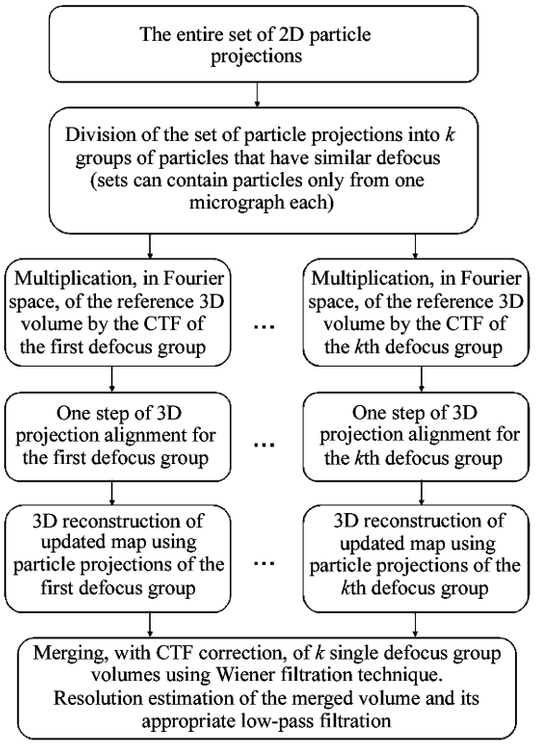
$$\delta\theta \cong \arctan(1/r). \tag{2.5.7.16}$$

Next, keeping in mind that projection directions are parametrized by two Eulerian angles (φ, θ), one generates a set of projection directions quasi-uniformly distributed over half a unit



Initial 3D model of the structure known to resolution r Å
Generation of a quasi-uniformly distributed set of reference 2D projections of the current map using an angular step that depends on the resolution r
Calculation of 2D cross-correlation functions between each EM particle projection and the whole set of reference projections. This step yields three Eulerian angles and two translation parameters for all experimental projections.
3D reconstruction of updated map using newly found orientation parameters for particle projections, estimation of its resolution and appropriate low-pass filtration
Map improved?
no
stop
yes

Fig. 2.5.7.4. Schematic of the 3D projection-alignment procedure.



The entire set of 2D particle projections
Division of the set of particle projections into k groups of particles that have similar defocus (sets can contain particles only from one micrograph each)
Multiplication, in Fourier space, of the reference 3D volume by the CTF of the first defocus group
Multiplication, in Fourier space, of the reference 3D volume by the CTF of the kth defocus group
One step of 3D projection alignment for the first defocus group
One step of 3D projection alignment for the kth defocus group
3D reconstruction of updated map using particle projections of the first defocus group
3D reconstruction of updated map using particle projections of the kth defocus group
Merging, with CTF correction, of k single defocus group volumes using Wiener filtration technique. Resolution estimation of the merged volume and its appropriate low-pass filtration

Fig. 2.5.7.5. Schematic of 3D projection alignment with CTF correction performed on the level of 3D maps reconstructed from projection images sorted into groups that share similar defocus settings.

sphere (or, in the case of a symmetric structure, over an asymmetric subunit) by taking fixed steps along the altitude or tilt angle θ and a number of samples azimuthally in proportion to $\sin\theta$ (Penczek *et al.*, 1994). So, for a chosen constant increment $\delta\theta$ and given θ angle the increment of the φ angle varies according to

$$\Delta\varphi = \delta\theta/|\sin\theta|. \qquad (2.5.7.17)$$

If all three Eulerian angles are to be sampled, as is necessary in some applications, then ψ is sampled uniformly in steps of $\delta\theta$.

In order to find the orientation parameters of projection images, one step of projection matching is performed. The reference structure is projected in all directions given by (2.5.7.17), yielding a set of reference images. Next, for each projection image, 2D cross-correlation functions with all reference images are calculated using one of the methods described in Section 2.5.7.6 and the overall maximum yields the translation, the in-plane rotation angle, the number of the most similar reference image (thus the remaining two Eulerian angles) and information about whether the image should be mirrored. Given this, a new 3D structure can be calculated using a 3D reconstruction algorithm (see Section 2.5.6). This simple protocol constitutes the core of 3D projection alignment (Fig. 2.5.7.4).

In a simple implementation of the 3D projection-matching procedure, all projection data are assembled into *defocus groups*, *i.e.*, groups of projection images that have similar defocus settings (Frank *et al.*, 2000). During refinement, for each defocus group the reference volume is multiplied by the CTF with the appropriate defocus value, one step of projection matching is performed and a refined structure is reconstructed for this group (Fig. 2.5.7.5). In addition, the within-group resolution is estimated using the Fourier shell correlation (FSC) approach (2.5.7.19) applied to two volumes calculated from two subsets of projection images randomly split into halves. After all defocus groups have been processed, the individual refined volumes are merged in Fourier space with a CTF correction using Wiener-filter methodology (Penczek *et al.*, 1997),

$$F_{\text{merged}} = \frac{\sum_k \text{CTF}_k \text{SSNR}_k F_k}{\sum_k \text{CTF}_k^2 \text{SSNR}_k + 1}, \qquad (2.5.7.18)$$

where SSNR_k is the spectral signal-to-noise ratio estimated for each defocus group using (2.5.7.22). Subsequently, the resolution of the merged volume is estimated by merging the half-volumes into two half-merged volumes using (2.5.7.18) and comparing them using (2.5.7.19). Next, the merged volume is filtered using (2.5.7.25) and the structure is centred so that its centre of mass is placed at the centre of the volume in which it is embedded.

The 3D projection-matching approach works very well during the initial stages of the refinement as it constitutes a very efficient approach to an exhaustive search for orientation parameters of all projection data. Once the orientation parameters are known to a degree of accuracy, it is straightforward to modify the procedure such that only subsets of reference projections are generated at a time and projection images are compared only with reference projections within a specified angular distance from their angular direction established during previous iteration. This modification speeds up the procedure significantly and makes it possible to refine structures to very high resolution by using a very small angular step $\delta\theta$. Another possible modification is to introduce an additional step of 2D alignment of the projection data that share the same angular direction (Ludtke *et al.*, 1999). The advantage is that this can correct possible errors of alignment to the projection of a limited-resolution reference structure and also, to an extent, reduces the danger of bias from artifacts in the reference structure. Finally, it is also possible to incorporate into the refinement strategy a correction for the envelope function of the microscope (Ludtke *et al.*, 1999). The 3D projection-matching strategy is widely popular and most EM software packages have implementations of various versions of basic strategies, as outlined above (Frank *et al.*, 1996; Ludtke *et al.*, 1999; Hohn *et al.*, 2007).

A possible improvement over the 3D projection-matching procedure can be achieved by working in transformed spaces in which the distinction between orientation search and 3D reconstruction is removed: (1) spherical harmonics (Provencher & Vogel, 1988; Vogel & Provencher, 1988), which have found applications exclusively in the determination of icosahedral structures (Yin *et al.*, 2001, 2003); (2) Radon transform (Radermacher, 1994), with selected applications in the determination of asymmetric particles (Ruiz *et al.*, 2003); or (3) Fourier transform, implemented in the *FREALIGN* package (Grigorieff, 2007). In *FREALIGN*, the transformation between the arbitrarily oriented Fourier 2D central section and the 3D Fourier Euclidean grid is implemented using trilinear interpolation that includes *ad hoc* correction for the CTF effects. In high-resolution structure-refinement mode, the program uses a gradient-based Powell optimization algorithm (Powell, 1973), thus overcoming the main deficiency of 3D projection-matching algorithms.

A unified approach to direct minimization of (2.5.7.6) was proposed by Yang *et al.* (2005) and is implemented in the *SPARX* package as the YNP method (Hohn *et al.*, 2007). The premise of the YNP method is that the orientation parameters are approximately known (thus the initial 3D map) and both the orientation parameters and the density map are updated simultaneously in a gradient-based optimization scheme. In the YNP method, the derivatives with respect to the density distribution are calculated analytically and the derivatives with respect to orientation parameters are calculated using finite difference approximations. The YNP method is very efficient and its major advantage is that it avoids many problems associated with approximate solutions inherent in methods that work in transform spaces. The projection/backprojection operations are carried out rapidly using linear interpolation, which due to sufficient oversampling of the data does not have a significant adverse impact on the solution. Moreover, because the density map f is updated simultaneously with the orientation parameters, the computationally demanding separate step of 3D reconstruction is eliminated.

2.5.7.10. Resolution estimation and analysis of errors in single-particle reconstruction

The development of resolution measures in EM was greatly influenced by earlier work in X-ray crystallography. In EM, the problem is somewhat more difficult as, unlike in crystallography, both the amplitude and the phase information in the data are affected by alignment procedures (which we consider distant analogues of phase-extension methods in crystallography). Therefore, resolution measures in EM reflect the self-consistency of the results; however, as the data are subject to alignment, there is a significant risk of introducing artifacts resulting from the alignment of the noise component in the data. Ultimately, these artifacts will unduly 'improve' the resolution of the map.

The resolution measures used in EM fall into two categories: measures based on averaging of Fourier transforms of individual images and measures based on comparisons of averages calculated for subsets of the data. In the first group, we have the Q-factor (van Heel & Hollenberg, 1980; Kessel *et al.*, 1985) and the spectral signal-to-noise ratio (SSNR) introduced for the 2D case by Unser and co-workers (Unser *et al.*, 1987), and for the 3D case for a class of reconstruction algorithms data are based on direct Fourier inversion by Penczek (Penczek, 2002). The second group of measures includes the differential phase residual (DPR) (Frank *et al.*, 1981) and the Fourier ring correlation (FRC) (Saxton & Baumeister, 1982). A marked advantage of these measures is that they are equally well applicable to 2D or 3D data. In the latter case, the volumes resulting from 3D reconstruction algorithms take the place of the 2D averages.

The resolution measures used in single-particle reconstruction are designed to evaluate the SSNR in the reconstruction as a function of spatial frequency (Penczek, 2002). The 'resolution' of the reconstruction is reported as a spatial frequency limit beyond which the SSNR drops below a selected level, for example below one.

The FSC is evaluated by taking advantage of the large number of single-particle images: the total data set is randomly split into halves; for each subset a 3D reconstruction is calculated (in two dimensions, a simple average); and two maps f and g are compared in Fourier space,

$$\mathrm{FSC}(f, g; u) = \frac{\sum_{|\|\mathbf{u}_n\|-r|\le\varepsilon}^{n_r} F(\mathbf{u}_n)G^*(\mathbf{u}_n)}{\left\{\left[\sum_{|\|\mathbf{u}_n\|-r|\le\varepsilon}^{n_r} |F(\mathbf{u}_n)|^2\right]\left[\sum_{|\|\mathbf{u}_n\|-r|\le\varepsilon}^{n_r} |G(\mathbf{u}_n)|^2\right]\right\}^{1/2}}. \quad (2.5.7.19)$$

In (2.5.7.19), 2ε is a preselected ring/shell thickness, the $\mathbf{u}_n$ form a uniform grid in Fourier space, $u = \|\mathbf{u}_n\|$ is the magnitude of the spatial frequency and n_r is the number of Fourier voxels in the shell corresponding to frequency u. The FSC yields a 1D curve of correlation coefficients as a function of u. Note that the FSC is insensitive to linear transformations of the densities of the objects. An FSC curve everywhere close to one reflects strong similarity between f and g; an FSC curve with values close to zero indicates the lack of similarity between f and g. Particularly convenient for the interpretation of the results in terms of 'resolution' is the relation between the FSC and the SSNR, which is easily derived by taking the expectation of (2.5.7.19) under the assumption that both f and g are sums of the same signal and different realizations of the noise, which are uncorrelated with the signal and between them (Saxton, 1978):

$$E[\mathrm{FSC}] \cong \frac{\mathrm{SSNR}}{\mathrm{SSNR}+1}. \quad (2.5.7.20)$$

By solving (2.5.7.20) for SSNR we obtain

$$\mathrm{SSNR} = \frac{\mathrm{FSC}}{1-\mathrm{FSC}}, \quad (2.5.7.21)$$

which, taking into account that the FSC was calculated from the data set split into halves, has to be modified to (Unser *et al.*, 1987)

$$\mathrm{SSNR} = 2\left(\frac{\mathrm{FSC}}{1-\mathrm{FSC}}\right). \quad (2.5.7.22)$$

In order to calculate the FSC that corresponds to a given SSNR, one inverts (2.5.7.22) to

$$\mathrm{FSC} = \frac{\mathrm{SSNR}}{\mathrm{SSNR}+2}. \quad (2.5.7.23)$$

Equations (2.5.7.21) and (2.5.7.22) serve as a basis for various 'resolution criteria' used in EM. The often-used 3σ criterion (van Heel, 1987*b*) equates resolution with the point at which the FSC is larger than zero at a 3σ level, where σ is the expected standard deviation of the FSC that has an expected value of zero, in essence finding a frequency for which the SSNR is significantly larger than zero. The 3σ criterion has a distinct disadvantage of reporting the resolution at a frequency at which there is no significant signal, while tempting the user to interpret the detail in the map at this resolution. Moreover, as the FSC approaches zero, its relative error increases, so the curve oscillates widely

around the zero level increasing the chance of selecting an incorrect resolution point. In other criteria one tries to equate the resolution with the frequency at which noise begins to dominate the signal. A good choice of the cut-off level is SSNR = 1.0, a level at which the power of the signal in the reconstruction is equal to the power of the noise. According to (2.5.7.22), this corresponds to FSC = 0.333. Another often-used cut-off level is FSC = 0.5, at which the SSNR in the reconstruction is 2.0 (Böttcher *et al.*, 1997; Conway *et al.*, 1997; Penczek, 1998).

The main reason behind the determination of the resolution of the EM maps is the necessary step of low-pass filtration of the results before the interpretation of the map is attempted. In order to avoid mistakes, particularly the danger of overinterpretation, one has to remove from the map unreliable Fourier coefficients. Inclusion of Fourier coefficients with a low SNR will result in the creation of spurious details and artifacts in the map. Thus, the optimal filtration should be based on the SSNR distribution in the map and the solution is given by a Wiener filter:

$$W(u) = \frac{\mathrm{SSNR}(u)}{\mathrm{SSNR}(u)+1}. \qquad (2.5.7.24)$$

Based on the relation of FSC to SSNR (2.5.7.22), we can write (2.5.7.24) as

$$W(u) = \frac{2\mathrm{FSC}(u)}{\mathrm{FSC}(u)+1}. \qquad (2.5.7.25)$$

In practice, because of the irregular shape of typical FSC curves (particularly for small values of FSC) it is preferable to approximate the shape of the Wiener filter (2.5.7.25) by one of the standard low-pass filters, such as Butterworth (Gonzalez & Woods, 2002) or hyperbolic tangent (Basokur, 1998).

The FRC/FSC methodology can be used to compare a noise-corrupted map with a noise-free ideal version of the same object. In single-particle reconstruction this situation emerges when an X-ray crystallographic structure of either the entire EM-determined structure or of some of its domains is available (Penczek *et al.*, 1999). In this case, we assume that in (2.5.7.19) f represents a sum of the signal and additive uncorrelated noise and g represents the noise-free signal, so is straightforward to calculate the expectation of (2.5.7.19) in order to obtain the relation between the cross-resolution (CRC) and the SSNR:

$$E[\mathrm{CRC}] \cong \left(\frac{\mathrm{SSNR}}{\mathrm{SSNR}+1}\right)^{1/2}. \qquad (2.5.7.26)$$

Thus

$$\mathrm{SSNR} = \frac{\mathrm{CRC}^2}{1-\mathrm{CRC}^2}. \qquad (2.5.7.27)$$

Interestingly, for the same SSNR cut-off levels, corresponding values of CRC are higher than those for FSC. For example, for SSNR = 1, CRC = 0.71, while FSC = 0.33. For SSNR = 2, CRC = 0.82, while FSC = 0.5.

2.5.7.11. Analysis of 3D cryo-EM maps

The amount of structural information that can be derived from a structure of a macromolecular complex determined by cryo-EM depends on two factors: the resolution of the map and the availability of additional structural information about the system. Generally, we will refer to complexes at a resolution better than 7 Å as high-resolution structures, as at this resolution the elements of secondary structure become directly visible. Maps at resolution lower than that we will call intermediate resolution, as at this scale of detail one can only determine a general arrangement of subunits. However, it is good to realize that there is a huge difference between the amount and reliability of information derived from a map of the same complex determined at 10 Å as compared to a map determined at 30 Å resolution. Similarly, very large complexes determined at 50 Å resolution will yield more information than very small complexes determined at 15 Å resolution. On the other hand, even intermediate-resolution EM maps provide extremely valuable information if they can be placed in the context of other structural work. The single-particle structure can be also investigated within a context of a more complex system using other, lower-resolution techniques, for example electron tomography. In this case, by using docking approaches one can determine the distribution, orientation and general arrangement of smaller cryo-EM determined complexes within larger subcellular systems. On a different scale of resolution, it is quite common to have structures of some domains or even of the entire complexes determined to atomic resolution by X-ray crystallography. Again, by using docking techniques it is possible to determine whether the conformation of the EM structure differs from that determined by X-ray crystallography or to map subunits and domains of the larger complex by fitting available atomic resolution structures.

The basic mode of visualization of cryo-EM maps is surface representation. The first step involves the choice of an appropriate threshold level for the displayed surface, particularly when the scaling of the cryo-EM data is arbitrary. A good guide is provided by the total molecular mass of the complex: given a pixel size of p Å, an average protein density $d = 1.36 \times 10^{-24}$ g Å^{-3} and the total molecular mass of the complex M Da, the number of voxels N_v occupied by the complex is

$$N_\mathrm{v} = M/\left(p^3 d N_\mathrm{A}\right), \qquad (2.5.7.28)$$

where N_A is the Avogadro's number (6.02×10^{23} atoms mole^{-1}). Based on that, one can find the threshold that for a given structure encompasses the determined number of voxels N_v [appropriate functions are implemented in *SPIDER* (Agrawal *et al.*, 1996; Frank *et al.*, 1996) and *SPARX* (Hohn *et al.*, 2007)]. At a sufficiently high resolution, cryo-EM maps can be analysed in the same manner as X-ray crystallographic maps and using the same graphical/analytical packages ('backbone tracing') (Jones *et al.*, 1991) (Fig. 2.5.7.6).

The complexity of cryo-EM maps of large macromolecular assemblies combined with their limited resolution invites attempts to automate some of the steps of analysis in an attempt to make the results more robust and less dependent on the researcher's bias. A good example of semi-automated analysis is the nucleic acid–protein separation in a 11.5 Å cryo-EM map of the 70S *E. coli* ribosome (Spahn *et al.*, 2000). In the procedure, the (continuous-valued) densities were analysed making use of (i) the difference in scattering density between protein and nucleic acids; (ii) continuity constraints that the image of any nucleic acid molecule must obey and (iii) knowledge of the molecular volumes of all proteins. As a result, it was possible to reproduce boundary assignments between ribosomal RNA (rRNA) and proteins made from higher-resolution X-ray maps of the ribosomal subunits with a high degree of accuracy, and allowed plausible predictions to be made for the placements of proteins and RNA components as yet unassigned. One of the conclusions derived from this separation was that the 23S rRNA is solely responsible for the catalysis of peptide-bond formation; thus, the ribosome is a ribozyme. The same conclusion was reached independently in the studies of the X-ray crystallographic structure of the 70S ribosome (Nissen *et al.*, 2000). The method by Spahn *et al.* cannot be easily extended to other

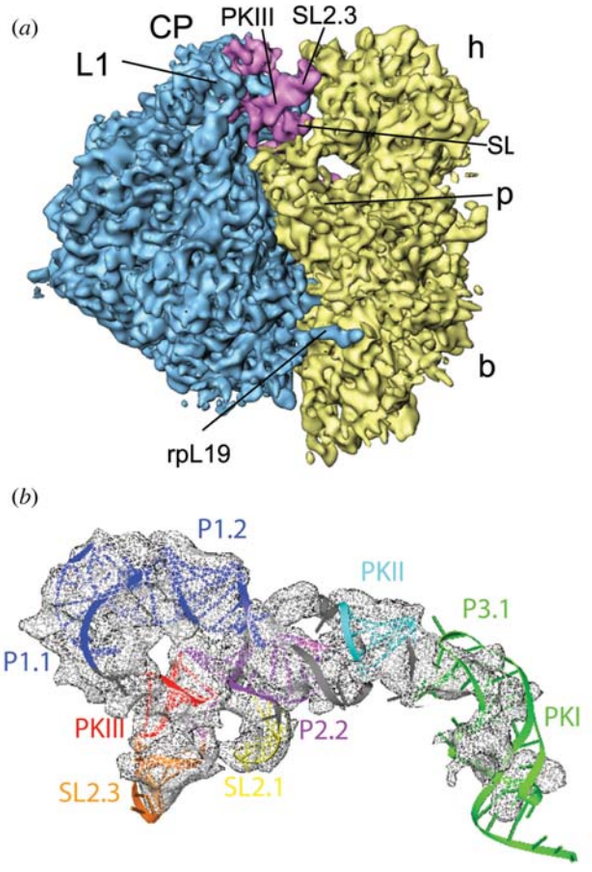


Fig. 2.5.7.6. A high-resolution cryo-EM map allows backbone tracing. (*a*) Cryo-EM map of the cricket paralysis virus (CrPV) IRES RNA in complex with the yeast 80S ribosome determined at 7.3 Å resolution. The map is shown from the L1 protuberance side with the ribosomal 40S subunit in yellow, the 60S subunit in blue and the CrPV IRES in magenta. Landmarks for the 40S subunit: b, body; h, head; p, platform. Landmarks for the 60S subunit: CP, central protuberance; L1, L1 protuberance. PKIII denotes helix PKIII of the CrPV IRES RNA and SL the two stem loops present in the secondary structure of the RNA. (*b*) Structure of the CrPV IRES RNA. Based on the cryo-EM map and additional biochemical knowledge, the complete chain of the RNA is found (189 nucleotides could be traced). The IRES molecular model is shown as a coloured ribbon docked into the cryo-EM density (grey mesh). PK and P denote the individual helical elements of the IRES and SL denotes the stem loops (Schüler *et al.*, 2006).

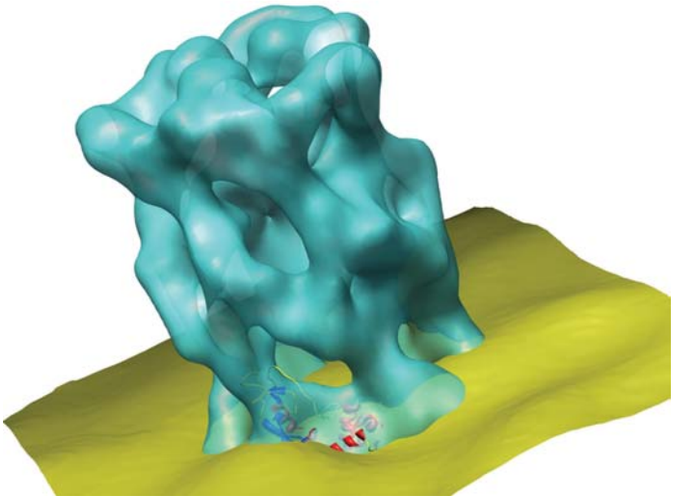

Fig. 2.5.7.7. Hrs (blue) embedded into the membrane (yellow) of an early endosome. Two functional domains have been docked into the cryo-EM density map of hexameric Hrs, determined to 16 Å resolution, and are shown as ribbons coloured by secondary structure (Pullan *et al.*, 2006). The structures of the VHS and FYVE domains have been determined crystallographically (Mao *et al.*, 2000) and are docked into the EM density map of the Hrs. The knowledge of the location of the FYVE and VHS domains, which are reported to bind to PI(3)P molecules found within the endosomal membrane (Kutateladze *et al.*, 1999), has guided the hypothetical placement of Hrs within the endosomal membrane. The immersion of the end caps of Hrs into the endosomal membrane demonstrates an 'end-on' binding model of the Hrs particles with the membrane. According to this model, either end cap can embed into the membrane, allowing the other end cap to carry out other essential protein trafficking functions, or to embed into another membrane, thus preventing fusion of membranes during early endosomal fusion.

macromolecules that comprise only protein and generally it is very difficult to delineate at intermediate resolution subunits of large macromolecular assemblies, automatically or not, in the absence of independent knowledge about their shape. The reason is that both the density and shape of the subunits are affected by the limited resolution differently depending on their spatial context. In general, subunits that are isolated and located on the surface or protruding from the structure will have relatively lower density while at the same time their overall shape will be better preserved and easier to discern. Subunits located inside the structure and surrounded by other structural elements, while having higher density, are more difficult to recognize, as they fuse with the surrounding mass densities. Therefore, it is difficult to provide a general method that could cope with the problem of automated mass-density analysis.

As most cryo-EM structures are determined at intermediate resolution, the most common mode of analysis is either to compare the map with the available X-ray crystallographic structures of its domains or to consider the result in the context of larger, subcellular structures obtained by electron tomography. In both cases correlation techniques are used extensively to obtain objective results or to validate the results obtained by manual fitting.

In docking of X-ray crystallographic structures into EM maps, the first step is the conversion of atomic coordinates from X-ray molecular models, as given in Protein Data Bank (PDB) files, into an electron-density map in a way that would mimic the physical image formation process. Although sophisticated methods of computational emulation of the image-formation process in the electron microscope are available, very simple approaches to conversion yield quite satisfactory results at the resolution of the EM results. The most common one is to assume that the Coulomb potential of an atom is proportional to its atomic number and add these atomic numbers within a Euclidean grid with a cell size equal to the EM pixel size in Å. The atomic coordinates of atoms are interpolated within the grid using trilinear interpolation. After such conversion, the X-ray map can be handled using the general image-processing tools of a single-particle software package. Initial orientation (or orientations, if the general placement is not immediately visually apparent) of the X-ray map can be easily performed manually within any number of graphical packages, for example *Chimera* (Pettersen *et al.*, 2004). The initial six orientation parameters (three translations and three Eulerian angles) are next transferred to the EM package (for details see Baldwin & Penczek, 2007) and the manual docking is refined using correlation techniques (Fig. 2.5.7.7). Similarly, the handedness of the EM map can be established or confirmed by performing fitting of the X-ray determined structure to two EM maps that differ by their hand.

Docking of EM maps into the broader cellular context of structures determined by electron tomography can provide information about the distribution of complexes and their interactions within the cell. Conceptually, the approach is very similar to that of particle picking, *i.e.*, template matching, with the main difference being that calculations are performed in three instead of two dimensions. Given a 3D structure of a single-particle EM complex, a set of 3D templates is prepared by rotating the

template around its centre of mass using the quasi-uniformly distributed three Eulerian angles [equation (2.5.7.17) with $\Delta\psi = \delta\theta$]. However, in application to tomography the angular step $\delta\theta$ can be relatively large, resulting in a much smaller number of templates than in two dimensions, the reason being the rather low resolution of typical electron tomograms (not exceeding 50 Å). Next, a brute-force 3D cross-correlation search with all templates is performed (Frangakis *et al.*, 2002). After windowing out 3D subvolumes containing putative complexes, subsequent averaging and classification can be performed.

Cryo-EM is a unique structural technique in its ability to detect conformational variability of large molecular assemblies within one sample that may contain a mixture of complexes in various conformational states. In addition to the expected conformational heterogeneity of the assemblies, due to fluctuations of the structure around the ground state one can expect to capture molecules in different functional states, especially if the binding of a ligand induces a conformational change in the macromolecular assembly. Therefore, a data set of images from an EM experiment must be interpreted as a mixture of projections from similar but not identical structures. The analysis of the extent of the resulting variability requires the calculation of the real-space distribution of 3D variance/covariance in macromolecules reconstructed from a set of their projections. The problem is difficult, as there is no clear relation between the variance in sets of projections that have the same angular direction and the variance of the 3D structure calculated from these projections. Penczek, Chao *et al.* (2006) proposed calculating the variance in the 3D mass distribution of the structure using a statistical bootstrap resampling technique, in which a new set of projections is selected with replacements from the available whole set of N projections. In the new set, some of the original projections will appear more than once, while others will be omitted. This selection process is repeated a number of times and for each new set of projections the corresponding 3D volume is calculated. Next, the voxel-by-voxel bootstrap variance $\sigma_{\rm B}^2$ of the resulting set of volumes is calculated. The target variance is obtained using a relationship between the variance of arithmetic means for sampling with replacements and the sample variance,

$$\sigma^2 = N\sigma_{\rm B}^2. \qquad (2.5.7.29)$$

The estimated structure-variance map can be used for (i) detection of different functional states (for example, those characterized by binding of a ligand) and subsequent classification of the data set into homogeneous groups (Penczek, Frank & Spahn, 2006*a*), (ii) analysis of the significance of small details in 3D reconstructions, (iii) analysis of the significance of details in difference maps, and (iv) docking of known structural domains into EM density maps.

The bootstrap technique also leads to the analysis of conformational modes of macromolecular complexes, and this is due to the fact that the covariance matrix of the structure can be directly calculated from the bootstrap volumes. The covariance matrix obtained this way would be very large. One possibility is to calculate only correlation coefficients between regions of interest that have large variance (Penczek, Chao *et al.*, 2006). Another possibility is to use the iterative Lanczos technique (Parlett, 1980) and calculate eigenvolumes directly from bootstrap volumes without forming the covariance matrix. These eigenvolumes are related to conformational modes of the molecule, as captured by the projection data of the sample (Penczek, Frank & Spahn, 2006*b*). Thus, this direct relation to the actual cryo-EM projection data positively distinguishes this approach from other techniques in which conformations are postulated based on flexible models of the EM map (Ming *et al.*, 2002; Mitra *et al.*, 2005).

2.5.8. Direct phase determination in electron crystallography

By D. L. Dorset

2.5.8.1. Problems with 'traditional' phasing techniques

The concept of using experimental electron-diffraction intensities for quantitative crystal structure analyses has already been presented in Section 2.5.4. Another aspect of quantitative structure analysis, employing high-resolution images, has been presented in Sections 2.5.5 to 2.5.7. That is to say, electron micrographs can be regarded as an independent source of crystallographic phases.

Before direct methods (Chapter 2.2) were developed as the standard technique for structure determination in small-molecule X-ray crystallography, there were two principal approaches to solving the crystallographic phase problem. First, 'trial and error' was used, finding some means to construct a reasonable model for the crystal structure *a priori*, *e.g.* by matching symmetry properties shared by the point group of the molecule or atomic cluster and the unit-cell space group. Secondly, the autocorrelation function of the crystal, known as the Patterson function (Chapter 2.3), was calculated (by the direct Fourier transform of the available intensity data) to locate salient interatomic vectors within the unit cell.

The same techniques had been used for electron-diffraction structure analysis (nowadays known as *electron crystallography*). In fact, advocacy of the first method persists. Because of the perturbations of diffracted intensities by multiple-beam dynamical scattering (Chapter 5.2), it has often been suggested that trial and error be used to construct the scattering model for the unit crystal in order to test its convergence to observed data after simulation of the scattering events through the crystal. This indirect approach assumes that no information about the crystal structure can be obtained directly from observed intensity data. Under more favourable scattering conditions nearer to the kinematical approximation, *i.e.* for experimental data from thin crystals made up of light atoms, trial-and-error modelling, simultaneously minimizing an atom–atom nonbonded potential function with the crystallographic residual, has enjoyed widespread use in electron crystallography, especially for the determination of linear polymer structures (Brisse, 1989; Pérez & Chanzy, 1989).

Interpretation of Patterson maps has also been important for structure analysis in electron crystallography. Applications have been discussed by Vainshtein (1964), Zvyagin (1967) and Dorset (1994*a*). In face of the dynamical scattering effects for electron scattering from heavy-atom crystals realized later (*e.g.* Cowley & Moodie, 1959), attempts had also been made to modify this autocorrelation function by using a power series in $|F_{\mathbf{h}}|$ to sharpen the peaks (Cowley, 1956). (Here $F_{\mathbf{h}} \equiv \Phi_{\mathbf{h}}$, replacing the notation for the kinematical electron-diffraction structure factor employed in Section 2.5.4.) More recently, Vincent and coworkers have selected first-order-Laue-zone data from inorganics to minimize the effect of dynamical scattering on the interpretability of their Patterson maps (Vincent & Exelby, 1991, 1993; Vincent & Midgley, 1994). Vainshtein & Klechkovskaya (1993) have also reported use of the Patterson function to solve the crystal structure of a lead soap from texture electron-diffraction intensity data.

It is apparent that trial-and-error techniques are most appropriate for *ab initio* structure analysis when the underlying crystal structures are reasonably easy to model. The requisite positioning of molecular (or atomic) groups within the unit cell may be facilitated by finding atoms that fit a special symmetry position [see *IT* A (2005)]. Alternatively, it is helpful to know the molecular orientation within the unit cell (*e.g.* provided by the Patterson function) to allow the model to be positioned for a conformational or translational search. [Examples would include

the polymer-structure analyses cited above, as well as the layer-packing analysis of some phospholipids (Dorset, 1987).] While attempts at *ab initio* modelling of three-dimensional crystal structures, by searching an n-dimensional parameter space and seeking a global internal energy minimum, has remained an active research area, most success so far seems to have been realized with the prediction of two-dimensional layers (Scaringe, 1992). In general, for complicated unit cells, determination of a structure by trial and error is very difficult unless adequate constraints can be placed on the search.

Although Patterson techniques have been very useful in electron crystallography, there are also inherent difficulties in their use, particularly for locating heavy atoms. As will be appreciated from comparison of scattering-factor tables for X-rays [*IT* C (2004), Chapter 6.1] with those for electrons [*IT* C (2004), Chapter 4.3], the relative values of the electron form factors are more compressed with respect to atomic number than are those for X-ray scattering. As discussed in Chapter 2.3, it is desirable that the ratio of summed scattering-factor terms, $r = \sum_{\text{heavy}} Z^2 / \sum_{\text{light}} Z^2$, where Z is the scattering-factor value at $\sin\theta/\lambda = 0$, be near unity. A practical comparison would be the value of r for copper (DL-alaninate) solved from electron-diffraction data by Vainshtein *et al.* (1971). For electron diffraction, $r = 0.47$ compared to the value 2.36 for X-ray diffraction. Orientation of salient structural features, such as chains and rings, would be equally useful for light-atom moieties in electron or X-ray crystallography with Patterson techniques. As structures become more complicated, interpretation of Patterson maps becomes more and more difficult unless an automated search can be carried out against a known structural fragment (Chapter 2.3).

2.5.8.2. Direct phase determination from electron micrographs

The 'direct method' most familiar to the electron microscopist is the high-resolution electron micrograph of a crystalline lattice. Retrieval of an average structure from such a micrograph assumes that the experimental image conforms adequately to the 'weak phase object' approximation, as discussed in Section 2.5.5. If this is so, the use of image-averaging techniques, *e.g.* Fourier filtration or correlational alignment, will allow the unit-cell contents to be visualized after the electron-microscope phase contrast transfer function is deconvoluted from the average image, also discussed in Section 2.5.5. Image analyses can also be extended to three dimensions, as discussed in Section 2.5.6, basically by employing tomographic reconstruction techniques to combine information from the several tilt projections taken from the crystalline object. The potential distribution of the unit cell to the resolution of the imaging experiment can then be used, *via* the Fourier transform, to obtain crystallographic phases for the electron-diffraction amplitudes recorded at the same resolution. This method for phase determination has been the mainstay of protein electron crystallography.

Once a set of phases is obtained from the Fourier transform of the deconvoluted image, they must, however, be referred to an allowed crystallographic origin. For many crystallographic space groups, this choice of origin may coincide with the location of a major symmetry element in the unit cell [see *IT* A (2005)]. Hence, since the Fourier transform of translation is a phase term, if an image shift $[\delta(\mathbf{r} + \mathbf{r}_0)]$ is required to translate the origin of the repeating mass unit $\varphi(\mathbf{r})$ from the arbitrary position in the image to a specific site allowed by the space group,

$$\mathrm{g}(\mathbf{r}) = \varphi(\mathbf{r}) \otimes \delta(\mathbf{r} + \mathbf{r}_0) = \varphi(\mathbf{r} + \mathbf{r}_0),$$

where the operation '$\otimes$' denotes convolution. The Fourier transform of this shifted density function will be

$$G(\mathbf{s}) = F(\mathbf{s}) \exp(2\pi i \mathbf{s} \cdot \mathbf{r}_0) = |F(\mathbf{s})| \exp[i(\phi_s + 2\pi i \mathbf{s} \cdot \mathbf{r}_0)].$$

In addition to the crystallographic phases ϕ_s, it will, therefore, be necessary to find the additional phase-shift term $2\pi i \mathbf{s} \cdot \mathbf{r}_0$ that will access an allowed unit-cell origin. Such origin searches are carried out automatically by some commercial image-averaging computer-software packages.

In addition to applications to thin protein crystals (*e.g.* Henderson *et al.*, 1990; Jap *et al.*, 1991; Kühlbrandt *et al.*, 1994), there are numerous examples of molecular crystals that have been imaged to a resolution of 3–4 Å, many of which have been discussed by Fryer (1993). For π-delocalized compounds, which are the most stable in the electron beam against radiation damage, the best results (2 Å resolution) have been obtained at 500 kV from copper perchlorophthalocyanine epitaxically crystallized onto KCl. As shown by Uyeda *et al.* (1978–1979), the averaged images clearly depict the positions of the heavy Cu and Cl atoms, while the positions of the light atoms in the organic residue are not resolved. (The utility of image-derived phases as a basis set for phase extension will be discussed below.) A number of aromatic polymer crystals have also been imaged to about 3 Å resolution, as reviewed recently (Tsuji, 1989; Dorset, 1994*b*).

Aliphatic molecular crystals are much more difficult to study because of their increased radiation sensitivity. Nevertheless, monolamellar crystals of the paraffin n-$C_{44}H_{90}$ have been imaged to 2.5 Å resolution with a liquid-helium cryomicroscope (Zemlin *et al.*, 1985). Similar images have been obtained at room temperature from polyethylene (Revol & Manley, 1986) and also a number of other aliphatic polymer crystals (Revol, 1991).

As noted by J. M. Cowley and J. C. H. Spence in Section 2.5.1, dynamical scattering can pose a significant barrier to the direct interpretation of high-resolution images from many inorganic materials. Nevertheless, with adequate control of experimental conditions (limiting crystal thickness, use of high-voltage electrons) some progress has been made. Pan & Crozier (1993) have described 2.0 Å images from zeolites in terms of the phase-grating approximation. A three-dimensional structural study has been carried out on an aluminosilicate by Wenk *et al.* (1992) with thin samples that conform to the weak-phase-object approximation at the 800 kV used for the imaging experiment. Heavy and light (*e.g.* oxygen) atoms were located in the micrographs in good agreement with an X-ray crystal structure. Heavy-atom positions from electron microscopic and X-ray structure analyses have also been favourably compared for two heavy-metal oxides (Hovmöller *et al.*, 1984; Li & Hovmöller, 1988).

2.5.8.3. Probabilistic estimate of phase invariant sums

Conventional direct phasing techniques, as commonly employed in X-ray crystallography (*e.g.* see Chapter 2.2), have also been used for *ab initio* electron-crystallographic analyses. As in X-ray crystallography, probabilistic estimates of a linear combination of phases (Hauptman & Karle, 1953; Hauptman, 1972) are made after normalized structure factors are calculated *via* electron form factors, *i.e.*

$$|E_{\mathbf{h}}^2| = I_{\text{obs}} / \varepsilon \sum_i f_i^2, \text{ where } \langle |E|^2 \rangle = 1.000.$$

(Here, an overall temperature factor can be found from a Wilson plot. Because of multiple scattering, the value of B may be found occasionally to lie close to 0.0 Å^2.) The phase invariant sums

$$\psi = \phi_{\mathbf{h}_1} + \phi_{\mathbf{h}_2} + \phi_{\mathbf{h}_3} + \ldots$$

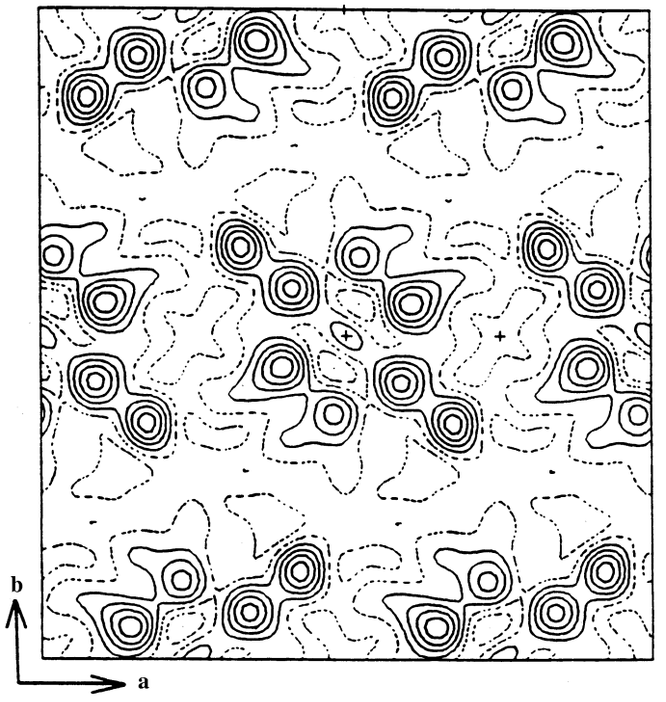

Fig. 2.5.8.1. Potential map for diketopiperazine ([001] projection) after a direct phase determination with texture electron-diffraction intensity data obtained originally by Vainshtein (1955).

can be particularly effective for structure analysis. Of particular importance historically have been the Σ_2-triple invariants where $\mathbf{h}_1 + \mathbf{h}_2 + \mathbf{h}_3 = 0$ and $\mathbf{h}_1 \neq \mathbf{h}_2 \neq \mathbf{h}_3$. The probability of predicting $\psi = 0$ is directly related to the value of

$$A = (2\sigma_3/\sigma_2^{3/2})|E_{\mathbf{h}_1} E_{\mathbf{h}_2} E_{\mathbf{h}_3}|,$$

where $\sigma_{\mathbf{h}} = \sum_{j=1}^{N} Z_j^n$ and Z is the value of the scattering factor at $\sin\theta/\lambda = 0$. Thus, the values of the phases are related to the measured structure factors, just as they are found to be in X-ray crystallography. The normalization described above imposes the point-atom structure (compensating for the fall-off of an approximately Gaussian form factor) often assumed in deriving the joint probability distributions. Especially for van der Waals structures, the constraint of positivity also holds in electron crystallography. (It is also quite useful for charged atoms so long as the reflections are not measured at very low angles.) Other useful phase invariant sums are the Σ_1 triples, where $\mathbf{h}_1 = \mathbf{h}_2 = -1/2\mathbf{h}_3$, and the quartets, where $\mathbf{h}_1 + \mathbf{h}_2 + \mathbf{h}_3 + \mathbf{h}_4 = 0$ and $\mathbf{h}_1 \neq \mathbf{h}_2 \neq \mathbf{h}_3 \neq \mathbf{h}_4$. The prediction of a correct phase for an invariant is related in each case to the normalized structure-factor magnitudes.

The procedure for phase determination, therefore, is identical to the one used in X-ray crystallography (see Chapter 2.2). Using vectorial combinations of Miller indices, one generates triple and quartet invariants from available measured data and ranks them according to parameters such as A, defined above, which, as shown in Chapter 2.2, are arguments of the Cochran formula. The invariants are thus listed in order of their reliability. This, in fact, generates a set of simultaneous equations in crystallographic phase. In order to begin solving these equations, it is permissible to define arbitrarily the phase values of a limited number of reflections (three for a three-dimensional primitive unit cell) for reflections with Miller-index parity $hkl \neq ggg$ and $\sum_i h_i k_i l_i \neq ggg$, where g is an even number. This defines the origin of a unit cell. For noncentrosymmetric unit cells, the condition for defining the origin, which depends on the space group, is somewhat more complicated and an enantiomorph-defining reflection must be added.

In the evaluation of phase-invariant sums above a certain probability threshold, phase values are determined algebraically after origin (and enantiomorph) definition until a large enough set is obtained to permit calculation of an interpretable potential map (*i.e.* where atomic positions can be seen). There may be a few invariant phase sums above this threshold probability value which are incorrectly predicted, leading either to false phase assignments or at least to phase assignments inconsistent with those found from other invariants. A small number of such errors can generally be tolerated. Another problem arises when an insufficient quantity of new phase values is assigned directly from the phase invariants after the origin-defining phases are defined. This difficulty may occur for small data sets, for example. If this is the case, it is possible that a new reflection of proper index parity can be used to define the origin. Alternatively, $\phi_n = a, b, c \ldots$ algebraic unknowns can be used to establish the phase linkage among certain reflections. If the structure is centrosymmetric, and when enough reflections are given at least symbolic phase assignments, 2^n maps are calculated and the correct structure is identified by inspection of the potential maps. When all goes well in this so-called 'symbolic addition' procedure, the symbols are uniquely determined and there is no need to calculate more than a single map. If algebraic values are retained for certain phases because of limited vectorial connections in the data set, then a few maps may need to be generated so that the correct structure can be identified using the chemical knowledge of the investigator. The atomic positions identified can then be used to calculate phases for all observed data (*via* the structure-factor calculation) and the structure can be refined by Fourier (or, sometimes, least-squares) techniques to minimize the crystallographic R factor.

The first actual application of direct phasing techniques to experimental electron-diffraction data, based on symbolic addition procedures, was to two methylene subcell structures (an *n*-paraffin and a phospholipid; Dorset & Hauptman, 1976). Since then, evaluation of phase invariants has led to numerous other structures. For example, early texture electron-diffraction data sets obtained in Moscow (Vainshtein, 1964) were shown to be suitable for direct analysis. The structure of diketopiperazine (Dorset, 1991*a*) was determined from these electron-diffraction data (Vainshtein, 1955) when directly determined phases allowed computation of potential maps such as the one shown in Fig. 2.5.8.1. Bond distances and angles are in good agreement with the X-ray structure, particularly after least-squares refinement (Dorset & McCourt, 1994*a*). In addition, the structures of urea (Dorset, 1991*b*), using data published by Lobachev & Vainshtein (1961), paraelectric thiourea (Dorset, 1991*b*), using data published by Dvoryankin & Vainshtein (1960), and three mineral structures (Dorset, 1992*a*), from data published by Zvyagin (1967), have been determined, all using the original texture (or mosaic single-crystal) diffraction data. The most recent determination based on such texture diffraction data is that of basic copper chloride (Voronova & Vainshtein, 1958; Dorset, 1994*c*).

Symbolic addition has also been used to assign phases to selected-area diffraction data. The crystal structure of boric acid (Cowley, 1953) has been redetermined, adding an independent low-temperature analysis (Dorset, 1992*b*). Additionally, a direct structure analysis has been reported for graphite, based on high-voltage intensity data (Ogawa *et al.*, 1994). Two-dimensional data from several polymer structures have also been analysed successfully (Dorset, 1992*c*) as have three-dimensional intensity data (Dorset, 1991*c*,*d*; Dorset & McCourt, 1993).

Phase information from electron micrographs has also been used to aid phase determination by symbolic addition. Examples include the epitaxically oriented paraffins *n*-hexatriacontane (Dorset & Zemlin, 1990), *n*-tritriacontane (Dorset & Zhang, 1991) and a 1:1 solid solution of n-$C_{32}H_{66}$/n-$C_{36}H_{74}$ (Dorset,

1990*a*). Similarly, lamellar electron-diffraction data to *ca* 3 Å resolution from epitaxically oriented phospholipids have been phased by analysis of Σ_1 and Σ_2-triplet invariants (Dorset, 1990*b*, 1991*e*,*f*), in one case combined with values from a 6 Å resolution electron-microscope image (Dorset *et al.*, 1990, 1993). Most recently, such data have been used to determine the layer packing of a phospholipid binary solid solution (Dorset, 1994*d*).

An *ab initio* direct phase analysis was carried out with zonal electron-diffraction data from copper perchlorophthalocyanine. Using intensities from a *ca* 100 Å thick sample collected at 1.2 MeV, the best map from a phase set with symbolic unknowns retrieves the positions of all the heavy atoms, equivalent to the results of the best images (Uyeda *et al.*, 1978–1979). Using these positions to calculate an initial phase set, the positions of the remaining light C, N atoms were found by Fourier refinement so that the final bond distances and angles were in good agreement with those from X-ray structures of similar compounds (Dorset *et al.*, 1991). A similar analysis has been carried out for the perbromo analogue (Dorset *et al.*, 1992). Although dynamical scattering and secondary scattering significantly perturb the observed intensity data, the total molecular structure can be visualized after a Fourier refinement. Most recently, a three-dimensional structure determination was reported for C_{60} buckminsterfullerene based on symbolic addition with results most in accord with a rotationally disordered molecular packing (Dorset & McCourt, 1994*b*).

2.5.8.4. The tangent formula

Given a triple phase relationship

$$\phi_{\mathbf{h}} \simeq \phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}},$$

where $\mathbf{h}$, $\mathbf{k}$ and $\mathbf{h}-\mathbf{k}$ form a vector sum, it is often possible to find a more reliable estimate of $\phi_{\mathbf{h}}$ when all the possible vectorial contributions to it within the observed data set $\mathbf{k}_{\mathbf{r}}$ are considered as an average, *viz:*

$$\phi_{\mathbf{h}} \simeq \langle \phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}} \rangle_{\mathbf{k}_{\mathbf{r}}}.$$

For actual phase determination, this can be formalized as follows. After calculating normalized structure-factor magnitudes $|E_{\mathbf{h}}|$ from the observed $|F_{\mathbf{h}}|$ to generate all possible phase triples within a reasonably high $A_{\mathbf{h}}$ threshold, new phase values can be estimated after origin definition by use of the tangent formula (Karle & Hauptman, 1956):

$$\tan \phi_{\mathbf{h}} = \frac{\sum_{\mathbf{k}_{\mathbf{r}}} W_{\mathbf{h}} |E_{\mathbf{k}}||E_{\mathbf{h}-\mathbf{k}}| \sin(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})}{\sum_{\mathbf{k}_{\mathbf{r}}} W_{\mathbf{h}} |E_{\mathbf{k}}||E_{\mathbf{h}-\mathbf{k}}| \cos(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})}.$$

The reliability of the phase estimate depends on the variance $V(\phi_{\mathbf{h}})$, which is directly related to the magnitude of $\alpha_{\mathbf{h}}$, *i.e.*

$$\alpha_{\mathbf{h}}^2 = \left[\sum_{\mathbf{k}_{\mathbf{r}}} A_{\mathbf{h},\mathbf{k}} \cos(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})\right]^2 + \left[\sum_{\mathbf{k}_{\mathbf{r}}} A_{\mathbf{h},\mathbf{k}} \sin(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})\right]^2;$$

$A_{\mathbf{h},\mathbf{k}}$ is identical to the A value defined in the previous section. In the initial stages of phase determination $\alpha_{\mathbf{h}}$ is replaced by an expectation value α_{E} until enough phases are available to permit its calculation.

The phase solutions indicated by the tangent formula can thus be ranked according to the phase variance and the determination of phases can be made symbolically from the most probable triple-product relationships. This procedure is equivalent to the one described above for the evaluation of phase-invariant sums by symbolic addition. This procedure may allow determination of a large enough basis phase set to produce an interpretable map.

An alternative procedure is to use an automatic version of the tangent formula in a multisolution process. This procedure is described in Chapter 2.2. After origin definition, enough algebraic unknowns are defined (two values if centrosymmetric and four values, cycling through phase quadrants, if noncentrosymmetric) to access as many of the unknown phases as possible. These are used to generate a number of trial phase sets and the likelihood of identifying the correct solution is based on the use of some figure of merit.

Multisolution approaches employing the tangent formula include *MULTAN* (Germain *et al.*, 1971), *QTAN* (Langs & DeTitta, 1975) and *RANTAN* (Yao, 1981). *RANTAN* is a version of *MULTAN* that allows for a larger initial random phase set (with suitable control of weights in the tangent formula). *QTAN* utilizes the $\alpha_{\mathbf{h}_{\mathrm{est}}}$ definition, where

$$\alpha_{\mathbf{h}_{\mathrm{est}}} = \left\{\sum_{\mathbf{k}} A_{\mathbf{h},\mathbf{k}}^2 + 2 \sum_{\mathbf{k} \neq} \sum_{\mathbf{k}'} A_{\mathbf{h},\mathbf{k}} A'_{\mathbf{h},\mathbf{k}} \frac{I_1(A_{\mathbf{h},\mathbf{k}}) I_1(A'_{\mathbf{h},\mathbf{k}})}{I_0(A_{\mathbf{h},\mathbf{k}}) I_0(A'_{\mathbf{h},\mathbf{k}})}\right\}^{1/2},$$

for evaluating the phase variance. (Here I_0, I_1 are modified Bessel functions.) After multiple solutions are generated, it is desirable to locate the structurally most relevant phase sets by some figure of merit. There are many that have been suggested (Chapter 2.2). The most useful figure of merit in *QTAN* has been the NQEST (De Titta *et al.*, 1975) estimate of negative quartet invariants (see Chapter 2.2). More recently, this has been superseded by the minimal function (Hauptman, 1993):

$$R(\phi) = \frac{\sum_{\mathbf{h},\mathbf{k}} A_{\mathbf{h},\mathbf{k}} (\cos \phi_{\mathbf{h},\mathbf{k}} - t_{\mathbf{h},\mathbf{k}})^2}{\sum_{\mathbf{h},\mathbf{k}} A_{\mathbf{h},\mathbf{k}}},$$

where $t_{\mathbf{h},\mathbf{k}} = I_1(A_{\mathbf{h},\mathbf{k}})/I_0(A_{\mathbf{h},\mathbf{k}})$ and $\phi_{\mathbf{h},\mathbf{k}} = \phi_{\mathbf{h}} + \phi_{\mathbf{k}} + \phi_{-\mathbf{h}-\mathbf{k}}$.

In the first application (Dorset *et al.*, 1979) of multisolution phasing to electron-diffraction data (using the program *QTAN*), *n*-beam dynamical structure factors generated for cytosine and disodium 4-oxypyrimidine-2-sulfinate were used to assess the effect of increasing crystal thickness and electron accelerating voltage on the success of the structure determination. At 100 kV samples at least 80 Å thick were usable for data collection and at 1000 kV this sample thickness limit could be pushed to 300 Å – or, perhaps, 610 Å if a partial structure were accepted for later Fourier refinement. NQEST identified the best phase solutions. Later *QTAN* was used to evaluate the effect of elastic crystal bend on the structure analysis of cytosine (Moss & Dorset, 1982).

In actual experimental applications, two forms of thiourea were investigated with *QTAN* (Dorset, 1992*d*), using published three-dimensional electron-diffraction intensities (Dvoryankin & Vainshtein, 1960, 1962). Analysis of the centrosymmetric paraelectric structure yielded results equivalent to those found earlier by symbolic addition (Dorset, 1991*b*). Analysis of the noncentrosymmetric ferroelectric form was also quite successful (Dorset, 1992*d*). In both cases, the correct structure was found at the lowest value of NQEST. Re-analysis of the diketopiperazine structure with *QTAN* also found the correct structure (Dorset & McCourt, 1994*a*) within the four lowest values of NQEST, but not the one at the lowest value. The effectiveness of this figure of merit became more questionable when *QTAN* was used to solve the noncentrosymmetric crystal structure of a polymer (Dorset, McCourt, Kopp *et al.*, 1994). The solution could not be found readily when NQEST was used but was easily identified when the minimal function $R(\phi)$ was employed instead.

MULTAN has been used to phase simulated data from copper perchlorophthalocyanine (Fan *et al.*, 1985). Within the 2 Å

resolution of the electron-microscope image, if one seeks phases for diffraction data in reciprocal-space regions where the objective lens phase contrast transfer function $|C(s)| \leq 0.2$, the method proves to be successful. The method is also quite effective for phase extension from 2 Å to 1 Å diffraction resolution, where the low-angle data serve as a large initial phase set for the tangent formula. However, no useful results were found from an *ab initio* phase determination carried out solely with the electron-diffraction structure-factor magnitudes. Similar results were obtained when *RANTAN* was used to phase experimental data from this compound (Fan *et al.*, 1991), *i.e.* the multisolution approach worked well for phase extension but not for *ab initio* phase determination. Additional tests were subsequently carried out with *QTAN* on an experimental *hk*0 electron-diffraction data set collected at 1200 kV (Dorset, McCourt, Fryer *et al.*, 1994). Again, *ab initio* phase determination is not possible by this technique. However, if a basis set was constructed from the Fourier transform of a 2.4 Å image, a correct solution could be found, but not at the lowest value of NQEST. This figure of merit was useful, however, when the basis set was taken from the symbolic addition determination mentioned in the previous section.

2.5.8.5. Density modification

Another method of phase determination, which is best suited to refining or extending a partial phase set, is the Hoppe–Gassmann density modification procedure (Hoppe & Gassmann, 1968; Gassmann & Zechmeister, 1972; Gassmann, 1976). The procedure is very simple but also very computer-intensive. Starting with a small set of (phased) $F_{\mathbf{h}}$, an initial potential map $\varphi(\mathbf{r})$ is calculated by Fourier transformation. This map is then modified by some real-space function, which restricts peak sizes to a maximum value and removes all negative density regions. The modified map $\varphi'(\mathbf{r})$ is then Fourier-transformed to produce a set of phased structure factors. Phase values are accepted *via* another modification function in reciprocal space, *e.g.* $E_{\rm calc}/E_{\rm obs} \geq p$, where p is a threshold quantity. The new set is then transformed to obtain a new $\varphi(\mathbf{r})$ and the phase refinement continues iteratively until the phase solution converges (judged by lower crystallographic R values).

The application of density modification procedures to electron-crystallographic problems was assessed by Ishizuka *et al.* (1982), who used simulated data from copper perchlorophthalocyanine within the resolution of the electron-microscope image. The method was useful for finding phase values in reciprocal-space regions where the transfer function $|C(s)| \leq 0.2$. As a technique for phase extension, density modification was acceptable for test cases where the resolution was extended from 1.67 to 1.0 Å, or 2.01 to 1.21 Å, but it was not very satisfactory for a resolution enhancement from 2.5 to 1.67 Å. There appear to have been no tests of this method yet with experimental data. However, the philosophy of this technique will be met again below in the description of the maximum entropy and likelihood procedure.

2.5.8.6. Convolution techniques

One of the first relationships ever derived for phase determination is the Sayre (1952) equation:

$$F_{\mathbf{h}} = \frac{\theta}{V} \sum_{\mathbf{k}} F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}},$$

which is a simple convolution of phased structure factors multiplied by a function of the atomic scattering factors. For structures with nonoverlapping atoms, consisting of one atomic species, it is an exact expression. Although the convolution term resembles part of the tangent formula above, no statistical averaging is implied (Sayre, 1980). In X-ray crystallography this relationship has not been used very often, despite its accuracy. Part of the reason for this is that it requires relatively high resolution data for it to be useful. It can also fail for structures comprised of different atomic species.

Since, relative to X-ray scattering factors, electron scattering factors span a narrower range of magnitudes at $\sin\theta/\lambda = 0$, it might be thought that the Sayre equation would be particularly useful in electron crystallography. In fact, Liu *et al.* (1988) were able to extend phases for simulated data from copper perchlorophthalocyanine starting at the image resolution of 2 Å and reaching the 1 Å limit of an electron-diffraction data set. This analysis has been improved with a 2.4 Å basis set obtained from the Fourier transform of an electron micrograph of this material at 500 kV and extended to the 1.0 Å limit of a 1200 kV electron-diffraction pattern (Dorset *et al.*, 1995). Using the partial phase sets for zonal diffraction data from several polymers by symbolic addition (see above), the Sayre equation has been useful for extending into the whole *hk*0 set, often with great accuracy. The size of the basis set is critical but the connectivity to access all reflections is more so. Fan and co-workers have had considerable success with the analysis of incommensurately modulated structures. The average structure (basis set) is found by high-resolution electron microscopy and the 'superlattice' reflections, corresponding to the incommensurate modulation, are assigned phases in hyperspace by the Sayre convolution. Examples include a high T_c superconductor (Mo *et al.*, 1992) and the mineral ankangite (Xiang *et al.*, 1990). Phases of regular inorganic crystals have also been extended from the electron micrograph to the electron-diffraction resolution by this technique (Hu *et al.*, 1992).

In an investigation of how direct methods might be used for phase extension in protein electron crystallography, low-resolution phases from two proteins, bacteriorhodopsin (Henderson *et al.*, 1986) and halorhodopsin (Havelka *et al.*, 1993) were extended to higher resolution with the Sayre equation (Dorset *et al.*, 1995). For the noncentrosymmetric bacteriorhodopsin *hk*0 projection a 10 Å basis set was used, whereas a 15 Å set was accepted for the centrosymmetric halorhodopsin projection. In both cases, extensions to 6 Å resolution were reasonably successful. For bacteriorhodopsin, for which data were available to 3.5 Å, problems with the extension were encountered near 5 Å, corresponding to a minimum in a plot of average intensity *versus* resolution. Suggestions were made on how a multisolution procedure might be successful beyond this point.

2.5.8.7. Maximum entropy and likelihood

Maximum entropy has been applied to electron crystallography in several ways. In the sense that images are optimized, the entropy term

$$S = -\sum_i P_i \ln P_i,$$

where $P_i = p_i / \sum_i p_i$ and p_i is a pixel density, has been evaluated for various test electron-microscope images. For crystals, the true projected potential distribution function is thought to have the maximum value of S. If the phase contrast transfer function used to obtain a micrograph is unknown, test images (*i.e.* trial potential maps) can be calculated for different values of $\Delta f_{\rm trial}$. The value that corresponds to the maximum entropy would be near the true defocus. In this way, the actual objective lens transfer function can be found for a single image (Li, 1991) in addition to the other techniques suggested by this group.

Another use of the maximum-entropy concept is to guide the progress of a direct phase determination (Bricogne & Gilmore, 1990; Gilmore *et al.*, 1990). Suppose that there is a small set H of known phases $\phi_{\mathbf{h}\in H}$ (corresponding either to origin

definition, or the Fourier transform of an electron micrograph, or both) with associated unitary structure-factor amplitudes $|U_{\mathbf{h}\in H}|$. [The unitary structure factor is defined as $|U_{\mathbf{h}}| = |E_{\mathbf{h}}|/(N)^{1/2}$.] As usual, the task is to expand into the unknown phase set K to solve the crystal structure. From Bayes' theorem, the procedure is based on an operation where $p(\text{map}|\text{data}) \propto p(\text{map})p(\text{data}|\text{map})$. This means that the probability of successfully deriving a potential map, given diffraction data, is estimated. This so-called posterior probability is approximately proportional to the product of the probability of generating the map (known as the prior) and the probability of generating the data, given the map (known as the likelihood). The latter probability consults the observed data and can be used as a figure of merit.

Beginning with the basis set H, a trial map is generated from the limited number of phased structure factors. As discussed above, the map can be immediately improved by removing all negative density. The map can be improved further if its entropy is maximized using the equation given above for S. This produces the so-called maximum-entropy prior $q^{\text{ME}}(X)$.

So far, it has been assumed that all $|U_{\mathbf{h}\in K}| = 0$. If large reflections from the K set are now added and their phase values are permuted, then a number of new maps can be generated and their entropies can be maximized as before. This creates a phasing 'tree' with many possible solutions; individual branch points can have further reflections added *via* permutations to produce further sub-branches, and so on. Obviously, some figure of merit is needed to 'prune' the tree, *i.e.* to find likely paths to a solution.

The desired figure of merit is the likelihood $L(H)$. First a quantity

$$\Lambda_{\mathbf{h}} = 2NR \exp[-N(r^2 + R^2)] I_o(2NrR),$$

where $r = |^{\text{ME}}U_{\mathbf{h}}|$ (the calculated unitary structure factors) and $R = |^{o}U_{\mathbf{h}}|$ (the observed unitary structure factors), is defined. From this one can calculate

$$L(H) = \sum_{\mathbf{h}\notin H} \ln \Lambda_{\mathbf{h}}.$$

The null hypothesis $L(H_o)$ can also be calculated from the above when $r = 0$, so that the likelihood gain

$$LLg = L(H) - L(H_o)$$

ranks the nodes of the phasing tree in order of the best solutions.

Applications have been made to experimental electron-crystallographic data. A small-molecule structure starting with phases from an electron micrograph and extending to electron-diffraction resolution has been reported (Dong *et al.*, 1992). Other experimental electron-diffraction data sets used in other direct phasing approaches (see above) also have been assigned phases by this technique (Gilmore, Shankland & Bricogne, 1993). These include intensities from diketopiperazine and basic copper chloride. An application of this procedure in protein structure analysis has been published by Gilmore *et al.* (1992) and Gilmore, Shankland & Fryer (1993). Starting with 15 Å phases, it was possible to extend phases for bacteriorhodopsin to the limits of the electron-diffraction pattern, apparently with greater accuracy than possible with the Sayre equation (see above).

2.5.8.8. Influence of multiple scattering on direct electron-crystallographic structure analysis

The aim of electron-crystallographic data collection is to minimize the effect of dynamical scattering, so that the unit-cell potential distribution or its Fourier transform is represented significantly in the recorded signal. It would be a mistake, however, to presume that these data ever conform strictly to the kinematical approximation, for there is always some deviation from this ideal scattering condition that can affect the structure analysis. Despite this fact, some direct phasing procedures have been particularly 'robust', even when multiple scattering perturbations to the data are quite obvious (*e.g.* as evidenced by large crystallographic residuals).

The most effective direct phasing procedures seem to be those based on the Σ_2 triple invariants. These phase relationships will not only include the symbolic addition procedure, as it is normally carried out, but also the tangent formula and the Sayre equation (since it is well known that this convolution can be used to derive the functional form of the three-phase invariant). The strict ordering of $|E_{\mathbf{h}}|$ magnitudes is, therefore, not critically important so long as there are no major changes from large to small values (or *vice versa*). This was demonstrated in direct phase determinations of simulated n-beam dynamical diffraction data from a sulfur-containing polymer (Dorset & McCourt, 1992). Nevertheless, there is a point where measured data cannot be used. For example, intensities from *ca* 100 Å-thick epitaxically oriented copper perchlorophthalocyanine crystals become less and less representative of the unit-cell transform at lower electron-beam energies (Tivol *et al.*, 1993) and, accordingly, the success of the phase determination is compromised (Dorset, McCourt, Fryer *et al.*, 1994). The similarity between the Sayre convolution and the interactions of structure-factor terms in, *e.g.*, the multislice formulation of n-beam dynamical scattering was noted by Moodie (1965). It is interesting to note that dynamical scattering interactions observed by direct excitation of Σ_2 and Σ_1 triples in convergent-beam diffraction experiments can actually be exploited to determine crystallographic phases to very high precision (Spence & Zuo, 1992, pp. 56–63).

While the evaluation of positive quartet invariant sums (see Chapter 2.2) seems to be almost as favourable in the electron diffraction case as is the evaluation of Σ_2 triples, negative quartet invariants seem to be particularly sensitive to dynamical diffraction. If dynamical scattering can be modelled crudely by a convolutional smearing of the diffraction intensities, then the lowest structure-factor amplitudes, and hence the estimates of lowest $|E_{\mathbf{h}}|$ values, will be the ones most compromised. Since the negative quartet relationships require an accurate prediction of small 'cross-term' $|E_{\mathbf{h}}|$ values, multiple scattering can, therefore, limit the efficacy of this invariant for phase determination. In initial work, negative quartets have been mostly employed in the NQEST figure of merit, and analyses (Dorset, McCourt, Fryer *et al.*, 1994; Dorset & McCourt, 1994*a*) have shown how the degradation of weak kinematical $|E_{\mathbf{h}}|$ terms effectively reduced its effectiveness for locating correct structure solutions *via* the tangent formula, even though the tangent formula itself (based on triple phase estimates) was quite effective for phase determination. Substitution of the minimal function $R(\phi)$ for NQEST seems to have overcome this difficulty. [It should be pointed out, though, that only the Σ_2-triple contribution to $R(\phi)$ is considered.]

Structure refinement is another area where the effects of dynamical scattering are also problematic. For example, in the analysis of the paraelectric thiourea structure (Dorset, 1991*b*) from published texture diffraction data (Dvoryankin & Vainshtein, 1960), it was virtually impossible to find a chemically reasonable structure geometry by Fourier refinement, even though the direct phase determination itself was quite successful. The best structure was found only when higher-angle intensities (*i.e.* those least affected by dynamical scattering) were used to generate the potential map. Later analyses on heavy-atom-containing organics (Dorset *et al.*, 1992) found that the lowest kinematical R-factor value did not correspond to the chemically correct structure geometry. This observation was also made in the

least-squares refinement of diketopiperazine (Dorset & McCourt, 1994*a*). It is obvious that, if a global minimum is sought for the crystallographic residual, then dynamical structure factors, rather than kinematical values, should be compared to the observed values (Dorset *et al.*, 1992). Ways of integrating such calculations into the refinement process have been suggested (Sha *et al.*, 1993). Otherwise one must constrain the refinement to chemically reasonable bonding geometry in a search for a local *R*-factor minimum.

Corrections for such deviations from the kinematical approximation are complicated by the presence of other possible data perturbations, especially if microareas are being sampled, *e.g.* in typical selected-area diffraction experiments. Significant complications can arise from the diffraction incoherence observed from elastically deformed crystals (Cowley, 1961) as well as secondary scattering (Cowley *et al.*, 1951). These complications were also considered for the larger (*e.g.* millimetre diameter) areas sampled in an electron-diffraction camera when recording texture diffraction patterns (Turner & Cowley, 1969), but, because of the crystallite distributions, it is sometimes found that the two-beam dynamical approximation is useful (accounting for a number of successful structure analyses carried out in Moscow).

MT is grateful to Professor J. C. H. Spence for critical reading of the manuscript of Section 2.5.3, for correcting the English and for helpful comments, and to Professor M. Terauchi and Dr K. Tsuda of Tohoku University and Dr K. Saitoh of Nagoya University for useful discussions.

3.1. Distances, angles, and their standard uncertainties

By D. E. Sands

3.1.1. Introduction

A crystal structure analysis provides information from which it is possible to compute distances between atoms, angles between interatomic vectors, and the uncertainties in these quantities. In Cartesian coordinate systems, these geometric computations require the Pythagorean theorem and elementary trigonometry. The natural coordinate systems of crystals, though, are determined by symmetry, and only in special cases are the basis vectors (or coordinate axes) of these systems constrained to be of equal lengths or mutually perpendicular.

It is possible, of course, to transform the positional parameters of the atoms to a Cartesian system and perform the subsequent calculations with the transformed coordinates. Along with the coordinates, the transformations must be applied to anisotropic thermal factors, variance–covariance matrices and other important quantities. Moreover, leaving the natural coordinate system of the crystal sacrifices the simplified relationships imposed by translational and point symmetry; for example, if an atom has fractional coordinates x^1, x^2, x^3, an equivalent atom will be at $1 + x^1$, x^2, x^3, *etc.*

Fortunately, formulation of the calculations in generalized rectilinear coordinate systems is straightforward, and readily adapted to computer languages (Section 3.1.12 illustrates the use of Fortran for such calculations). The techniques for these computations are those of tensor analysis, which provides a compact and elegant notation. While an effort will be made to be self-sufficient in this chapter, some proficiency in vector algebra is assumed, and the reader not familiar with the basics of tensor analysis should refer to Chapter 1.1 and Sands (1982*a*).

3.1.2. Scalar product

The scalar product of vectors **u** and **v** is defined as

$$\mathbf{u} \cdot \mathbf{v} = uv \cos\varphi, \tag{3.1.2.1}$$

where u and v are the lengths of the vectors and φ is the angle between them. In terms of components,

$$\mathbf{u} \cdot \mathbf{v} = (u^i \mathbf{a}_i) \cdot (v^j \mathbf{a}_j) \tag{3.1.2.2}$$

$$\mathbf{u} \cdot \mathbf{v} = u^i v^j \mathbf{a}_i \cdot \mathbf{a}_j \tag{3.1.2.3}$$

$$\mathbf{u} \cdot \mathbf{v} = u^i v^j g_{ij}. \tag{3.1.2.4}$$

In all equations in this chapter, the convention is followed that summation is implied over an index that is repeated once as a subscript and once as a superscript in an expression; thus, the right-hand side of (3.1.2.4) implies the sum of nine terms

$$u^1 v^1 g_{11} + u^1 v^2 g_{12} + \ldots + u^3 v^3 g_{33}.$$

The g_{ij} in (3.1.2.4) are the components of the metric tensor [see Chapter 1.1 and Sands (1982*a*)]

$$g_{ij} = \mathbf{a}_i \cdot \mathbf{a}_j. \tag{3.1.2.5}$$

Subscripts are used for quantities that transform the same way as the basis vectors $\mathbf{a}_i$; such quantities are said to transform covariantly. Superscripts denote quantities that transform the same way as coordinates x^i; these quantities are said to transform contravariantly (Sands, 1982*a*).

Equation (3.1.2.4) is in a form convenient for computer evaluation, with indices i and j taking successively all values from 1 to 3. The matrix form of (3.1.2.4) is useful both for symbolic manipulation and for computation,

$$\mathbf{u} \cdot \mathbf{v} = \boldsymbol{u}^T \boldsymbol{g} \boldsymbol{v}, \tag{3.1.2.6}$$

where the superscript italic T following a matrix symbol indicates a transpose. Written out in full, (3.1.2.6) is

$$\mathbf{u} \cdot \mathbf{v} = (u^1 u^2 u^3) \begin{pmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{pmatrix} \begin{pmatrix} v^1 \\ v^2 \\ v^3 \end{pmatrix}. \tag{3.1.2.7}$$

If $\boldsymbol{u}$ is the column vector with components u^1, u^2, u^3, $\boldsymbol{u}^T$ is the corresponding row vector shown in (3.1.2.7).

3.1.3. Length of a vector

By (3.1.2.1), the scalar product of a vector with itself is

$$\mathbf{v} \cdot \mathbf{v} = (v)^2. \tag{3.1.3.1}$$

The length of **v** is, therefore, given by

$$v = (v^i v^j g_{ij})^{1/2}. \tag{3.1.3.2}$$

Computation of lengths in a generalized rectilinear coordinate system is thus simply a matter of evaluating the double summation $v^i v^j g_{ij}$ and taking the square root.

3.1.4. Angle between two vectors

By (3.1.2.1) and (3.1.2.4), the angle φ between vectors **u** and **v** is given by

$$\varphi = \cos^{-1}[u^i v^j g_{ij}/(uv)]. \tag{3.1.4.1}$$

An even more concise expression of equations such as (3.1.4.1) is possible by making use of the ability of the metric tensor $\boldsymbol{g}$ to convert components from contravariant to covariant (Sands, 1982*a*). Thus,

$$v_i = g_{ij} v^j, \quad u_j = g_{ij} u^i, \tag{3.1.4.2}$$

and (3.1.2.4) may be written succinctly as

$$\mathbf{u} \cdot \mathbf{v} = u^i v_i \tag{3.1.4.3}$$

Copyright © 2010 International Union of Crystallography

or

$$\mathbf{u} \cdot \mathbf{v} = u_i v^i. \tag{3.1.4.4}$$

With this notation, the angle calculation of (3.1.4.1) becomes

$$\varphi = \cos^{-1}[u^i v_i/(uv)] = \cos^{-1}[u_i v^i/(uv)]. \tag{3.1.4.5}$$

The summations in (3.1.4.3), (3.1.4.4) and (3.1.4.5) include only three terms, and are thus equivalent in numerical effort to the computation in a Cartesian system, in which the metric tensor is represented by the unit matrix and there is no numerical distinction between covariant components and contravariant components.

Appreciation of the elegance of tensor formulations may be enhanced by noting that corresponding to the metric tensor $\boldsymbol{g}$ with components g_{ij} there is a contravariant metric tensor $\boldsymbol{g}^*$ with components

$$g^{ij} = \mathbf{a}^i \cdot \mathbf{a}^j. \tag{3.1.4.6}$$

The $\mathbf{a}^i$ are contravariant basis vectors, known to crystallographers as reciprocal axes. Expressions parallel to (3.1.4.2) may be written, in which $\boldsymbol{g}^*$ plays the role of converting covariant components to contravariant components. These tensors thus express mathematically the crystallographic notions of crystal space and reciprocal space [see Chapter 1.1 and Sands (1982*a*)].

3.1.5. Vector product

The scalar product defined in Section 3.1.2 is one multiplicative operation of two vectors that may be defined; another is the vector product, which is denoted as $\mathbf{u} \wedge \mathbf{v}$ (or $\mathbf{u} \times \mathbf{v}$ or $[\mathbf{uv}]$). The vector product of vectors $\mathbf{u}$ and $\mathbf{v}$ is defined as a vector of length $uv \sin\varphi$, where φ is the angle between the vectors, and of direction perpendicular to both $\mathbf{u}$ and $\mathbf{v}$ in the sense that $\mathbf{u}$, $\mathbf{v}$ and $\mathbf{u} \wedge \mathbf{v}$ form a right-handed system; $\mathbf{u} \wedge \mathbf{v}$ is generated by rotating $\mathbf{u}$ into $\mathbf{v}$ and advancing in the direction of a right-handed screw. The magnitude of $\mathbf{u} \wedge \mathbf{v}$, given by

$$|\mathbf{u} \wedge \mathbf{v}| = uv \sin\varphi \tag{3.1.5.1}$$

is equal to the area of the parallelogram defined by $\mathbf{u}$ and $\mathbf{v}$.

It follows from the definition that

$$\mathbf{u} \wedge \mathbf{v} = -\mathbf{v} \wedge \mathbf{u}. \tag{3.1.5.2}$$

3.1.6. Permutation tensors

Many relationships involving vector products may be expressed compactly and conveniently in terms of the permutation tensors, defined as

$$\varepsilon_{ijk} = \mathbf{a}_i \cdot \mathbf{a}_j \wedge \mathbf{a}_k \tag{3.1.6.1}$$

$$\varepsilon^{ijk} = \mathbf{a}^i \cdot \mathbf{a}^j \wedge \mathbf{a}^k. \tag{3.1.6.2}$$

Since $\mathbf{a}_i \cdot \mathbf{a}_j \wedge \mathbf{a}_k$ represents the volume of the parallelepiped defined by vectors $\mathbf{a}_i$, $\mathbf{a}_j$, $\mathbf{a}_k$, it follows that ε_{ijk} vanishes if any two indices are equal to each other. The same argument applies, of course, to ε^{ijk}. That is,

$$\varepsilon_{ijk} = 0, \quad \varepsilon^{ijk} = 0, \quad \text{if } j = i \text{ or } k = i \text{ or } k = j. \tag{3.1.6.3}$$

If the indices are all different,

$$\varepsilon_{ijk} = PV, \quad \varepsilon^{ijk} = PV^* \tag{3.1.6.4}$$

for even permutations of *ijk* (123, 231, or 312), and

$$\varepsilon_{ijk} = -PV, \quad \varepsilon^{ijk} = -PV^* \tag{3.1.6.5}$$

for odd permutations (132, 213, or 321). Here, $P = +1$ for right-handed axes, $P = -1$ for left-handed axes, V is the unit-cell volume, and $V^* = 1/V$ is the volume of the reciprocal cell defined by the reciprocal basis vectors $\mathbf{a}^i$, $\mathbf{a}^j$, $\mathbf{a}^k$.

A discussion of the properties of the permutation tensors may be found in Sands (1982*a*). In right-handed Cartesian systems, where $P = 1$, and $V = V^* = 1$, the permutation tensors are equivalent to the permutation symbols denoted by e_{ijk}.

3.1.7. Components of vector product

As is shown in Sands (1982*a*), the components of the vector product $\mathbf{u} \wedge \mathbf{v}$ are given by

$$\mathbf{u} \wedge \mathbf{v} = \varepsilon_{ijk} u^i v^j \mathbf{a}^k, \tag{3.1.7.1}$$

where again $\mathbf{a}^k$ is a reciprocal basis vector (some writers use $\mathbf{a}^*$, $\mathbf{b}^*$, $\mathbf{c}^*$ to represent the reciprocal axes). A special case of (3.1.7.1) is

$$\mathbf{a}_i \wedge \mathbf{a}_j = \varepsilon_{ijk} \mathbf{a}^k, \tag{3.1.7.2}$$

which may be taken as a defining equation for the reciprocal basis vectors. Similarly,

$$\mathbf{a}^i \wedge \mathbf{a}^j = \varepsilon^{ijk} \mathbf{a}_k, \tag{3.1.7.3}$$

which completes the characterization of the dual vector system with basis vectors $\mathbf{a}_i$ and $\mathbf{a}^j$ obeying

$$\mathbf{a}_i \cdot \mathbf{a}^j = \delta_i^j. \tag{3.1.7.4}$$

In (3.1.7.4), δ_i^j is the Kronecker delta, which equals 1 if $i = j$, 0 if $i \neq j$. The relationships between these quantities are explored at some length in Sands (1982*a*).

3.1.8. Some vector relationships

The results developed above lead to several useful relationships between vectors; for derivations, see Sands (1982*a*).

3.1.8.1. Triple vector product

$$\mathbf{u} \wedge (\mathbf{v} \wedge \mathbf{w}) = (\mathbf{u} \cdot \mathbf{w})\mathbf{v} - (\mathbf{u} \cdot \mathbf{v})\mathbf{w} \tag{3.1.8.1}$$

$$(\mathbf{u} \wedge \mathbf{v}) \wedge \mathbf{w} = -(\mathbf{v} \cdot \mathbf{w})\mathbf{u} + (\mathbf{u} \cdot \mathbf{w})\mathbf{v}. \tag{3.1.8.2}$$

3.1.8.2. Scalar product of vector products

$$(\mathbf{u} \wedge \mathbf{v}) \cdot (\mathbf{w} \wedge \mathbf{z}) = (\mathbf{u} \cdot \mathbf{w})(\mathbf{v} \cdot \mathbf{z}) - (\mathbf{u} \cdot \mathbf{z})(\mathbf{v} \cdot \mathbf{w}). \quad (3.1.8.3)$$

A derivation of this result may be found also in Shmueli (1974).

3.1.8.3. Vector product of vector products

$$(\mathbf{u} \wedge \mathbf{v}) \wedge (\mathbf{w} \wedge \mathbf{z}) = (\mathbf{u} \cdot \mathbf{w} \wedge \mathbf{z})\mathbf{v} - (\mathbf{v} \cdot \mathbf{w} \wedge \mathbf{z})\mathbf{u} \quad (3.1.8.4)$$

$$(\mathbf{u} \wedge \mathbf{v}) \wedge (\mathbf{w} \wedge \mathbf{z}) = (\mathbf{u} \cdot \mathbf{v} \wedge \mathbf{z})\mathbf{w} - (\mathbf{u} \cdot \mathbf{v} \wedge \mathbf{w})\mathbf{z}. \quad (3.1.8.5)$$

3.1.9. Planes

Among several ways of characterizing a plane in a general rectilinear coordinate system is a description in terms of the coordinates of three non-collinear points that lie in the plane. If the points are U, V and W, lying at the ends of vectors **u**, **v** and **w**, the vectors $\mathbf{u} - \mathbf{v}$, $\mathbf{v} - \mathbf{w}$ and $\mathbf{w} - \mathbf{u}$ are in the plane. The vector

$$\mathbf{z} = (\mathbf{u} - \mathbf{v}) \wedge (\mathbf{v} - \mathbf{w}) \quad (3.1.9.1)$$

is normal to the plane. Expansion of (3.1.9.1) yields

$$\mathbf{z} = (\mathbf{u} \wedge \mathbf{v}) + (\mathbf{v} \wedge \mathbf{w}) + (\mathbf{w} \wedge \mathbf{u}). \quad (3.1.9.2)$$

Making use of (3.1.7.1),

$$\mathbf{z} = \varepsilon_{ijk}(u^j v^k + v^j w^k + w^j u^k)\mathbf{a}^i. \quad (3.1.9.3)$$

If now **x** is any vector from the origin to the plane, $\mathbf{x} - \mathbf{u}$ is in the plane, and

$$(\mathbf{x} - \mathbf{u}) \cdot \mathbf{z} = 0. \quad (3.1.9.4)$$

From (3.1.9.2),

$$\mathbf{u} \cdot \mathbf{z} = \mathbf{u} \cdot \mathbf{v} \wedge \mathbf{w}. \quad (3.1.9.5)$$

Rearrangement of (3.1.9.4) with $\mathbf{x} \cdot \mathbf{z}$ on the left and $\mathbf{u} \cdot \mathbf{z}$ on the right, and using (3.1.9.3) for **z** on the left leads to

$$\varepsilon_{ijk}x^i(u^j v^k + v^j w^k + w^j u^k) = \varepsilon_{ijk}u^i v^j w^k. \quad (3.1.9.6)$$

If, in particular, the points are on the coordinate axes, their designations are $[u^1, 0, 0]$, $[0, v^2, 0]$ and $[0, 0, w^3]$, and (3.1.9.6) becomes

$$x^1/u^1 + x^2/v^2 + x^3/w^3 = 1, \quad (3.1.9.7)$$

which may be written

$$x^i h_i = 1 \quad (3.1.9.8)$$

or

$$\mathbf{x} \cdot \mathbf{h} = 1 \quad (3.1.9.9)$$

in which the vector **h** has coordinates

$$\mathbf{h} = (1/u^1, 1/v^2, 1/w^3). \quad (3.1.9.10)$$

That is, the covariant components of **h** are given by the reciprocals of the intercepts of the plane on the axes. The vector **h** is normal to the plane it describes (Sands, 1982*a*) and the length of **h** is the reciprocal of the distance d of the plane from the origin; *i.e.*,

$$h = 1/d. \quad (3.1.9.11)$$

If the indices h_i are relatively prime integers, the theory of numbers tells us that the Diophantine equation (3.1.9.8) has solutions x^i that are integers. Points whose contravariant components are integers are lattice points, and such a plane passes through an infinite number of lattice points and is called a *lattice plane*. Thus, the h_i for lattice planes are the familiar Miller indices of crystallography.

Calculations involving planes become quite manageable when the normal vector **h** is introduced. Thus, the distance l from a point P with coordinates p^i to a plane characterized by **h** is

$$l = (1 - \mathbf{p} \cdot \mathbf{h})/h, \quad (3.1.9.12)$$

where a negative sign indicates that the point is on the opposite side of the plane from the origin.

The dihedral angle τ between planes with normals **h** and $\mathbf{h}'$ is

$$\tau = \cos^{-1}[-\mathbf{h} \cdot \mathbf{h}'/(hh')]. \quad (3.1.9.13)$$

A variation of (3.1.9.13) expresses τ in terms of vector **u** in the first plane, vector **w** in the second plane, and vector **v**, the intersection of the planes, as (Shmueli, 1974)

$$\tau = \cos^{-1}[(\mathbf{u} \wedge \mathbf{v}) \cdot (\mathbf{v} \wedge \mathbf{w})/|\mathbf{u} \wedge \mathbf{v}||\mathbf{v} \wedge \mathbf{w}|]. \quad (3.1.9.14)$$

A similar calculation gives angles of torsion. Let $\mathbf{t}_h$ and $\mathbf{u}_h$ be, respectively, the projections of vectors **t** and **u** onto the plane with normal **h**.

$$\mathbf{t}_h = \mathbf{t} - (\mathbf{t} \cdot \mathbf{h})\mathbf{h}/h^2 \quad (3.1.9.15)$$

$$\mathbf{u}_h = \mathbf{u} - (\mathbf{u} \cdot \mathbf{h})\mathbf{h}/h^2. \quad (3.1.9.16)$$

The angle between $\mathbf{t}_h$ and $\mathbf{u}_h$ represents a torsion about **h** (Sands, 1982*b*). Another approach to the torsion angle, which gives equivalent results (Shmueli, 1974), is to compute the angle between $\mathbf{t} \wedge \mathbf{h}$ and $\mathbf{u} \wedge \mathbf{h}$ using (3.1.8.3).

3.1.10. Variance–covariance matrices

Refinement of a crystal structure yields both the parameters that describe the structure and estimates of the uncertainties of those parameters. Refinement by the method of least squares minimizes a weighted sum of squares of residuals. In the matrix notation of Hamilton's classic book (Hamilton, 1964), values of

the m parameters to be determined are expressed by the $m \times 1$ column vector $\boldsymbol{X}$ given by

$$\boldsymbol{X} = (\boldsymbol{A}^T\boldsymbol{P}\boldsymbol{A})^{-1}\boldsymbol{A}^T\boldsymbol{P}\boldsymbol{F}, \tag{3.1.10.1}$$

where $\boldsymbol{F}$ is an $n \times 1$ matrix representing the observations (structure factors or squares of structure factors), $\boldsymbol{P}$ is an $n \times n$ weight matrix that is proportional to the variance–covariance matrix of the observed $\boldsymbol{F}$, $\boldsymbol{A}$ is an $n \times m$ design matrix consisting of the derivatives of each element of $\boldsymbol{F}$ with respect to each of the parameters and $\boldsymbol{A}^T$ is the transpose of $\boldsymbol{A}$. The variance–covariance matrix of the parameters is then given by

$$\boldsymbol{M} = \boldsymbol{V}^T\boldsymbol{P}\boldsymbol{V}(\boldsymbol{A}^T\boldsymbol{P}\boldsymbol{A})^{-1}/(n-m). \tag{3.1.10.2}$$

Here, $\boldsymbol{V}$ is the $n \times 1$ matrix of residuals, consisting of the differences between the observed and calculated values of the elements of $\boldsymbol{F}$. Since $\boldsymbol{V}^T\boldsymbol{P}\boldsymbol{V}/(n-m)$ is just a single number, $\boldsymbol{M}$ is proportional to the inverse least-squares matrix $(\boldsymbol{A}^T\boldsymbol{P}\boldsymbol{A})^{-1}$.

Once the variance–covariance matrix of the parameters is known, the variances and covariances of any quantities derived from these parameters can be computed. The variance of a single function f is given by

$$\sigma^2(f) = \frac{\partial f}{\partial x^i}\frac{\partial f}{\partial x^j}\mathrm{cov}(x^i, x^j), \tag{3.1.10.3}$$

where, as usual, we are using the summation convention and summing over all parameters included in f. A generalization of (3.1.10.3) for two functions is

$$\mathrm{cov}(f_1, f_2) = \frac{\partial f_1}{\partial x^i}\frac{\partial f_2}{\partial x^j}\mathrm{cov}(x^i, x^j). \tag{3.1.10.4}$$

[The covariance of two quantities is, of course, just the variance if the two quantities are the same. For an elementary discussion of statistical covariance and correlation, see Sands (1977).] Equation (3.1.10.4) may now be extended to any number of functions (Sands, 1966); the $k \times k$ variance–covariance matrix $\boldsymbol{C}$ of k functions of m parameters is given in terms of the $m \times m$ variance–covariance matrix of the parameters by

$$\boldsymbol{C} = \boldsymbol{D}\boldsymbol{M}\boldsymbol{D}^T, \tag{3.1.10.5}$$

in which the ijth element of the $k \times m$ matrix $\boldsymbol{D}$ is the derivative of function f_i with respect to parameter j. Element C_{II} (no summation implied over I) is the variance of function f_I, and C_{IJ} is the covariance of functions f_I and f_J.

The calculation of $\boldsymbol{C}$ must, of course, include the contributions of all sources of error, so $\boldsymbol{M}$ in (3.1.10.5) should include the variances and covariances of the unit-cell dimensions and of any other relevant parameters with non-negligible uncertainties.

It may be easier, in some cases, to carry out calculations of variances and covariances in steps. For example, the variance–covariance matrix of a set of distances may be computed and then other quantities may be determined as functions of the distances. It is imperative that all nonvanishing covariances be included in every stage of the calculation; only in special cases are the covariances negligible, and often they are large enough to affect the results seriously (Sands, 1977).

These principles may be used to explore the effects of symmetry or of transformations on the variance–covariance matrices of atomic parameters and derived quantities. Using the notation of Sands (1966), with x_A^i and x_B^i the positional parameters i of atoms A and B, respectively, we define $\boldsymbol{M}_{AA}$, $\boldsymbol{M}_{AB}$, $\boldsymbol{M}_{BA}$ and $\boldsymbol{M}_{BB}$ as 3×3 matrices with ijth elements $\mathrm{cov}(x_A^i, x_A^j)$, $\mathrm{cov}(x_A^i, x_B^j)$, $\mathrm{cov}(x_B^i, x_A^j)$ and $\mathrm{cov}(x_B^i, x_B^j)$, respectively. If atom B' is generated from atom B by symmetry operator $\boldsymbol{S}$, such that

$$\mathbf{x}_{B'} = \boldsymbol{S}\mathbf{x}_B \tag{3.1.10.6}$$

$$x_{B'}^i = S_j^i x_B^j, \tag{3.1.10.7}$$

it is shown in Sands (1966) that the variance–covariance matrices involving atom B' are

$$\boldsymbol{M}_{AB'} = \boldsymbol{M}_{AB}\boldsymbol{S}^T \tag{3.1.10.8}$$

$$\boldsymbol{M}_{B'A} = \boldsymbol{S}\boldsymbol{M}_{BA} \tag{3.1.10.9}$$

$$\boldsymbol{M}_{B'B'} = \boldsymbol{S}\boldsymbol{M}_{BB}\boldsymbol{S}^T. \tag{3.1.10.10}$$

If symmetry operator $\boldsymbol{S}$ is applied to both atoms A and B to generate atoms A' and B', the corresponding matrices may be expressed by the matrix equation

$$\begin{pmatrix} \boldsymbol{M}_{A'A'} & \boldsymbol{M}_{A'B'} \\ \boldsymbol{M}_{B'A'} & \boldsymbol{M}_{B'B'} \end{pmatrix} = \begin{pmatrix} \boldsymbol{S}\boldsymbol{M}_{AA}\boldsymbol{S}^T & \boldsymbol{S}\boldsymbol{M}_{AB}\boldsymbol{S}^T \\ \boldsymbol{S}\boldsymbol{M}_{BA}\boldsymbol{S}^T & \boldsymbol{S}\boldsymbol{M}_{BB}\boldsymbol{S}^T \end{pmatrix}. \tag{3.1.10.11}$$

If $\boldsymbol{G}$ is a matrix that transforms to a new set of axes,

$$\mathbf{a}' = \boldsymbol{G}\mathbf{a}, \tag{3.1.10.12}$$

the transformed variance–covariance matrix of the atomic parameters is

$$\boldsymbol{M}' = (\boldsymbol{G}^{\boldsymbol{T}})^{-1}\boldsymbol{M}\boldsymbol{G}^{-1}. \tag{3.1.10.13}$$

To apply these formulae to calculations of the errors and covariances of interatomic distances and angles, consider the triangle of atoms A, B, C with edges $l_1 = AB$, $l_2 = BC$, $l_3 = CA$, and angles $\alpha_1, \alpha_2, \alpha_3$ at A, B, C, respectively. If the atoms are not related by symmetry,

$$\sigma^2(l_1) = \boldsymbol{l}_1^T\mathbf{g}(\boldsymbol{M}_{AA} - \boldsymbol{M}_{AB} - \boldsymbol{M}_{BA} + \boldsymbol{M}_{BB})\mathbf{g}\boldsymbol{l}_1/l_1^2 \tag{3.1.10.14}$$

$$\mathrm{cov}(l_1, l_2) = \boldsymbol{l}_1^T\mathbf{g}(\boldsymbol{M}_{AB} - \boldsymbol{M}_{AC} - \boldsymbol{M}_{BB} + \boldsymbol{M}_{BC})\mathbf{g}\boldsymbol{l}_2/l_1 l_2. \tag{3.1.10.15}$$

If atom B is generated from atom A by symmetry matrix $\boldsymbol{S}$, the results, as derived in Sands (1966), are

$$\sigma^2(l_1) = \boldsymbol{l}_1^T\mathbf{g}(\boldsymbol{M}_{AA} - \boldsymbol{S}\boldsymbol{M}_{AA} - \boldsymbol{M}_{AA}\boldsymbol{S}^T + \boldsymbol{S}\boldsymbol{M}_{AA}\boldsymbol{S}^T)\mathbf{g}\boldsymbol{l}_1/l_1^2 \quad (3.1.10.16)$$

$$\sigma^2(l_2) = \boldsymbol{l}_2^T\mathbf{g}(\boldsymbol{S}\boldsymbol{M}_{AA}\boldsymbol{S}^T - \boldsymbol{M}_{AC}\boldsymbol{S}^T - \boldsymbol{S}\boldsymbol{M}_{AC} + \boldsymbol{M}_{CC})\mathbf{g}\boldsymbol{l}_2/l_2^2 \quad (3.1.10.17)$$

$$\sigma^2(l_3) = \boldsymbol{l}_3^T\mathbf{g}(\boldsymbol{M}_{AA} - \boldsymbol{M}_{AC} - \boldsymbol{M}_{CA} + \boldsymbol{M}_{CC})\mathbf{g}\boldsymbol{l}_3/l_3^2 \quad (3.1.10.18)$$

$$\mathrm{cov}(l_1, l_2) = \boldsymbol{l}_1^T\mathbf{g}(\boldsymbol{M}_{AA}\boldsymbol{S}^T - \boldsymbol{S}\boldsymbol{M}_{AA}\boldsymbol{S}^T - \boldsymbol{M}_{AC} + \boldsymbol{S}\boldsymbol{M}_{AC})\mathbf{g}\boldsymbol{l}_2/l_1l_2 \quad (3.1.10.19)$$

$$\mathrm{cov}(l_1, l_3) = \boldsymbol{l}_1^T\mathbf{g}(-\boldsymbol{M}_{AA} + \boldsymbol{S}\boldsymbol{M}_{AA} + \boldsymbol{M}_{AC} - \boldsymbol{S}\boldsymbol{M}_{AC})\mathbf{g}\boldsymbol{l}_3/l_1l_3 \quad (3.1.10.20)$$

$$\mathrm{cov}(l_2, l_3) = \boldsymbol{l}_2^T\mathbf{g}(-\boldsymbol{S}\boldsymbol{M}_{AA} + \boldsymbol{M}_{CA} + \boldsymbol{S}\boldsymbol{M}_{AC} - \boldsymbol{M}_{CC})\mathbf{g}\boldsymbol{l}_3/l_2l_3. \quad (3.1.10.21)$$

In equations (3.1.10.14)–(3.1.10.21), $\boldsymbol{l}_i$ is a column vector with components the differences of the coordinates of the atoms connected by the vector. Representative formulae involving the angles α_1, α_2, α_3 are

$$\sigma^2(\alpha_1) = [\cos^2\alpha_2\sigma^2(l_1) - 2\cos\alpha_2\ \mathrm{cov}(l_1, l_2) + 2\cos\alpha_2\cos\alpha_3\ \mathrm{cov}(l_1, l_3) + \sigma^2(l_2) - 2\cos\alpha_3\ \mathrm{cov}(l_2, l_3) + \cos^2\alpha_3\sigma^2(l_3)](l_2/l_1l_3\sin\alpha_1)^2 \quad (3.1.10.22)$$

$$\mathrm{cov}(\alpha_1, \alpha_2) = [\cos\alpha_1\cos\alpha_2\sigma^2(l_1) + (\cos\alpha_2\cos\alpha_3 - \cos\alpha_1)\ \mathrm{cov}(l_1, l_2) + (\cos\alpha_1\cos\alpha_3 - \cos\alpha_2)\ \mathrm{cov}(l_1, l_3) - \cos\alpha_3\sigma^2(l_2) + (1 + \cos^2\alpha_3)\ \mathrm{cov}(l_2, l_3) - \cos\alpha_3\sigma^2(l_3)]/(l_1^2\sin\alpha_1\sin\alpha_2) \quad (3.1.10.23)$$

$$\mathrm{cov}(\alpha_1, l_1) = [-\cos\alpha_2\sigma^2(l_1) + \mathrm{cov}(l_1, l_2) - \cos\alpha_3\ \mathrm{cov}(l_1, l_3)](l_2/l_1l_3\sin\alpha_1) \quad (3.1.10.24)$$

$$\mathrm{cov}(\alpha_1, l_2) = [-\cos\alpha_2\ \mathrm{cov}(l_1, l_2) + \sigma^2(l_2) - \cos\alpha_3\ \mathrm{cov}(l_2, l_3)](l_2/l_1l_3\sin\alpha_1). \quad (3.1.10.25)$$

If any of the angles approach 0 or 180°, the denominators in (3.1.10.22)–(3.1.10.25) will become very small, necessitating high-precision arithmetic. Indeterminacies resulting from special relationships between atomic positions may require rederivation of the equations for variances and covariances, to take the relationships into account explicitly and avoid the indeterminacies. A true symmetry condition requiring, for example, a linear bond should cause little problem, and the corresponding variance will be zero. It is the indeterminacies not originating from crystal symmetry that demand caution, in recognizing them and in coping with them correctly.

A general expression for the variance of a dihedral angle, in terms of the variances and covariances of the coordinates of the four atoms, is (Shmueli, 1974)

$$\sigma^2(\tau) = \sum_k\sum_n \frac{\partial\tau}{\partial x^i_{(k)}}\frac{\partial\tau}{\partial x^j_{(n)}}\mathrm{cov}[x^i_{(k)}, x^j_{(n)}], \quad (3.1.10.26)$$

where, in addition to the usual tensor summation over i and j from 1 to 3, summation must be carried out over the four atoms (*i.e.*, k and n vary from 1 to 4). Special cases of (3.1.10.26), corresponding to various levels of approximation of diagonal matrices and isotropic errors, are given in Shmueli (1974). Formulae in dyadic notation are given in Waser (1973) for the variances and covariances of dihedral angles, of best planes, of torsion angles, and of other molecular parameters.

3.1.11. Mean values

The weighted mean of a set of quantities X_i is

$$\langle X\rangle = \sum w_iX_i/\sum w_i, \quad (3.1.11.1)$$

where the weights are typically chosen to minimize the variance of $\langle X\rangle$. The variance may be computed from the variance–covariance matrix $\boldsymbol{M}$ of the X_i by

$$\sigma^2(\langle X\rangle) = \mathbf{w}^T\boldsymbol{M}\mathbf{w}/(\sum w_i)^2. \quad (3.1.11.2)$$

Minimization of $\sigma^2(\langle X\rangle)$ leads to weights given by

$$\mathbf{w} = \boldsymbol{M}^{-1}\mathbf{v}, \quad (3.1.11.3)$$

where the components of vector $\mathbf{v}$ are all equal ($v_i = v_j$ for all i and j); since (3.1.11.1) and (3.1.11.2) require only relative weights, we can assign $v_i = 1$ for all i. Placing these weights in (3.1.11.2) yields

$$\sigma^2(\langle X\rangle) = 1/\sum w_i. \quad (3.1.11.4)$$

For the case of uncorrelated X_i, the weights are inversely proportional to the corresponding variances

$$w_i = 1/\sigma^2(X_i). \quad (3.1.11.5)$$

For the case of two correlated variables,

$$w_i = 1/[\sigma^2(X_i) - \mathrm{cov}(X_1, X_2)]. \quad (3.1.11.6)$$

Derivation and discussion of these equations may be found in Sands (1966, 1982*b*).

The presence of systematic errors in the experimental data often results in these formulae producing estimates of the standard uncertainties of molecular dimensions that are too small; it has been suggested that such error estimates should be multiplied by 1.5 to make them more realistic (Taylor & Kennard, 1983). It is essential also that averages be computed only of similar quantities, and interatomic distances corresponding to different bond orders or different environments may not represent the same physical quantities; that is, there are reasons for the discrepancies, and averaging may obscure important information. Another source of error in molecular geometry parameters determined from crystallographic measurements is thermal motion, and distances should be corrected for such effects before making comparisons (Busing & Levy, 1964; Johnson, 1970, 1980).

A discussion of the appropriateness of weighted and unweighted means may be found in Taylor & Kennard (1985), which suggests that the unweighted mean might even be preferable if environmental effects are large.

3.1.12. Computation

It has been mentioned that the tensor formulation used in this chapter is particularly amenable to machine computation. As a simple illustration of this point, the following Fortran program will compute the lengths of vectors **X** and **Y** and the angle between them.

```
      DIMENSION X(3),Y(3),G(3,3),SUM(3)
      READ (5,10)(X(I),I = 1,3)
      READ (5,10)(Y(I),I = 1,3)
      READ (5,10)((G(I,J),J = 1,3),I = 1,3)
10    FORMAT (3F10.5)
      DO 20 I = 1,3
20    SUM(I) = 0
      DO 30 I = 1,3
      DO 30 J = 1,3
      SUM(1) = SUM(1) + X(I) * X(J) * G(I,J)
      SUM(2) = SUM(2) + Y(I) * Y(J) * G(I,J)
      SUM(3) = SUM(3) + X(I) * Y(J) * G(I,J)
30    CONTINUE
      DIST1 = SQRT(SUM(1))
      DIST2 = SQRT(SUM(2))
      ANGLE = 57.296 * ACOS(SUM(3)/(DIST1 * DIST2))
      WRITE (6,10) DIST1,DIST2,ANGLE
      END
```

3.2. The least-squares plane

By R. E. Marsh and V. Schomaker†

3.2.1. Introduction

By way of introduction, we remark that in earlier days of crystal structure analysis, before the advent of high-speed computers and routine three-dimensional analyses, molecular planarity was often assumed so that atom coordinates along the direction of projection could be estimated from two-dimensional data [see, *e.g.*, Robertson (1948)]. Today, the usual aim in deriving the coefficients of a plane is to investigate the degree of planarity of a group of atoms as found in a full, three-dimensional structure determination. We further note that, for such purposes, a crystallographer will often be served just as well by establishing the plane in an almost arbitrary fashion as by resorting to the most elaborate, nit-picking and pretentious least-squares treatment. The approximate plane and the associated perpendicular distances of the atoms from it will be all he needs as scaffolding for his geometrical and structural imagination; reasonable common sense will take the place of explicit attention to error estimates.

Nevertheless, we think it appropriate to lay out in some detail the derivation of the 'best' plane, in a least-squares sense, through a group of atoms and of the standard uncertainties associated with this plane. We see two cases: (1) The weights of the atoms in question are considered to be isotropic and uncorrelated (*i.e.* the weight matrix for the positions of all the atoms is diagonal, when written in terms of Cartesian axes, and for each atom the three diagonal elements are equal). In such cases the weights may have little or nothing to do with estimates of random error in the atom positions (they may have been assigned merely for convenience or convention), and, therefore, no one should feel that the treatment is proper in respect to the theory of errors. Nevertheless, it may be desired to incorporate the error estimates (variances) of the atom positions into the *results* of such calculations, whereupon these variances (which may be anisotropic, with correlation between atoms) need to be propagated. In this case the distinction between *weights* (or their inverses) and *variances* must be kept very clear. (2) The weights are anisotropic and are presumably derived from a variance–covariance matrix, which may include correlation terms between different atoms; the objective is to achieve a truly proper Gaussian least-squares result.

3.2.2. Least-squares plane based on uncorrelated, isotropic weights

This is surely the most common situation; it is not often that one will wish to take the trouble, or be presumptive enough, to assign anisotropic or correlated weights to the various atoms. And one will sometimes, perhaps even often, not be genuinely interested in the hypothesis that the atoms actually are rigorously coplanar; for instance, one might be interested in examining the best plane through such a patently nonplanar molecule as cyclohexane. Moreover, the calculation is simple enough, given the availability of computers and programs, as to be a practical realization of the off-the-cuff treatment suggested in our opening paragraph. The problem of deriving the plane's coefficients is intrinsically nonlinear in the way first discussed by Schomaker *et al.* (1959; SWMB). Any formulation other than as an eigenvalue–eigenvector problem (SWMB), as far as we can tell, will sometimes go astray. As to the propagation of errors, numerous treatments have been given, but none that we have seen is altogether satisfactory.

We refer all vectors and matrices to Cartesian axes, because that is the most convenient in calculation. However, a more elegant formulation can be written in terms of general axes [*e.g.*, as in Shmueli (1981)].

The notation is troublesome. Indices are needed for atom number and Cartesian direction, and the exponent 2 is needed as well, which is difficult if there are superscript indices. The best way seems to be to write all the indices as subscripts and distinguish among them by context – $i, j, 1, 2, 3$ for directions; k, l, p (and sometimes $K, \ldots$) for atoms. In any case, *atom* first then *direction* if there are two subscripts; *direction*, if only one index for a vector component, but *atom* (in this section at least) if for a weight or a vector. And σ_{d_1}, *e.g.*, for the standard uncertainty of the distance of atom 1 from a plane. For simplicity in practice, we use Cartesian coordinates throughout.

The first task is to find the plane, which we write as

$$0 = \mathbf{m} \cdot \mathbf{r} - d \equiv \mathsf{m}^T\mathsf{r} - d,$$

where $\mathbf{r}$ is here the vector from the origin to any point on the plane (but usually represents the measured position of an atom), $\mathbf{m}$ is a unit vector parallel to the normal from the origin to the plane, d is the length of the normal, and m and r are the column representations of $\mathbf{m}$ and $\mathbf{r}$. The least-squares condition is to find the stationary values of $S \equiv [w_k(\mathsf{m}^T\mathsf{r}_k - d)^2]$ subject to $\mathsf{m}^T\mathsf{m} = 1$, with r_k, $k = 1, \ldots, n$, the vector from the origin to atom k and with weights, w_k, isotropic and without interatomic correlations for the n atoms of the plane. We also write S as $S \equiv [w(\mathsf{m}^T\mathsf{r} - d)^2]$, the subscript for atom number being implicit in the Gaussian summations ($[\ldots]$) over all atoms, as it is also in the angle-bracket notation for the weighted average over all atoms, for example in $\langle\mathsf{r}\rangle$ – the weighted centroid of the groups of atoms – just below.

First solve for d, the origin-to-plane distance.

$$0 = -\frac{1}{2}\frac{\partial S}{\partial d} = [w(\mathsf{m}^T\mathsf{r} - d)] = 0,$$
$$d = [w\mathsf{m}^T\mathsf{r}]/[w] \equiv \mathsf{m}^T\langle\mathsf{r}\rangle.$$

Then

$$S \equiv [w(\mathsf{m}^T\mathsf{r} - d)^2] = [w\{\mathsf{m}^T(\mathsf{r} - \langle\mathsf{r}\rangle)\}^2]$$
$$\equiv [w(\mathsf{m}^T\mathbf{s})^2] \equiv \mathsf{m}^T[w\mathsf{s}\mathsf{s}^T]\mathsf{m} \equiv \mathsf{m}^T\mathbf{A}\mathsf{m}.$$

Here $\mathbf{s}_k \equiv \mathsf{r}_k - \langle\mathsf{r}\rangle$ is the vector from the centroid to atom k. Then solve for $\mathbf{m}$. This is the eigenvalue problem – to diagonalize $\mathbf{A}$ (bear in mind that $\mathbf{A}_{ij}$ is just $[ws_is_j]$) by rotating the coordinate axes, *i.e.*, to find the 3×3 arrays $\mathbf{M}$ and $\mathbf{L}$, $\mathbf{L}$ diagonal, to satisfy

$$\mathbf{M}^T\mathbf{A}\mathbf{M} = \mathbf{L}, \qquad \mathbf{M}^T\mathbf{M} = \mathbf{I}.$$

$\mathbf{A}$ and $\mathbf{M}$ are symmetric; the columns m of $\mathbf{M}$ are the direction cosines of, and the diagonal elements of $\mathbf{L}$ are the sums of

† Deceased.

weighted squares of residuals from, the best, worst and intermediate planes, as discussed by SWMB.

3.2.2.1. Error propagation

Waser *et al.* (1973; WMC) carefully discussed how the random errors of measurement of the atom positions propagate into the derived quantities in the foregoing determination of a least-squares plane. This section presents an extension of their discussion. To begin, however, we first show how standard first-order perturbation theory conveniently describes the propagation of error into **M** and **L** when the positions r_k of the atoms are incremented by the amounts $\delta\mathsf{r}_k \equiv \xi_k$ and the corresponding quantities $\mathbf{s}_k \equiv \mathsf{r}_k - \langle\mathsf{r}\rangle$ (the vectors from the centroid to the atoms) by the amounts η_k, $(\mathbf{s} \rightarrow \mathbf{s} + \eta)$, $\eta_k \equiv \xi_k - \langle\xi\rangle$. (The need to account for the variation in position of the centroid, *i.e.* to distinguish between η_k and ξ_k, was overlooked by WMC.) The consequent increments in **A**, **M** and **L** are

$$\begin{aligned}\delta\mathbf{A} &= [w\eta\mathbf{s}^T] + [w\mathbf{s}\eta^T] \equiv \alpha,\\ \delta\mathbf{M} &= \mathbf{M}\mu,\\ \delta\mathbf{L} &\equiv \lambda.\end{aligned}$$

Here the columns of μ are expressed as linear combinations of the columns of **M**. Note also that both perturbations, μ and λ, which are the adjustments to the orientations and associated eigenvalues of the principal planes, will depend on the reduced coordinates **s** and the perturbing influences ξ by way of α, which in turn depends only on the reduced coordinates and the reduced shifts η_k. In contrast,

$$\delta\mathsf{d} = \delta(\mathsf{m}^T\langle\mathsf{r}\rangle) = (\delta\mathsf{m}^T)\langle\mathsf{r}\rangle + \mathsf{m}^T\langle\xi\rangle;$$

the change in the origin-to-plane distance for the plane defined by the column vectors **m** of **M**, depends on the $\langle\mathsf{r}\rangle$ and $\langle\xi\rangle$ directly as well as on the **s** and η by way of the $\delta\mathbf{m}$.

The first-order results arising from the standard conditions, $\mathbf{M}^T\mathbf{M} = \mathbf{I}$, **L** diagonal, and $\mathbf{M}^T\mathbf{A}\mathbf{M} = \mathbf{L}$, are

$$\mu^T + \mu = 0, \lambda \text{ diagonal},$$

and

$$\mu^T\mathbf{M}^T\mathbf{A}\mathbf{M} + \mathbf{M}^T\alpha\mathbf{M} + \mathbf{M}^T\mathbf{A}\mathbf{M}\mu = \mu^T\mathbf{L} + \mathbf{L}\mu + \mathbf{M}^T\alpha\mathbf{M} = \lambda.$$

Stated in terms of the matrix components λ_{ij} and μ_{ij}, the first condition is $\mu_{ij} = -\mu_{ji}$, hence $\mu_{ii} = 0$, $i, j = 1, 2, 3$, and the second is $\lambda_{ij} = 0$, $i \neq j$. With these results the third condition then reads

$$\begin{aligned}\lambda_{jj} &= (\mathbf{M}^T\alpha\mathbf{M})_{jj}, && j = 1, 2, 3\\ \mu_{ij} &= (\mathbf{M}^T\alpha\mathbf{M})_{ij}/(L_{jj} - L_{ii}), && i \neq j, \quad i, j = 1, 2, 3.\end{aligned}$$

All this is analogous to the usual first-order perturbation theory, as, for example, in elementary quantum mechanics.

Now rotate to the coordinates defined by WMC, with axes parallel to the original eigenvectors [$\mathbf{M} = \mathbf{I}$, $A_{ij} = L_{ij}\delta_{ij}$, $(\mathbf{M}^T\alpha\mathbf{M})_{ij} = \alpha_{ij}$], restrict attention to the best plane ($M_{13} \equiv m_1 = 0$, $M_{23} \equiv m_2 = 0$, $M_{33} \equiv m_3 = 1$), and define ε^T as $(\delta m_1, \delta m_2, \delta d_c)$, keeping in mind $\delta m_3 = \mu_{33} = 0$; d_c itself, the original plane-to-centroid distance, of course vanishes. One then finds

$$\begin{aligned}\delta m_i \equiv \varepsilon_i &= \alpha_{i3}/(L_{33} - L_{ii})\\ &= [w(s_i\eta_3 + s_3\eta_i)]/([ws_3^2] - [ws_i^2]), \quad i = 1, 2,\\ \delta d_c \equiv \varepsilon_3 &= [w\xi_3]/[w] \equiv \langle\xi_3\rangle, \qquad \xi_k \equiv \delta r_k,\end{aligned}$$

and also

$$\delta d = \varepsilon_1\langle r_1\rangle + \varepsilon_2\langle r_2\rangle + \varepsilon_3.$$

These results have simple interpretations. The changes in direction of the plane normal (the δm_i) are rotations, described by ε_1 and ε_2, in response to changes in moments acting against effective torsion force constants. For ε_2, for example, the contribution of atom k to the total relevant moment, about direction 1, is $-w_k s_{k3} s_{k2}$ ($w_k s_{k3}$ the 'force' and s_{k2} the lever arm), and its nominally first-order change has two parts, $-w_k s_{k2}\eta_3$ from the change in force and $-w_k s_{k3}\eta_2$ from the change in lever arm; the resisting torsion constant is $[ws_2^2] - [ws_3^2]$, which, reflection will show, is qualitatively reasonable if not quantitatively obvious. The perpendicular displacement of the plane from the original centroid $\langle r\rangle$ is ε_3, but there are two further contributions to δd, the change in distance from origin to plane along the plane normal, that arise from the two components of out-of-plane rotation of the plane about its centroid. Note that ε_3 is not given by $[w\eta_3]/[w] = [w(\xi_3 - \langle\xi_3\rangle)]/[w]$, which vanishes identically.

There is a further, somewhat delicate point: If the group of atoms is indeed essentially coplanar, the s_{k3} are of the same order of magnitude as the η_{ki}, unlike the s_{ki}, $i \neq 3$, which are in general about as big as the lateral extent of the group. It is then appropriate to drop all terms in η_i or ξ_i, $i \neq 3$, and, in the denominators, the terms in s_{k3}^2.

The covariances of the derived quantities (by *covariances* we mean here both variances and covariances) can now be written out rather compactly by extending the implicit designation of atom numbers to double sums, the first of each of two similar factors referring to the first atom index and the second to the second, *e.g.*, $\sum_{kl} ww(s_i s_j)\ldots \equiv \sum_{kl} w_k w_l (s_{ki} s_{ij})\ldots$. Note that the various covariances, *i.e.* the averages over the presumed population of random errors of replicated measurements, are indicated by overlines, angle brackets having been pre-empted for averages over sets of atoms.

$$\begin{aligned}\operatorname{cov}(m_i, m_j) &\equiv \overline{\varepsilon_i\varepsilon_j}\\ &= \frac{\sum_{kl} ww(s_i s_j\overline{\eta_3\eta_3} + s_3 s_3\overline{\eta_i\eta_j} + s_i s_3\overline{\eta_3\eta_j} + s_3 s_j\overline{\eta_i\eta_3})}{\{[w(s_3^2 - s_i^2)]\}\{[w(s_3^2 - s_j^2)]\}}, \; i, j = 1, 2\\ \operatorname{cov}(m_i, d_c) \equiv \overline{\varepsilon_i\varepsilon_3} &= \frac{\sum_{kl} ww(s_{ki}\overline{\eta_3\xi_3} + s_{k3}\overline{\eta_i\xi_3})}{\{[w(s_3^2 - s_i^2)]\}[w]}, \quad i, j = 1, 2\\ \sigma^2(d_c) \equiv \overline{\varepsilon_3^2} &= \frac{\sum_{kl} ww\overline{\xi_3\xi_3}}{[w]^2}\\ \sigma^2(d) \equiv \langle(\delta d)^2\rangle &= \langle r_1\rangle^2\overline{\varepsilon_1^2} + \langle r_2\rangle^2\overline{\varepsilon_2^2} + \overline{\varepsilon_3^2} + 2\langle r_1\rangle\langle r_2\rangle\overline{\varepsilon_1\varepsilon_2}\\ &\quad + 2\langle r_1\rangle\overline{\varepsilon_1\varepsilon_3} + 2\langle r_2\rangle\overline{\varepsilon_2\varepsilon_3}.\end{aligned}$$

Interatomic covariance (*e.g.*, $\overline{\eta_{k3}\eta_{l3}}$, $k \neq l$) thus presents no formal difficulty, although actual computation may be tedious. Nonzero covariance for the η's *may* arise explicitly from interatomic covariance (*e.g.*, $\overline{\xi_{ki}\xi_{lj}}$, $k \neq l$) of the errors in the atomic positions r_k, and it will *always* arise implicitly because $\langle\xi\rangle$ in $\eta_k = \xi_k - \langle\xi\rangle$ includes all the ξ_k and therefore has nonzero covariance with all of them and with itself, even if there is no interatomic covariance among the ξ_i's.

If both types of interatomic covariance (explicit and implicit) are negligible, the ε covariances simplify a great deal, the double

summations reducing to single summations. [The formal expression for $\sigma^2(d)$ does not change, so it will not be repeated.]

$$\begin{aligned}
\mathrm{cov}(m_i, m_j) &\equiv \overline{\varepsilon_i \varepsilon_j} \\
&= \frac{[w^2(s_i s_j \overline{\eta_3^2} + s_3^2 \overline{\eta_i \eta_j} + s_i s_3 \overline{\eta_3 \eta_j} + s_3 s_j \overline{\eta_i \eta_3}]}{\{[w(s_3^2 - s_i^2)]\}\{[w(s_3^2 - s_j^2)]\}}, \; i, j = 1, 2 \\
\mathrm{cov}(m_i, d_c) &\equiv \overline{\varepsilon_i \varepsilon_3} = \frac{[w^2(s_i \overline{\eta_3 \xi_3} + s_3 \overline{\eta_i \xi_3})]}{\{[w(s_3^2 - s_i^2)]\}[w]}, \quad i, j = 1, 2 \\
\sigma^2(d_c) &\equiv \overline{\varepsilon_3^2} = \frac{[w^2 \overline{\xi_3^2}]}{[w]^2}.
\end{aligned}$$

When the variances are the same for ξ as for η (*i.e.* $\overline{\xi_i \xi_j} = \overline{\eta_i \eta_j}$, all i, j) and the covariances all vanish ($\overline{\xi_i \xi_j} = 0, \; i \neq j$), the $\overline{\varepsilon_i \varepsilon_j}$ simplify further. If the variances are also isotropic ($\overline{\xi_i^2} = \overline{\xi_j^2} = \sigma^2$, all i, j), there is still further simplification to

$$\begin{aligned}
\sigma^2(m_i) \equiv \overline{\varepsilon_i^2} &= \frac{[w^2 \sigma^2 (s_i^2 + s_3^2)]}{\{[w(s_3^2 - s_i^2)]\}^2}, \quad i = 1, 2 \\
\sigma^2(d_c) \equiv \overline{\varepsilon_3^2} &= [w^2 \sigma^2]/[w]^2 \\
\mathrm{cov}(m_1, m_2) \equiv \overline{\varepsilon_1 \varepsilon_2} &= \frac{[w^2 \sigma^2 s_1 s_2]}{\{[w(s_3^2 - s_1^2)]\}\{[w(s_3^2 - s_2^2)]\}} \\
\mathrm{cov}(m_i, d_c) \equiv \overline{\varepsilon_i \varepsilon_3} &= \frac{[w^2 \sigma^2 s_i]}{\{[w(s_3^2 - s_i^2)]\}[w]}, \quad i = 1, 2.
\end{aligned}$$

If allowance is made for the difference in definition between ε_3 and δd, these expressions are equivalent to the ones (equations 7–9) given by WMC, who, however, do not appear to have been aware of the distinction between η and ξ and the possible consequences thereof.

If, finally, w^{-1} for each atom is taken equal to its $\overline{\eta_j^2} = \sigma^2$, all j, there is still further simplification.

$$\begin{aligned}
\sigma^2(m_i) \equiv \overline{\varepsilon_i^2} &= \frac{[w(s_3^2 + s_i^2)]}{\{[w(s_3^2 - s_i^2)]\}^2}, \quad i = 1, 2 \\
\sigma^2(d_c) \equiv \overline{\varepsilon_3^2} &= [w]/[w]^2 = 1/[w] \\
\mathrm{cov}(m_1, m_2) \equiv \overline{\varepsilon_1 \varepsilon_2} &= \frac{[w s_1 s_2]}{\{[w(s_3^2 - s_1^2)]\}\{[w(s_3^2 - s_2^2)]\}} \\
\mathrm{cov}(m_i, d_c) \equiv \overline{\varepsilon_i \varepsilon_3} &= \frac{[w s_i]}{\{[w(s_3^2 - s_i^2)]\}[w]}, \quad i = 1, 2.
\end{aligned}$$

For the earlier, more general expressions for the components of $\overline{\varepsilon \varepsilon^T}$ it is still necessary to find $\overline{\eta_{ki} \eta_{lj}}$ and $\overline{\eta_{ki} \xi_{l3}}$ in terms of $\overline{\xi_{ki} \xi_{lj}}$, with $\eta_{ki} \equiv \delta s_{ki} = \delta(r_{ki} - \langle r_{ki} \rangle) = \xi_{ki} - \langle \xi_i \rangle = \sum_l w_l (\xi_{ki} - \xi_{li})/[w]$.

$$\begin{aligned}
\overline{\eta_{ki} \eta_{pj}} &= \sum_{l,q} w_l w_q \overline{(\xi_{ki} - \xi_{li})(\xi_{pj} - \xi_{qj})}/[w]^2 \\
&= \overline{(\xi_{ki} - \langle \xi_i \rangle)(\xi_{pj} - \langle \xi_j \rangle)} \\
\overline{\eta_{ki} \xi_{p3}} &= \sum_l w_l \overline{(\xi_{ki} - \xi_{li}) \xi_{p3}}/[w] = \overline{\xi_{ki} \xi_{p3}} - \overline{\langle \xi_i \rangle \xi_{p3}}.
\end{aligned}$$

In the isotropic, 'no-correlation' case, for example, these reduce to

$$\begin{aligned}
\overline{\eta_{ki} \eta_{pi}} &= -w_k \overline{\xi_{ki}^2}/[w] - w_p \overline{\xi_{pi}^2}/[w] \\
&\quad + [w^2 \overline{\xi_i^2}]/[w]^2, \quad k \neq p; \; i = 1, 2 \\
\overline{\eta_{ki}^2} &= (1 - 2w_k/[w]) \overline{\xi_{ki}^2} + [w^2 \overline{\xi_i^2}]/[w]^2, \quad i = 1, 2 \\
\overline{\eta_{k3} \eta_{p3}} &= -w_p \overline{\xi_{p3}^2}/[w],
\end{aligned}$$

and

$$\overline{\eta_{k3}^2} = \overline{\xi_{k3}^2} - w_k \overline{\xi_{k3}^2}/[w] = \overline{\xi_{k3}^2}(1 - w_k/[w]).$$

Here the difference between the correct covariance values and the values obtained on ignoring the variation in $\langle r \rangle$ may be important if the number of defining atoms is small, say, 5 or 4 or, in the extreme, 3.

3.2.2.2. The standard uncertainty of the distance from an atom to the plane

There are two cases, as has been pointed out, *e.g.*, by Ito (1982).

(1) The atom (atom K) was *not* included in the specification of the plane.

$$\begin{aligned}
d_K &= \mathsf{m}^T(\mathsf{r}_K - \langle \mathsf{r} \rangle) = r_{k3} - \langle r_3 \rangle \\
\delta d_K &= \xi_{K3} + s_{K1} \varepsilon_1 + s_{K2} \varepsilon_2 - \varepsilon_3 \\
\sigma_{d_K}^2 &= \overline{\xi_{K3}^2} + s_{K1}^2 \overline{\varepsilon_1^2} + s_{K2}^2 \overline{\varepsilon_2^2} + \overline{\varepsilon_3^2} \\
&\quad + 2 s_{K1} s_{K2} \overline{\varepsilon_1 \varepsilon_2} - 2 s_{K1} \overline{\varepsilon_1 \varepsilon_3} - 2 s_{K2} \overline{\varepsilon_2 \varepsilon_3} \\
&\quad + 2 s_{K1} \overline{\xi_{K3} \varepsilon_1} + 2 s_{K2} \overline{\xi_{K3} \varepsilon_2} - 2 \overline{\xi_{K3} \varepsilon_3}.
\end{aligned}$$

In the isotropic, 'no-correlation' case the last three terms, *i.e.* the terms in $\overline{\varepsilon_i \xi_{K3}}$, are all negligible or zero.

In either case the value for $\overline{\xi_{K3}^2}$ and the appropriate $\overline{\varepsilon_i \varepsilon_j}$ values from the least-squares-plane calculation need to be inserted.

(2) Atom K *was* included in the specification of the plane. The expression for $\sigma_{d_K}^2$ remains the same, but the averages in it may be importantly different.

For example, consider a plane defined by only three atoms, one of overwhelmingly great w at (0, 0, 0), one at (1, 0, 0) and one at (0, 1, 0). The centroid is at (0, 0, 0) and we take $K = 2$, *i.e.* σ_{d_2} is the item of interest. Of course, it is obvious without calculation that the standard uncertainties vanish for the distances of the three atoms from the plane they alone define; the purpose here is only to show, in one case for one of the atoms, that the calculation gives the same result, partly, it will be seen, because the change in orientation of the plane is taken into account. If the only variation in the atom positions is described by $\overline{\xi_{23}^2} = \sigma^2$, one has $s_{21} = 1$, $\varepsilon_3 = \varepsilon_2 = 0$, $\varepsilon_1 = -\xi_{23}$, and $\overline{\xi_{K3} \varepsilon_1} = \sigma^2$. The non-vanishing terms in the desired variance are then

$$\begin{aligned}
\sigma_{d_2}^2 &= \overline{\xi_{23}^2} + s_{21}^2 \overline{\varepsilon_1^2} + 2 s_{21} \overline{\xi_{23} \varepsilon_1} \\
&= (1 + 1 - 2)\sigma^2 = 0.
\end{aligned}$$

If, however, the problem concerns the same plane and a fourth atom at position $(1, 0, r_{43})$, *not* included in the specification of the plane and uncertain only in respect to r_{43} (which is arbitrary) with $\overline{\xi_{43}^2} = \sigma^2$ (the same mean-square variation in direction 3 as for atom 2) and $\overline{\xi_{43} \xi_{23}} = 0$, the calculation for $\sigma_{d_4}^2$ runs the same as before, except for the third term:

$$\sigma_{d_4}^2 = (1 + 1 - 0)\sigma^2 = 2\sigma^2.$$

Extreme examples of this kind show clearly enough that variation in the direction of the plane normal or in the normal component of the centroid position will sometimes be important, the remarks to the contrary by Shmueli (1981) and, for the centroid, the omission by WMC notwithstanding. If only a few atoms are used to define the plane (*e.g.*, three or, as is often the case, a very few more), both the covariance with the centroid position and uncertainty in the direction of the normal are likely to be important. The uncertainty in the normal may still be important, even if a goodly number of atoms are used to define the plane, whenever the test atom lies near or beyond the edge of the lateral domain defined by the other atoms.

3.2.3. The proper least-squares plane, with Gaussian weights

If it is desired to weight the points to be fitted by a plane in the sense of Gaussian least squares, then two items different from what we have seen in the crystallographic literature have to be brought into view: (1) the weights may be anisotropic and include interatomic correlations, because the error matrix of the atom coordinates may in general be anisotropic and include interatomic correlations; and (2) it has to be considered that the atoms truly lie on a plane and that their observed positions are to be adjusted to lie precisely on that plane, whatever its precise position may turn out to be and no matter what the direction, in response to the anisotropic weighting, of their approach to the plane.

An important consequence of (1), the nondiagonal character of the weight matrix, even with Cartesian coordinates, is that the problem is no longer an ordinary eigenvalue problem as treated by SWMB (1959),[1] not even if there is no interatomic correlation and the anisotropy is the same for each atom. On this last case the contrary remark in SWMB at the beginning of the footnote, p. 601, is incorrect, and the treatments in terms of the eigenvector–eigenvalue problem by Hamilton (1961, 1964, pp. 174–177) and Ito (1981*a*)[2] evade us. At best the problem is still not a genuine eigenvalue problem if the anisotropies of the atoms are not all alike.

Hypothesis (2), of perfect planarity, may be hard to swallow. It has to be tested, and for any set of atoms the conclusion may be that they probably do not lie on a plane. But if the hypothesis is provisionally adopted (and it has to be decided beforehand which of the following alternatives is to be followed), the adjusted positions are obtained by moving the atoms onto the plane

(*a*) along paths normal to the plane, or

(*b*) along the *proper* paths of 'least resistance' – that is, paths with, in general, both normal and lateral components differently directed for each atom so as to minimize the appropriately weighted quadratic form of differences between the observed and adjusted coordinates. The lateral motions (and the anisotropic weights that induce them) may change the relative weights of different atoms in accordance with the orientation of the plane; change the perpendicular distance of origin-to-plane; and change the orientation of the plane in ways that may at first give surprise.

Our first example of this has already been given.[3] A second, which actually inspired our first, is to be found in Hamilton (1964; example 5-8-1, p. 177), who discusses a rectangle of four points with identical error ellipsoids elongated in the long direction of the rectangle. The unweighted best line bisects the pattern along this direction, but the weighted best line is parallel to the short direction, if the elongation of the ellipsoids is sufficient. A third example (it is severely specialized so that a precise result can be attained without calculation) has three atoms ABC arranged like a $C_{2v}-mm$ molecule with bond angle 90°. The central atom, B, has overwhelming isotropic weight; A and C have parallel extremely elongated error ellipsoids, aligned parallel to the $A-B$ bond. The unweighted best line passes through B parallel to $A\cdots C$; the weighted best line passes through B and through C. Our last example is of a plane defined by a number of atoms of which one lies a considerable distance above the plane and at a distance from the normal through the centroid, but with the downward semi-axis of its extremely elongated prolate error ellipsoid intersecting that normal before it intersects the plane. If this atom is moved at right angles to the plane and further away from it, the centroid normal tips toward the atom, whereas it would tip away if the atom's weight function were isotropic or if the calculation were the usual one and in effect constrained the adjusted position of the atom to move at right angles to the plane.

The lead notion here – that the observed points are to be adjusted individually to fit a curve (surface) of required type exactly, rather than that the curve should simply be constructed to fit the observed points as well as possible in the sense of minimizing the weighted sum of squares of the distances along some preordained direction (perhaps normal to the plane, but perhaps as in ordinary curve fitting parallel to the y axis) – we first learned from the book by Deming (1943), *Statistical Adjustment of Data*, but it is to be found in Whittaker & Robinson (1929), Arley & Buch (1950), Hamilton (1964, our most used reference), and doubtless widely throughout the least-squares literature. It has recently been strongly emphasized by Lybanon (1984), who gives a number of modern references. It is the only prescription that properly satisfies the least-squares conditions, whereas (*a*) and other analogous prescriptions are only arbitrary regressions, in (*a*) a normal regression onto the plane.[4]

We have explored the problem of least-squares *adjustment* of observed positions subject to anisotropic weights with the help of three Fortran programs, one for the straight line and two for the plane. In the first plane program an approximate plane is derived, coordinates are rotated as in WMC (1973), and the parameters of the plane are adjusted and the atoms moved onto it, either normally or in full accord with the least-squares condition, but in either case subject to independent anisotropic weight matrices. The other plane program, described in Appendix A3.2.1, proceeds somewhat more directly, with the help of the method of Lagrange multipliers. However, neither program has been brought to a satisfactory state for the calculation of the variances and covariances of the derived quantities.

3.2.3.1. Formulation and solution of the general Gaussian plane

We conclude with an outline for a complete feasible solution, including interatomic weight-matrix elements. Consider atoms at observed vector positions $\mathbf{r}_k$, $k = 1, \ldots, n$, designated in the following equations by $\mathbf{R}$, an n-by-3 array, with $\boldsymbol{R}_{ki} = \boldsymbol{r}_{ki}$; the corresponding adjusted positions denoted by the array $\mathbf{R}_a$; n constraints (each adjusted position $\mathbf{r}_a$ – 'a' for 'adjusted' – must be

[1] A simple two-dimensional problem illustrates the point. A regular polygon of n atoms is to define a 'best' line (always a *central* line). If the error matrix (the same for each atom) is isotropic, the weighted sum of squares of deviations from the line is independent of its orientation for $n > 2$, *i.e.* the problem is a degenerate eigenvalue problem, with two equal eigenvalues. However, if the error ellipsoids are not isotropic and are all oriented radially or all tangentially (these are merely the two orientations tried), the sum has $n/2$ equal minima for even n and 2 equal minima for odd n, in the one-π range of possible orientations of the line. Possibly similar peculiarities might be imagined if the anisotropic weights were more complicated (*e.g.*, 'star' shaped) than can be described by a nonsingular matrix, or by any matrix. Such are of course excluded here.

[2] Ito observes that his method fails when there are only three points to define the plane, his least-squares normal equations becoming singular. But the situation is worse: his equations are singular for any number of points, if the points fit a plane exactly.

[3] See first footnote[1].

[4] Ito's second method (Ito, 1981*b*), of 'substitution', is also a regression, essentially like the regression along z at fixed x and y used long ago by Clews & Cochran (1949, p. 52) and like the regressions of y on fixed x that – despite the fact that both x and y are afflicted with random errors – are commonly taught or practised in schools, universities and laboratories nearly 200 years after Gauss, to the extent that Deming, Lybanon and other followers of Gauss have so far had rather little influence. Kalantar's (1987) short note is a welcome but still rare exception.

on the plane), and $3n+3$ adjustable parameters ($3n$ $\mathbf{R}_a$ components and the 3 components of the vector $\mathbf{b}$ of reciprocal intercepts of the plane), so that the problem has $n-3$ degrees of freedom. The $3n$-by-$3n$ weight matrix $\boldsymbol{P}$ may be anisotropic for the separate atoms, and may include interatomic elements; it is symmetric in the sense $\boldsymbol{P}_{kilj} = \boldsymbol{P}_{ljki}$, but $\boldsymbol{P}_{kilj}$ will not in general be equal to $\boldsymbol{P}_{kjli}$. The array $\boldsymbol{\Lambda}$ denotes n Lagrange multipliers, one for each atom and unrelated to the λ's of Section 3.2.2; m and d still represent the direction cosines of the plane normal and the perpendicular origin-to-plane distance.

For a linear least-squares problem we know (see, *e.g.*, Hamilton, 1964, p. 143) that the proper weight matrix is the reciprocal of the atomic error matrix ($\boldsymbol{P} = \boldsymbol{M}^{-1}$);[5] note that '$\boldsymbol{M}$' is unrelated to the '$\mathbf{M}$' of Section 3.2.2. The least-squares sum is now

$$S = (\mathbf{R} - \mathbf{R}_a)\boldsymbol{P}(\mathbf{R} - \mathbf{R}_a),$$

and the augmented sum for applying the method of Lagrange multipliers is

$$\Phi = S/2 - \boldsymbol{\Lambda}\mathsf{b}\mathbf{R}_a.$$

Here the summation brackets ([...]) have been replaced by matrix products, but the simplified notation is not matrix notation. It has to be regarded as only a useful mnemonic in which all the indices and their clutter have been suppressed in view of their inconveniently large number for some of the arrays. If the dimensions of each are kept in mind, it is easy to recall the indices, and if the indices are resupplied at any point, it is not difficult to discover what is really meant by any of the expressions or whether evaluations have to be executed in a particular order.

The conditions to be satisfied are

$$\begin{aligned} 0 &= \frac{-\partial\Phi}{\partial\mathbf{R}_a} = \boldsymbol{P}(\mathbf{R} - \mathbf{R}_a) + \boldsymbol{\Lambda}\mathsf{b}, \\ 0 &= \frac{-\partial\Phi}{\partial\mathsf{b}} = \boldsymbol{\Lambda}\mathbf{R}_a, \\ \mathbf{1} &= \mathsf{b}\mathbf{R}_a. \end{aligned}$$

That the partial derivatives of $S/2$ should be represented by $\boldsymbol{P}(\mathbf{R} - \mathbf{R}_a)$ depends upon the above-mentioned symmetry of $\boldsymbol{P}$. Note that each of the n unit elements of $\mathbf{1}$ expresses the condition that its $\mathbf{r}_a$ should indeed lie on the plane, and that $\boldsymbol{\Lambda}\mathsf{b}$ is just the same as $\mathsf{b}\boldsymbol{\Lambda}$. The perpendicular origin-to-plane distance and the direction cosines of the plane normal are $d^2 = 1/\mathsf{b}^T\mathsf{b}$ and $\mathsf{m} = \mathsf{b}/\sqrt{\mathsf{b}^T\mathsf{b}}$.

On multiplication by $\boldsymbol{M}$ the first condition solves for $\mathbf{R}_a$, and that expression combined separately with the second condition and with the third gives highly nonlinear equations (there is further mention of this nonlinearity in Appendix A3.2.1) that have to be solved for b and $\boldsymbol{\Lambda}$:

$$\begin{aligned} \mathbf{R}_a &= \mathbf{R} + \boldsymbol{M}\boldsymbol{\Lambda}\mathsf{b} = \mathbf{R} + \boldsymbol{M}\mathsf{b}\boldsymbol{\Lambda} \\ 0 &= \mathbf{F} \equiv (\boldsymbol{\Lambda}\boldsymbol{M}\boldsymbol{\Lambda})\mathsf{b} + \boldsymbol{\Lambda}\mathbf{R} \\ 0 &= \mathbf{G} \equiv (\mathsf{b}\boldsymbol{M}\mathsf{b})\boldsymbol{\Lambda} - (\mathbf{1} - \mathsf{b}\mathbf{R}). \end{aligned}$$

The best way of handling these equations, at least if it is desired to find their solutions both for $\mathbf{R}_a$, $\boldsymbol{\Lambda}$, and b and for the error matrix of these derived quantities in terms of the error matrix for $\mathbf{R}$, seems to be to find an approximate solution by one means or another, to make sure that it is the desired solution, if (as may be) there is ambiguity, and to shift the origin to a point far enough from the plane and close enough to the centroid normal to avoid the difficulties discussed by SWMB. Then linearize the first and second equations by differentiation and solve the results first iteratively to fit the current residuals $\mathbf{F}_0$ and $\mathbf{G}_0$ and then for nominally infinitesimal increments $\delta\mathsf{b}$ and $\delta\boldsymbol{\Lambda}$. In effect, one deals with equations $\mathbf{Q}\mathbf{X} = \mathbf{Y}$, where $\mathbf{Q}$ is the $(n+3)\times(n+3)$ matrix of coefficients of the following set of equations, $\mathbf{X}$ is the $(n+3)$-dimensional vector of increments $\delta\mathsf{b}$ and $\delta\boldsymbol{\Lambda}$, and $\mathbf{Y}$ is the vector either of the first terms or of the second terms on the right-hand side of the equations.

$$\begin{aligned} (\boldsymbol{\Lambda}\boldsymbol{M}\boldsymbol{\Lambda})\delta\mathsf{b} + (\boldsymbol{M}\boldsymbol{\Lambda}\mathsf{b} + \boldsymbol{\Lambda}\boldsymbol{M}\mathsf{b} + \mathbf{R})\delta\boldsymbol{\Lambda} &= -\mathbf{F}_0 - \boldsymbol{\Lambda}\delta\mathbf{R} \\ (\boldsymbol{M}\mathsf{b}\boldsymbol{\Lambda} + \mathsf{b}\boldsymbol{M}\boldsymbol{\Lambda} + \mathbf{R})\delta\mathsf{b} + (\mathsf{b}\boldsymbol{M}\mathsf{b})\delta\boldsymbol{\Lambda} &= -\mathbf{G}_0 - \mathsf{b}\delta\mathbf{R}. \end{aligned}$$

When $\mathbf{X}$ becomes the vector ε of errors in b and $\boldsymbol{\Lambda}$ as induced by errors $\eta \equiv \delta\mathbf{R}$ in the measured atom positions, these equations become, in proper matrix notation, $\mathbf{Q}\varepsilon = \mathbf{Z}\eta$, with solution $\varepsilon = \mathbf{Q}^{-1}\mathbf{Z}\eta$, where $\mathbf{Z}$ is the $(n+3)$-dimensional vector of components, first of b then of $\boldsymbol{\Lambda}$. The covariance matrix $\overline{\varepsilon\varepsilon^T}$, from which all the covariances of b, $\mathbf{R}_a$, and $\mathbf{R}$ (including for the latter any atoms that were not included for the plane) can be derived, is then given by

$$\overline{\varepsilon\varepsilon^T} = \mathbf{Q}^{-1}\mathbf{Z}\overline{\eta\eta^T}\mathbf{Z}^T(\mathbf{Q}^{-1})^T.$$

This is not as simple as the familiar expression for propagation of errors for a least-squares problem solved without the use of Lagrange multipliers, *i.e.* $\overline{\varepsilon\varepsilon^T} = \mathbf{B}^{-1}$, where $\mathbf{B}$ is the matrix of the usual normal equations, both because $\mathbf{B} = \mathbf{B}^T$ is no longer valid and because the middle factor $\mathbf{Z}\overline{\eta\eta^T}\mathbf{Z}^T$ is no longer equal to $\mathbf{B}^{-1}$.

It is easy to verify that $\boldsymbol{\Lambda}$ consists of a set of coefficients for combining the n row vectors of $\boldsymbol{M}\mathsf{b}$, in the expression for $\mathbf{R}_a$, into corrections to $\mathbf{R}$ such that each adjusted position lies exactly on the plane:

$$\begin{aligned} \mathsf{b}\mathbf{R}_a &= \mathsf{b}\mathbf{R} + \mathsf{b}\boldsymbol{M}\mathsf{b}(\mathsf{b}\boldsymbol{M}\mathsf{b})^{-1}(\boldsymbol{1} - \mathsf{b}\mathbf{R}) \\ &= \mathsf{b}\mathbf{R} + \boldsymbol{1} - \mathsf{b}\mathbf{R} = \boldsymbol{1}. \end{aligned}$$

At the same time one can see how the lateral shifts occur in response to the anisotropy of $\boldsymbol{M}$, especially if, now, only the anisotropic case without interatomic correlations is considered. For atom k write b in terms of its components along the principal axes of $\mathbf{M}_k$, associated with the eigenvalues α, β and γ; the shifts are then proportional to $\mathbf{M}_{\alpha\alpha}b_\alpha^2$, $\mathbf{M}_{\beta\beta}b_\beta^2$ and $\mathbf{M}_{\gamma\gamma}b_\gamma^2$, each along its principal axis, and the sums of the contributions of these shift components to the total displacement along the plane normal or along either of two orthogonal directions in the plane can readily be visualized. In effect $\mathbf{M}_k$ is the compliance matrix for these shifts of atom k. Similarly, it can be seen that in the isotropic case with interatomic correlations a pair of equally weighted atoms

[5] Is this statement firm for a nonlinear problem? We use it, assuming that at convergence the problem has become effectively linear. But in fact this will depend on how great the nonlinearity is, in comparison with the random errors (variances) that eventually have to be considered. Another caveat may be in order in regard to our limited knowledge of Gauss's second derivation of the method of least squares, the one he preferred [see Whittaker & Robinson (1929)] and which establishes for a linear system that the best *linear combination* of a set of observations, afflicted by random errors, for estimating any arbitrary derived quantity – best in the sense of being unbiased and having minimal mean-square error – is given by the method of least squares with the weight matrix set equal to the inverse error matrix of the observations. Hamilton, and Whittaker & Robinson, prove this only for the case that the derived parameters are not constrained, whereas here they are. We believe, however, that the best choice of weights is a question concerning only the observations, and that it cannot be affected by the method used for minimizing $\boldsymbol{S}$ subject to any constraints, whether by eliminating some of the parameters by invoking the constraints directly or by the use of Lagrange multipliers.

located, for example, at some distance apart and at about the same distance from the plane, will have different shifts (and different influences on d and m) depending on whether the covariance between the errors in the perpendicular components of their observed positions relative to the plane is small, or, if large, whether it is positive or is negative. If the covariance is large and positive, the adjusted positions will both be pulled toward the plane, strongly resisting, however, the apparent necessity that both reach the plane by moving by different amounts; in consequence, there will be a strong tendency for the plane to tilt toward the more distant atom, and possibly even away from the nearer one. But if the covariance is large and negative, the situation is reversed: the more distant atom can readily move more than the nearer one, while it is very difficult to move them together; the upshot is then that the plane will move to meet the original midpoint of the two atoms while they tilt about that midpoint to accommodate the plane.

It is attractive to solve our problem with the 'normal' formulation of the plane, $\mathsf{mr} = d$, and so directly avoid the problems that arise for $d \approx 0$. The solution in terms of the reciprocal intercepts b has been given first, however, because reducing by two (d and a Lagrange multiplier) the number of parameters to be solved for may more than make up for the nuisance of having to move the origin. The solution in terms of d follows.

The augmented variation function is now

$$\Phi = (\mathbf{R} - \mathbf{R}_a)\boldsymbol{P}(\mathbf{R} - \mathbf{R}_a)/2 - \boldsymbol{\Lambda}(\mathsf{m}\mathbf{R}_a - d\boldsymbol{1}) + \mu\mathsf{m}\mathsf{m}/2,$$

the term in the new Lagrange multiplier, μ, and the term in $d\boldsymbol{1}$ having been added to the previous expression. The $\boldsymbol{1}$, an n-vector of 1's, is needed to express the presence of n terms in the $\boldsymbol{\Lambda}$ sum. There are then five equations to be satisfied – actually $n + 1 + 3n + 3 + 1 = 4n + 5$ ordinary equations – in the $3n$ $\mathbf{R}_a$ components, the n $\boldsymbol{\Lambda}$'s, the 3 m components, μ, and $d - 4n + 5$ unknowns in all, as required. These equations are as follows:

$$\begin{aligned}
\mathsf{m}\mathbf{R}_a &= d\boldsymbol{1} \\
\mathsf{m}\mathsf{m} &= 1 \\
0 &= -\left(\frac{\partial\Phi}{\partial\mathbf{R}_a}\right) = \boldsymbol{P}(\mathbf{R} - \mathbf{R}_a) + \boldsymbol{\Lambda}\mathsf{m} \\
0 &= \frac{\partial\Phi}{\partial\mathsf{m}} = -\boldsymbol{\Lambda}\mathbf{R}_a + \mu\mathsf{m} \\
0 &= \frac{\partial\Phi}{\partial d} = \boldsymbol{\Lambda}\boldsymbol{1}.
\end{aligned}$$

As before, multiply the third equation by $\boldsymbol{M}$ and solve for $\mathbf{R}_a$. Then substitute the result into the first and fourth equations to obtain

$$\begin{aligned}
\mathsf{m}\mathbf{R} + \mathsf{m}\boldsymbol{M}\mathsf{m}\boldsymbol{\Lambda} &= d\boldsymbol{1}, \\
\mathsf{m}\mathsf{m} &= 1, \\
\boldsymbol{\Lambda}\mathbf{R} + \boldsymbol{\Lambda}\boldsymbol{M}\boldsymbol{\Lambda}\mathsf{m} &= \mu\mathsf{m}, \\
\boldsymbol{\Lambda}\boldsymbol{1} &= 0
\end{aligned}$$

as the $n + 5$ mostly nonlinear equations to be solved for m, $\boldsymbol{\Lambda}$, d and μ by linearizing (differentiation), solving for increments, and iterating, in the pattern described more fully above. An approximate solution for m and d has first to be obtained somehow, perhaps by the method of SWMB (with isotropic uncorrelated weights), checked for suitability, and extended to a full complement of first approximations by

$$\begin{aligned}
\boldsymbol{\Lambda} &= (\mathsf{m}\boldsymbol{M}\mathsf{m})^{-1}(d\boldsymbol{1} - \mathsf{m}\mathbf{R}) \\
\mu &= \mathsf{m}\boldsymbol{\Lambda}\mathbf{R} + \mathsf{m}\boldsymbol{\Lambda}\boldsymbol{M}\boldsymbol{\Lambda}\mathsf{m},
\end{aligned}$$

which readily follow from the previous equations. As in the 'intercepts' solution the linearized expression for the increments in μ, $\boldsymbol{\Lambda}$, d and m can be used together with the equation for $\mathbf{R}_a$ to obtain all the covariances needed in the treatment described in Section 3.2.2.

3.2.3.2. Concluding remarks

Proper tests of statistical significance of this or that aspect of a least-squares plane can be made if the plane has been based on a proper weight matrix as discussed in Section 3.2.3; if it can be agreed that the random errors of observation are normally distributed; and if an agreeable test (*null*) hypothesis can be formulated. For example, one may ask for the probability that a degree of fit of the observed positions to the least-squares plane at least as poor as the fit that was found might occur if the atoms in truth lie precisely on a plane. The χ^2 test answers this question: a table of probabilities displayed as a function of χ^2 and ν provides the answer. Here χ^2 is just our minimized

$$S = \mathsf{b}\boldsymbol{\Lambda}\boldsymbol{M}\boldsymbol{P}\boldsymbol{M}\boldsymbol{\Lambda}\mathsf{b} = \mathsf{b}\boldsymbol{\Lambda}\boldsymbol{M}\boldsymbol{\Lambda}\mathsf{b},$$

and

$$\begin{aligned}
\nu &= n_{\text{observations}} - n_{\text{adjusted parameters}} - n_{\text{constraints}} \\
&= 3n - (n + 3) - n = n - 3,
\end{aligned}$$

is the number of degrees of freedom for the problem of the plane (erroneously cited in at least one widely used crystallographic system of programs as $3n - 3$). There will not usually be any reason to believe that the atoms are exactly coplanar in any case; nevertheless, this test may well give a satisfying indication of whether or not the atoms are, in the investigator's judgment, essentially coplanar. It must be emphasized that χ^2 as calculated in Section 3.2.3 will include proper allowance for uncertainties in the d and orientation of the plane with greater reliability than the estimates of Section 3.2.2, which are based on nominally arbitrary weights. Both, however, will allow for the large variations in d and *tilt* that can arise in either case if n is small. Some of the earlier, less complete discussions of this problem have been mentioned in Section 3.2.2.

Among the problems not considered here are ones of fitting more than one plane to a set of observed positions, *e.g.* of two planes fitted to three sets of atoms associated, respectively, with the first plane, the second plane, and both planes, and of the angle between the two planes. For the atoms common to both planes there will be a fundamental point of difference between existing programs (in which, in effect, the positions of the atoms in common are inconsistently adjusted to one position on the first plane and, in general, a different position on the second) and what we would advocate as the proper procedure of requiring the adjusted positions of such atoms to lie on the line of intersection of the two planes. As to the dihedral angle there is a difficulty, noted by WMC (1973, p. 2705), that the usual formulation of $\sigma^2(\theta_0)$ in terms of the cosine of the dihedral angle reduces to 0/0 at $\theta_0 = 0$. However, this variance is obviously well defined if the plane normals and their covariances are well defined. The essential difficulty lies with the ambiguity in the direction of the line of intersection of the planes in the limit of zero dihedral angle. For the torsion angle about a line defined by two atoms, there should be no such difficulty. It seems likely that for the two-plane problem proposed above, the issue that decides whether

the dihedral angle will behave like the standard dihedral angle or, instead, like the torsion angle, will be found to be whether or not two or more atoms are common to both planes.

All that we have tried to bring out about the covariances of derived quantities involving the plane requires that the covariances of the experimental atom positions (reduced in our formulations to Cartesian coordinates) be included. However, such covariances of derived quantities are often not available in practice, and are usually left unused even if they are. The need to use the covariances, not just the variances, has been obvious from the beginning. It has been emphasized in another context by Schomaker & Marsh (1983) and much more strongly and generally by Waser (1973), whose pleading seems to have been generally ignored, by now, for about thirty years.

APPENDIX A3.2.1

Consider n atoms at observed vector positions r (expressed in Cartesians), n constraints (each adjusted position r_a – 'a' for 'adjusted' – must be on the plane) and $3n+3$ adjustable parameters ($3n$ r_a components and the 3 components of the vector a of reciprocal intercepts of the plane), so that the problem has $n-3$ degrees of freedom. The weight matrices $\mathbf{P}$ may be differently anisotropic for each atom, but there are no interatomic correlations. As before, square brackets, '[...]', represent the Gaussian sum over all atoms, usually suppressing the atom indices. We also write λ, *not* the λ of Section 3.2.2, for the Lagrange multipliers (one for each atom); m for the direction cosines of the plane normal; and d for the perpendicular origin-to-plane distance.

As before, $\mathbf{P}_k$ is the reciprocal of the atomic error matrix: $\mathbf{P}_k = \mathbf{M}_k^{-1}$ (correspondingly, $\boldsymbol{P} \equiv \boldsymbol{M}^{-1}$) but '$\mathbf{M}$' is no longer the '$\mathbf{M}$' of Section 3.2.2. The appropriate least-squares sum is

$$S = [(\mathsf{r} - \mathsf{r}_a)^T \mathbf{P} (\mathsf{r} - \mathsf{r}_a)]$$

and the augmented sum for applying the method of Lagrange multipliers is

$$\Phi = S/2 - [\lambda \mathsf{a}^T \mathsf{r}_a].$$

Φ is to be minimized with respect to variations of the adjusted atom positions r_{ka} and plane reciprocal intercepts b_i, leading to the equations

$$0 = \frac{-\partial \phi}{\partial \mathsf{r}_a^T} = \mathbf{P}(\mathsf{r} - \mathsf{r}_a) + \lambda \mathsf{b} \text{ and}$$
$$0 = \frac{-\partial \Phi}{\partial \mathsf{b}^T} = [\lambda \mathsf{r}_a],$$

subject to the plane conditions $\mathsf{b}^T \mathsf{r}_a = 1$, each atom, with $d^2 = 1/(\mathsf{b}^T \mathsf{b})$, $\mathsf{m} = \mathsf{b}/\sqrt{\mathsf{b}^T \mathsf{b}}$. These equations are nonlinear.

A convenient solution runs as follows: first multiply the first equation by $\mathbf{M}$ and solve for the adjusted atom positions in terms of the Lagrange multipliers λ and the reciprocal intercepts b of the plane; then multiply *that* result by b^T applying the plane conditions, and solve for the λ's

$$\mathsf{r}_a = \mathsf{r} + \lambda \mathbf{M} \mathsf{b}, \quad \mathbf{M} \equiv \mathbf{P}^{-1}$$
$$1 = \mathsf{b}^T \mathsf{r} + \lambda \mathsf{b}^T \mathbf{M} \mathsf{b},$$
$$\lambda = (1 - \mathsf{b}^T \mathsf{r})/(\mathsf{b}^T \mathbf{M} \mathsf{b}).$$

Next insert these values for the λ's and r_a's into the second equation:

$$0 = \frac{\partial \Phi}{\partial \mathsf{b}^T} = [\lambda \mathsf{r}_a] = \left[\frac{1 - \mathsf{b}^T \mathsf{r}}{\mathsf{b}^T \mathbf{M} \mathsf{b}} \left(\mathsf{r} + \frac{1 - \mathsf{b}^T \mathsf{r}}{\mathsf{b}^T \mathbf{M} \mathsf{b}} \mathbf{M} \mathsf{b} \right) \right].$$

This last equation, $F(\mathsf{b}) = 0$, is to be solved for b. It is highly nonlinear: $F(\mathsf{b}) = O(\mathsf{b}^3)/O(\mathsf{b}^4)$. One can proceed to a first approximation by writing $0 = [(1 - \mathsf{b}^T \mathsf{r})\mathsf{r}]$; *i.e.*, $[\mathbf{rr}] \cdot \mathsf{b} = [\mathbf{r}]$, in dyadic notation. [$\mathbf{M} = \mathbf{I}$, all atoms; $1 - \mathsf{b}^T \mathsf{r} = 0$ in the multiplier of $\mathbf{M}\mathsf{b}/(\mathsf{b}^T \mathbf{M} \mathsf{b})$.] A linear equation in b, this approximation usually works well.[6] We have also used the iterative Frazer, Duncan & Collar eigenvalue solution as described by SWMB (1959), which works even when the plane passes exactly through the origin. To continue the solution of the nonlinear equations, by linearizing and iterating, write $F(\mathsf{b}) = 0$ in the form

$$0 = [\lambda \mathsf{r} + \lambda^2 \mathbf{M} \mathsf{b}]$$
$$\approx \left[\mathsf{r} \frac{\partial \lambda}{\partial \mathsf{b}} + 2 \mathbf{M} \mathsf{b} \lambda \frac{\partial \lambda}{\partial \mathsf{b}} + \lambda^2 \mathbf{M} \right] \delta \mathsf{b} + [\lambda(\mathsf{r} + \lambda \mathbf{M} \mathsf{b})]_0,$$

solve for $\delta\mathsf{b}$, reset b to $\mathsf{b} + \delta\mathsf{b}$, *etc.,* until the desired degree of convergence of $|\delta\mathsf{b}|/|\mathsf{b}|$ toward zero has been attained. By $\partial\lambda/\partial\mathsf{b}$ is meant the partial derivative of the above expression for λ with respect to b, as detailed in the next paragraph.

In the Fortran program *DDLELSP* (double precision Deming Lagrange, with error estimates, least-squares plane, written to explore this solution) the preceding equation is recast as

$$\mathbf{B} \delta \mathsf{b} \equiv \left[\lambda^2 \mathbf{M} + (\mathsf{r} + 2\lambda \mathbf{M} \mathsf{b}) \frac{\partial \lambda}{\partial \mathsf{b}} \right] \delta \mathsf{b}$$
$$\equiv \mathbf{Y} = -[\lambda(\mathsf{r} + \lambda \mathbf{M} \mathsf{b})]_0,$$

with

$$\frac{\partial \lambda}{\partial \mathsf{b}} = \mathsf{r}^T / \mathsf{b}^T \mathbf{M} \mathsf{b} - [2(1 - \mathsf{b}^T \mathsf{r})/(\mathsf{b}^T \mathbf{M} \mathsf{b})^2]$$
$$= -(\mathsf{r}^T + 2\lambda \mathsf{b}^T \mathbf{M})/\mathsf{b}^T \mathbf{M} \mathsf{b}.$$

The usual goodness of fit, GOF2 in *DDLELSP*, evaluates to

$$\text{GOF2} = \left(\frac{S_{\min}}{n-3} \right)^{1/2} = \left(\frac{1}{n-3} [\lambda^2 \mathsf{b}^T \mathbf{M} \mathbf{P} \mathbf{M} \mathsf{b}] \right)^{1/2}$$
$$= \left(\frac{1}{n-3} [\lambda^2 \mathsf{b}^T \mathbf{M} \mathsf{b}] \right)^{1/2}$$
$$= \left(\frac{1}{n-3} \left[\frac{(1 - \mathsf{b}^T \mathsf{r})^2}{\mathsf{b}^T \mathbf{M} \mathsf{b}} \right] \right)^{1/2}.$$

[6] We do not fully understand the curious situation of this equation. It arises immediately if the isotropic problem is formulated as one of minimizing $[(1 - \mathsf{b}^T \mathsf{r})^2]$ by varying b, and it fails then [SWMB (1959) referred to it as 'an incorrect method'], as it obviously must – observe the denominator – if the plane passes too close to the origin. However, it fails in other circumstances also. The main point about it is perhaps that it is linear in b and is obtained as the supposedly exact and *unique* solution of the isotropic problem, whereas the problem has no unique solution but three solutions instead (SWMB, 1959). From the point of view of Gaussian least squares, the essential fault in minimizing $S_{\text{lin}} = [(1 - \mathsf{b}^T \mathsf{r})^2]$ may be that the apparently simple weighting function in it, *i.e.* the identity, is actually complicated and unreasonable. In terms of distance deviations from the plane, we have $S_{\text{lin}} = [w(d - \mathsf{m}^T \mathsf{r})^2]$, with $w = \mathsf{b}^T \mathsf{b} = d^{-2}$. Prudence requires that the origin be shifted to a point sufficiently far from the plane and close enough to the centroid normal to avoid the difficulties discussed by SWMB. Note that for the one-dimensional problem of fitting a constant to a set of measurements of a single entity the Deming–Lagrange treatment with the condition $1 = cx_a$ and weights w reduces immediately to the standard result $1/c = [wx]/[w]$.

This is only an approximation, because the residuals $1 - \mathsf{b}^T\mathsf{r}$ are not the differences between the observations and appropriate linear functions of the parameters, nor are their variances (the $\mathsf{b}^T\mathbf{M}\mathsf{b}$'s) independent of the parameters (or, in turn, the errors in the observations).

We ask also about the perpendicular distances, e, of atoms to plane and the mean-square deviation $\overline{(\delta e)^2}$ to be expected in e.

$$e = (1 - \mathsf{b}^T\mathsf{r})/\sqrt{\mathsf{b}^T\mathsf{b}} = d(1 - \mathsf{b}^T\mathsf{r})$$
$$\delta e = -d(\mathsf{b}^T\eta + \mathsf{r}^T\varepsilon) + O(\eta^2).$$

Here η and ε are the errors in r and b. Neglecting '$O(\eta^2)$' then leads to

$$\overline{(\delta e)^2} = d^2(\mathsf{b}^T\overline{\eta\eta^T}\mathsf{b} + 2\mathsf{b}^T\overline{\eta\varepsilon^T}\mathsf{r} + \mathsf{r}^T\overline{\varepsilon\varepsilon^T}\mathsf{r}).$$

We have $\overline{\eta\eta^T} = \mathbf{M} = \mathbf{P}^{-1}$, but $\overline{\eta\varepsilon^T}$ and $\overline{\varepsilon\varepsilon^T}$ perhaps still need to be evaluated.

3.3. Molecular modelling and graphics

By R. Diamond and L. M. D. Cranswick

3.3.1. Graphics

By R. Diamond

3.3.1.1. Coordinate systems, notation and standards

3.3.1.1.1. Cartesian and crystallographic coordinates

It is usual, for purposes of molecular modelling and of computer graphics, to adopt a Cartesian coordinate system using mutually perpendicular axes in a right-handed system using the ångström unit or the nanometre as the unit of distance along such axes, and largely to ignore the existence of crystallographic coordinates expressed as fractions of unit-cell edges. Transformations between the two are thus associated, usually, with the input and output stages of any software concerned with modelling and graphics, and it will be assumed after this section that all coordinates are Cartesian using the chosen unit of distance as the unit of coordinates. For a discussion of coordinate transformations and rotations without making this assumption see Chapter 1.1 in which formulations using co- and contravariant forms are presented.

The relationship between these systems may be written

$$\mathbf{X} = \boldsymbol{M}\mathbf{x} \quad \mathbf{x} = \boldsymbol{M}^{-1}\mathbf{X}$$

in which $\mathbf{X}$ and $\mathbf{x}$ are position vectors in direct space, written as column vectors, with $\mathbf{x}$ expressed in crystallographic fractional coordinates (dimensionless) and $\mathbf{X}$ in Cartesian coordinates (dimension of length).

There are two forms of $\boldsymbol{M}$ in common use. The first of these sets the first component of $\mathbf{X}$ parallel to $\mathbf{a}^*$ and the third parallel to $\mathbf{c}$ and is

$$\boldsymbol{M} = \begin{pmatrix} a\varphi/\sin\alpha & 0 & 0 \\ a(\cos\gamma - \cos\alpha\cos\beta)/\sin\alpha & b\sin\alpha & 0 \\ a\cos\beta & b\cos\alpha & c \end{pmatrix}$$

$$\boldsymbol{M}^{-1} = \begin{pmatrix} \sin\alpha/a\varphi & 0 & 0 \\ (\cos\alpha\cos\beta - \cos\gamma)/b\varphi\sin\alpha & 1/b\sin\alpha & 0 \\ (\cos\alpha\cos\gamma - \cos\beta)/c\varphi\sin\alpha & -1/c\tan\alpha & 1/c \end{pmatrix}$$

in which

$$\varphi = \sqrt{1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2\cos\alpha\cos\beta\cos\gamma} = \sin\alpha\sin\beta\sin\gamma^*.$$

φ is equal to the volume of the unit cell divided by abc, and is unchanged by cyclic permutation of α, β and γ and of α^*, β^* and γ^*. The Cartesian and crystallographic axes have the same chirality if the positive square root is taken.

The second form sets the first component of $\mathbf{X}$ parallel to $\mathbf{a}$ and the third component of $\mathbf{X}$ parallel to $\mathbf{c}^*$ and is

$$\boldsymbol{M} = \begin{pmatrix} a & b\cos\gamma & c\cos\beta \\ 0 & b\sin\gamma & c(\cos\alpha - \cos\beta\cos\gamma)/\sin\gamma \\ 0 & 0 & c\varphi/\sin\gamma \end{pmatrix}$$

$$\boldsymbol{M}^{-1} = \begin{pmatrix} 1/a & -1/a\tan\gamma & (\cos\alpha\cos\gamma - \cos\beta)/a\varphi\sin\gamma \\ 0 & 1/b\sin\gamma & (\cos\beta\cos\gamma - \cos\alpha)/b\varphi\sin\gamma \\ 0 & 0 & \sin\gamma/c\varphi \end{pmatrix}.$$

A third form, suitable only for rhombohedral cells, is

$$\boldsymbol{M} = \frac{a}{3}\begin{pmatrix} p+2q & p-q & p-q \\ p-q & p+2q & p-q \\ p-q & p-q & p+2q \end{pmatrix}$$

$$\boldsymbol{M}^{-1} = \frac{1}{3a}\begin{pmatrix} \frac{1}{p}+\frac{2}{q} & \frac{1}{p}-\frac{1}{q} & \frac{1}{p}-\frac{1}{q} \\ \frac{1}{p}-\frac{1}{q} & \frac{1}{p}+\frac{2}{q} & \frac{1}{p}-\frac{1}{q} \\ \frac{1}{p}-\frac{1}{q} & \frac{1}{p}-\frac{1}{q} & \frac{1}{p}+\frac{2}{q} \end{pmatrix}$$

in which

$$p = \pm\sqrt{1 + 2\cos\alpha} \quad q = \pm\sqrt{1 - \cos\alpha},$$

which preserves the equivalence of axes. Here the chiralities of the Cartesian and crystallographic axes are the same if p is chosen positive, and different otherwise, and the two sets of axes coincide in projection along the triad if q is chosen positive and are π out of phase otherwise.

3.3.1.1.2. Homogeneous coordinates

Homogeneous coordinates have found wide application in computer graphics. For some equipment their use is essential, and they are of value analytically even if the available hardware does not require their use.

Homogeneous coordinates employ four quantities, X, Y, Z and W, to define the position of a point, rather than three. The fourth coordinate has a scaling function so that it is the quantity X/W (as delivered to the display hardware) which controls the left–right positioning of the point within the picture. A point with $|X/W| < 1$ is in the picture, normally, and those with $|X/W| > 1$ are outside it, but see Section 3.3.1.3.5.

There are many reasons why homogeneous coordinates may be adopted, among them the following:

(i) X, Y, Z and W may be held as integers, thus enabling fast arithmetic whilst offering much of the flexibility of floating-point working. A single W value may be common to a whole array of X, Y, Z values.

(ii) Perspective transformations can be implemented without the need for any division. Only high-speed matrix multiplication using integer arithmetic is necessary, provided only that the drawing hardware can provide displacements proportional to the ratio of two signals, X and W or Y and W. Rotation, translation, scaling and the application of perspective are all effected by operations of the same form, namely multiplication of a four-vector by a 4×4 matrix. The hardware may thus be kept relatively simple since only one type of operation needs to be provided for.

(iii) Since kX, kY, kZ, kW represents the same point as X, Y, Z, W, the hardware may be arranged to maximize resolution without risk of integer overflow.

For analytical purposes it is convenient to regard homogeneous transformations in terms of partitioned matrices

$$\begin{pmatrix} \boldsymbol{M} & \mathbf{V} \\ \mathbf{U} & N \end{pmatrix}\begin{pmatrix} \mathbf{X} \\ W \end{pmatrix},$$

Copyright © 2010 International Union of Crystallography

where $\boldsymbol{M}$ is a 3×3 matrix, $\mathbf{V}$ and $\mathbf{X}$ are three-element column vectors, $\mathbf{U}$ is a three-element row vector and N and W are scalars.

Matrices and vectors which are equivalent under the considerations of (iii) above will be related by the sign $\simeq$ in what follows.

Hardware systems which use true floating-point representations have less need of homogeneous coordinates and for these N and W may normally be set to unity.

3.3.1.1.3. Notation

In this chapter the conventions of matrix algebra will be adhered to except where it is convenient to show operations on elements of vectors, matrices and tensors, where a subscript notation will be used with a modified summation convention in which summation is over lower-case subscripts *only*. Thus the equation

$$x_I = A_{Ij}X_j$$

is to be read 'For any I, x_I is $A_{Ij}X_j$ summed over j'.

Subscripts using the letter i or later in the alphabet will relate to the usual three dimensions and imply a three-term summation. Subscripts a to h are not necessarily so limited, and, in particular, the subscript a is used to imply summation over atoms of which there may be an arbitrary number.

We shall use the superscript T to denote a transpose, and also use the Kronecker delta, δ_{IJ}, which is 1 if $I = J$ and zero otherwise, and the tensor ε_{IJK} which is 1 if I, J and K are a cyclic permutation of 1, 2, 3, -1 if an anticyclic permutation, and zero otherwise.

$$\varepsilon_{IJK} = (I - J)(J - K)(K - I)/2 \quad 1 \leq I, J, K \leq 3.$$

A useful identity is then

$$\varepsilon_{iJK}\varepsilon_{iLM} = \delta_{JL}\delta_{KM} - \delta_{JM}\delta_{KL}.$$

Single modulus signs surrounding the symbol for a square matrix denote its determinant, and around a vector denote its length.

The symbol $\simeq$ is defined in the previous section.

3.3.1.1.4. Standards

The sections of this chapter concerned with graphics are primarily concerned with the mathematical aspects of graphics programming as they confront the applications programmer. The implementations outlined in Section 3.3.3 have all, so far as the author is aware, been developed *ab initio* by their inventors to deal with these aspects using their own and unrelated techniques and protocols. It is clear, however, that standards are now emerging, and it is to be hoped that future developments in applications software will handle the graphics aspects through one or other of these standards.

First among these standards is the Graphical Kernel System, GKS, defined in *American National Standards Institute, American National Standard for Information Processing Systems – Computer Graphics – Graphical Kernel System (GKS) Functional Description* (1985) and described and illustrated by Hopgood *et al.* (1986) and Enderle *et al.* (1984). GKS became a full International Standards Organization (ISO) standard in 1985, and its purpose is to standardize the interface between application software and the graphics system, thus enhancing portability of software. Specifications for Fortran, Pascal and Ada formulations are at an advanced stage of development. Its value to crystallographers is limited by the fact that it is only two-dimensional. A three-dimensional extension known as GKS-3D, defined in *International Standards Organisation, International Standard Information Processing Systems – Computer Graphics – Graphical Kernel System for Three Dimensions (GKS-3D), Functional Description* (1988) became an ISO standard in 1988. Perhaps of greatest interest to crystallographers, however, is the Programmers' Hierarchical Interactive Graphics System (PHIGS) (Brown, 1985; Abi-Ezzi & Bunshaft, 1986) since this allows hierarchical segmentation of picture content to exist in both the applications software and the graphics device in a related manner, which GKS does not. Some graphics devices now available support this type of working and its exploitation indicates the choice of PHIGS. Furthermore, Fortran implementations of GKS and GKS-3D require points to be stored in arrays dimensioned as $X(N)$, $Y(N)$, $Z(N)$ which may be equivalenced (in the Fortran sense) to $XYZ(N, 3)$ but not to $XYZ(3, N)$, which may not be convenient. PHIGS also became an International Standard in 1988: *American National Standards Institute, American National Standard for Information Processing Systems – Computer Graphics – Programmer's Hierarchical Graphics System (PHIGS) Functional Description, Archive File Format, Clear-Text Encoding of Archive File* (1988). PHIGS has also been extended to support the capability of raster-graphics machines to represent reflections, shadows, see-through effects *etc.* in a version known as PHIGS+ (van Dam, 1988).

Increasingly, manufacturers of graphics equipment are orienting their products towards one or other of these standards. While these standards are not the subject of this chapter it is recommended that they be studied before investing in equipment.

In addition to these standards, related standards are evolving under the auspices of the ISO for defining images in a file-storage, or metafile, form, and for the interface between the device-independent and device-dependent parts of a graphics package. Arnold & Bono (1988) describe the ANSI and ISO Computer Graphics Metafile standard which provides for the definition of (two-dimensional) images. The definition of three-dimensional scenes requires the use of (PHIGS) archive files.

3.3.1.2. Orthogonal (or rotation) matrices

It is a basic requirement for any graphics or molecular-modelling system to be able to control and manipulate the orientation of the structures involved and this is achieved using orthogonal matrices which are the subject of these sections.

3.3.1.2.1. General form

If a vector $\mathbf{v}$ is expressed in terms of its components resolved onto an axial set of vectors $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$ which are of unit length and mutually perpendicular and right handed in the sense that $(\mathbf{X} \times \mathbf{Y}) \cdot \mathbf{Z} = +1$, and if these components are v_I, and if a second set of axes $\mathbf{X}'$, $\mathbf{Y}'$, $\mathbf{Z}'$ is similarly established, with the same origin and chirality, and if $\mathbf{v}$ has components v'_I on these axes then

$$v'_I = a_{Ij}v_j,$$

in which a_{IJ} is the cosine of the angle between the ith primed axis and the jth unprimed axis. Evidently the elements a_{IJ} comprise a matrix $\boldsymbol{R}$, such that any row represents one of the primed axial vectors, such as $\mathbf{X}'$, expressed as components on the unprimed axes, and each column represents one of the unprimed axial vectors expressed as components on the primed axes. It follows that $\boldsymbol{R}^T = \boldsymbol{R}^{-1}$ since elements of the product $\boldsymbol{R}^T\boldsymbol{R}$ are scalar products among perpendicular unit vectors.

A real matrix whose transpose equals its inverse is said to be *orthogonal.*

Since $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ can simultaneously be superimposed on $\mathbf{X}'$, $\mathbf{Y}'$ and $\mathbf{Z}'$ without deformation or change of scale the relationship is one of rotation, and orthogonal matrices are often referred to as rotation matrices. The operation of replacing the vector $\mathbf{v}$ by $\boldsymbol{R}\mathbf{v}$ corresponds to rotating the axes from the unprimed to the primed set with $\mathbf{v}$ itself unchanged. Equally, the same operation corresponds to retaining fixed axes and rotating the vector in the opposite sense. The second interpretation is the one more frequently helpful since conceptually it corresponds more closely

to rotational operations on objects, and it is primarily in this sense that the following is written.

If three vectors **u**, **v** and **w** form the edges of a parallelepiped, then its volume V is

$$V = \mathbf{u} \cdot (\mathbf{v} \times \mathbf{w}) = \varepsilon_{ijk} u_i v_j w_k$$

and if these vectors are transformed by the matrix $\boldsymbol{R}$ as above, then the transformed volume V' is

$$V' = \varepsilon_{lmn} u'_l v'_m w'_n = \varepsilon_{lmn} a_{li} a_{mj} a_{nk} u_i v_j w_k.$$

But the determinant of $\boldsymbol{R}$ is given by

$$|\boldsymbol{R}| \varepsilon_{IJK} = \varepsilon_{lmn} a_{lI} a_{mJ} a_{nK}$$

so that

$$V' = |\boldsymbol{R}| V$$

and the determinant of $\boldsymbol{R}$ must therefore be +1 for a transformation which is a pure rotation. Nevertheless orthogonal matrices with determinant -1 exist though these do not describe a pure rotation. They may always be described as the product of a pure rotation and inversion through the origin and are referred to here as improper rotations. In what follows all references to orthogonal matrices refer to those with positive determinant only, unless stated otherwise.

An important general form of an orthogonal matrix in three dimensions was derived as equation (1.1.4.32) and is

$$\boldsymbol{R} = \begin{pmatrix} l^2 + (m^2 + n^2)\cos\theta & lm(1 - \cos\theta) - n\sin\theta & nl(1 - \cos\theta) + m\sin\theta \\ lm(1 - \cos\theta) + n\sin\theta & m^2 + (n^2 + l^2)\cos\theta & mn(1 - \cos\theta) - l\sin\theta \\ nl(1 - \cos\theta) - m\sin\theta & mn(1 - \cos\theta) + l\sin\theta & n^2 + (l^2 + m^2)\cos\theta \end{pmatrix}$$

or

$$R_{IJ} = (1 - \cos\theta) l_I l_J + \delta_{IJ} \cos\theta - \varepsilon_{IJk} l_k \sin\theta,$$

in which l, m and n are the direction cosines of the axis of rotation (which are the same when referred to either set of axes under either interpretation) and θ is the angle of rotation. In this form, and with $\boldsymbol{R}$ operating on column vectors on the right, the sign of θ is such that, when viewed along the rotation axis *from* the origin *towards* the point *lmn,* the object is rotated clockwise for positive θ with a fixed right-handed axial system. If, under the same viewing conditions, the axes are to be rotated clockwise through θ with the object fixed then the components of vectors in the object, on the new axes, are given by $\boldsymbol{R}$ with the same *lmn* and with θ negated. This is the transpose of $\boldsymbol{R}$, and if $\boldsymbol{R}$ is constructed from a product, as below, then each factor matrix in the product must be transposed and their order reversed to achieve this. Note that if, for a given rotation, the viewing direction from the origin is reversed, l, m, n and θ are all reversed and the matrix is unchanged.

Any rotation about a reference axis such that two of the direction cosines are zero is termed a *primitive rotation*, and it is frequently a requirement to generate or to interpret a general rotation as a product of primitive rotations.

A second important general form is based on Eulerian angles and is the product of three such primitives. It is

$$\begin{aligned} \boldsymbol{R} &= \begin{pmatrix} \cos\varphi_3 & -\sin\varphi_3 & 0 \\ \sin\varphi_3 & \cos\varphi_3 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \cos\varphi_2 & 0 & \sin\varphi_2 \\ 0 & 1 & 0 \\ -\sin\varphi_2 & 0 & \cos\varphi_2 \end{pmatrix} \begin{pmatrix} \cos\varphi_1 & -\sin\varphi_1 & 0 \\ \sin\varphi_1 & \cos\varphi_1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ &= \begin{pmatrix} (\cos\varphi_3\cos\varphi_2\cos\varphi_1 & -(\cos\varphi_3\cos\varphi_2\sin\varphi_1 & \cos\varphi_3\sin\varphi_2 \\ \quad -\sin\varphi_3\sin\varphi_1) & \quad +\sin\varphi_3\cos\varphi_1) & \\ (\sin\varphi_3\cos\varphi_2\cos\varphi_1 & (-\sin\varphi_3\cos\varphi_2\sin\varphi_1 & \sin\varphi_3\sin\varphi_2 \\ \quad +\cos\varphi_3\sin\varphi_1) & \quad +\cos\varphi_3\cos\varphi_1) & \\ -\sin\varphi_2\cos\varphi_1 & \sin\varphi_2\sin\varphi_1 & \cos\varphi_2 \end{pmatrix} \end{aligned}$$

which is commonly employed in four-circle diffractometers for which $\varphi = -\varphi_1$, $\chi = \varphi_2$ and $\omega = -\varphi_3$. In terms of the fixed-axes–moving-object conceptualization this corresponds to a rotation φ_1 about Z followed by φ_2 about Y followed by φ_3 about Z. In the familiar diffractometer example, when $\chi = 0$ the φ and ω axes are both vertical and equivalent. If φ is altered first, then the χ axis is still in the direction of a fixed Y axis, but if ω is altered first it is not. Since all angles are to be rotations about fixed axes to describe a rotating object it follows that it is φ rather than ω which corresponds to φ_1. In general, when rotating parts are mounted on rotating parts the rotation closest to the moved object must be applied first, forming the right-most factor in any multiple transformation, with the rotation closest to the fixed part as the left-most factor, assuming data supplied as column vectors on the right.

Given an orthogonal matrix, in either numerical or analytical form, it may be required to discover θ and the axis of rotation, or to factorize it as a product of primitives. From the first form we see that the vector

$$v_I = \varepsilon_{Ijk} a_{jk},$$

consisting of the antisymmetric part of $\boldsymbol{R}$, has elements $-2\sin\theta$ times the direction cosines l, m, n, which establishes the direction immediately, and normalization using $l^2 + m^2 + n^2 = 1$ determines $\sin\theta$. Furthermore, the trace is $1 + 2\cos\theta$ so that the quadrant of θ is also fixed. This method fails, however, if the matrix is symmetrical, which occurs if $\theta = \pi$. In this case only the direction of the axis is required, which is given by

$$l : m : n = (a_{23})^{-1} : (a_{31})^{-1} : (a_{12})^{-1}$$

for nonzero elements, or $l = \sqrt{\frac{1}{2}(a_{11} + 1)}$ *etc.*, with the signs chosen to satisfy $a_{12} = 2lm$ *etc.*

The Eulerian form may be factorized by noting that $\tan\varphi_1 = -a_{32}/a_{31}$, $\tan\varphi_3 = a_{23}/a_{13}$, $\cos\varphi_2 = a_{33}$. There is then freedom to choose the sign of $\sin\varphi_2$, but the choice then fixes the quadrants of φ_1 and φ_3 through the elements in the last row and column, and the primitives may then be constructed. These expressions for φ_1 and φ_3 fail if $\sin\varphi_2 = 0$, in which case the rotation reduces to a primitive rotation about Z with angle $(\varphi_1 + \varphi_3)$, $\varphi_2 = 0$, or $(\varphi_3 - \varphi_1)$, $\varphi_2 = \pi$.

Eulerian angles are unlikely to be the best choice of primitive angles unless they are directly related to the parameters of a system, as with the diffractometer. It is often more important that the changes to primitive angles should be quasi-linearly related to θ for any small rotations, which is not the case with Eulerian angles when the required rotation axis is close to the X axis. In such a case linearized techniques for solving for the primitive angles will fail. Furthermore, if the required rotation is about Z only $(\varphi_1 + \varphi_3)$ is determinate.

Quasi-linear relationships between θ and the primitive rotations arise if the primitives are one each about X, Y and Z. Any order of the three factors may be chosen, but the choice must then be adhered to since these factors do not commute. For sufficiently small rotations the primitive rotations are then $l\theta$, $m\theta$ and $n\theta$, whilst for larger θ linearized iterative techniques for finding the primitive rotations are likely to be convergent and well conditioned.

The three-dimensional space of the angles φ_1, φ_2 and φ_3 in either case is nonlinearly related to θ. In the Eulerian case the worst nonlinearities occur at the origin of φ-space. Equally severe nonlinearities occur in the quasi-linear case also but are 90° away from the origin and less likely to be troublesome.

Neither of the foregoing general forms of orthogonal matrix has ideally convenient properties. The first is inconvenient because it uses four nonequivalent variables l, m, n and θ, with a linking equation involving l, m and n, so that they cannot be treated as independent variables for analytical purposes. The

second form (the product of primitives) is not ideal because the three angles, though independent, are not equivalent, the non-equivalence arising from the noncommutation of the primitive factors. In the remainder of this section we give two further forms of orthogonal matrix which each use three variables which are independent and strictly equivalent, and a third form using four whose squares sum to unity.

The first of these is based on the diagonal and uses the three independent variables p, q, r, from which we construct the auxiliary variables

$$P = \pm\sqrt{1+p-q-r},\ \ Q = \pm\sqrt{1-p+q-r},$$
$$R = \pm\sqrt{1-p-q+r},\ \ S = \pm\sqrt{1+p+q+r},$$

then

$$\boldsymbol{R} = \begin{pmatrix} p & \frac{1}{2}[PQ-RS] & \frac{1}{2}[PR+QS] \\ \frac{1}{2}[PQ+RS] & q & \frac{1}{2}[QR-PS] \\ \frac{1}{2}[PR-QS] & \frac{1}{2}[QR+PS] & r \end{pmatrix}$$

is orthogonal with positive determinant for any of the sixteen sign combinations. The signs of P, Q, R and S are, respectively, the signs of the direction cosines of the rotation axis and of $\sin\theta$. Using also $T = \sqrt{4-S^2}$, which may be deemed positive without loss of generality,

$$l = P/T, m = Q/T, n = R/T, \sin\theta = ST/2,$$
$$\cos\theta = 1 - T^2/2 = S^2/2 - 1.$$

Although p, q and r are independent, the point $[pqr]$ is bound, by the requirement that P, Q, R and S be real, to lie within a tetrahedron whose vertices are the points [111], $[1\bar{1}\bar{1}]$, $[\bar{1}1\bar{1}]$ and $[\bar{1}\bar{1}1]$, corresponding to the identity and to 180° rotations about each of the axes. The facts that the identity occurs at a vertex of the feasible region and that $(1-\cos\theta)$, rather than $\sin\theta$, is linear on p, q and r in this vicinity make this form suitable only for substantial rotations.

The second form consists in defining a rotation vector $\mathbf{r}$ with components u, v, w such that $u = lt$, $v = mt$, $w = nt$ with $t = \tan(\theta/2)$ and $\mathbf{r}\cdot\mathbf{r} = t^2$. Then the matrix

$$\boldsymbol{R} = \begin{pmatrix} \dfrac{1+u^2-v^2-w^2}{1+t^2} & \dfrac{2(uv-w)}{1+t^2} & \dfrac{2(uw+v)}{1+t^2} \\ \dfrac{2(uv+w)}{1+t^2} & \dfrac{1-u^2+v^2-w^2}{1+t^2} & \dfrac{2(vw-u)}{1+t^2} \\ \dfrac{2(uw-v)}{1+t^2} & \dfrac{2(vw+u)}{1+t^2} & \dfrac{1-u^2-v^2+w^2}{1+t^2} \end{pmatrix}$$

$$R_{IJ} = (1+t^2)^{-1}[\delta_{IJ}(1-u_k u_k) + 2(u_I u_J - \varepsilon_{IJl}u_l)]$$

is orthogonal and the variables u, v, w are independent, equivalent and unbounded, and, unlike the previous form, small rotations are quasi-linear on these variables. As examples, $\mathbf{r}$ = [100] gives 90° about X, $\mathbf{r}$ = [111] gives 120° about [111].

$\boldsymbol{R}$ then transforms a vector $\mathbf{d}$ according to

$$\boldsymbol{R}\mathbf{d} = \mathbf{d} + \frac{2}{1+t^2}\{(\mathbf{r}\times\mathbf{d}) + [\mathbf{r}\times(\mathbf{r}\times\mathbf{d})]\}.$$

Multiplying two such matrices together allows us to establish the manner in which the rotation vectors $\mathbf{r}_1$ and $\mathbf{r}_2$ combine.

$$\mathbf{r} = \frac{\mathbf{r}_2 + \mathbf{r}_1 + \mathbf{r}_2\times\mathbf{r}_1}{1-\mathbf{r}_2\cdot\mathbf{r}_1}$$

for a rotation $\mathbf{r}_1$ followed by $\mathbf{r}_2$, so that rotations expressed in terms of rotation angles and axes may be compounded into a single such rotation without the need to form and decompose a product matrix.

Note that if $\mathbf{r}_1$ and $\mathbf{r}_2$ are parallel this reduces to the formula for the tangent of the sum of two angles, and that if $\mathbf{r}_1\cdot\mathbf{r}_2 = 1$ the combined rotation is always 180°. Note, too, that reversing the order of application of the rotations reverses only the vector product.

If three rotations $\mathbf{r}_1$, $\mathbf{r}_2$ and $\mathbf{r}_3$ are applied successively, $\mathbf{r}_1$ first, then their combined rotation is

$$\begin{aligned}\mathbf{r} = [&\mathbf{r}_3(1-\mathbf{r}_1\cdot\mathbf{r}_2) + \mathbf{r}_2(1+\mathbf{r}_3\cdot\mathbf{r}_1) + \mathbf{r}_1(1-\mathbf{r}_3\cdot\mathbf{r}_2) \\ &+ \mathbf{r}_3\times\mathbf{r}_2 + \mathbf{r}_3\times\mathbf{r}_1 + \mathbf{r}_2\times\mathbf{r}_1] \\ &\times[1-\mathbf{r}_1\cdot\mathbf{r}_2 - \mathbf{r}_2\cdot\mathbf{r}_3 - \mathbf{r}_3\cdot\mathbf{r}_1 - \mathbf{r}_3\cdot(\mathbf{r}_2\times\mathbf{r}_1)]^{-1}.\end{aligned}$$

Note the irregular pattern of signs in the numerator.

Similar ideas, using a vector of magnitude $\sin(\theta/2)$, are developed in Aharonov *et al.* (1977).

The third form of orthogonal matrix uses four variables, λ, μ, ν and σ, which comprise a four-dimensional vector $\boldsymbol{\rho}$, such that $\lambda = ls$, $\mu = ms$, $\nu = ns$ with $s = \sin(\theta/2)$ and $\sigma = \cos(\theta/2)$. In terms of these variables

$$\boldsymbol{R} = \begin{pmatrix} (\lambda^2-\mu^2-\nu^2+\sigma^2) & 2(\lambda\mu-\nu\sigma) & 2(\lambda\nu+\mu\sigma) \\ 2(\mu\lambda+\nu\sigma) & (-\lambda^2+\mu^2-\nu^2+\sigma^2) & 2(\mu\nu-\lambda\sigma) \\ 2(\lambda\nu-\mu\sigma) & 2(\mu\nu+\lambda\sigma) & (-\lambda^2-\mu^2+\nu^2+\sigma^2) \end{pmatrix}.$$

Two further matrices $\boldsymbol{S}$ and $\boldsymbol{T}$ may be defined (Diamond, 1988),

$$\boldsymbol{S} = \begin{pmatrix} -\sigma & \nu & -\mu & \lambda \\ -\nu & -\sigma & \lambda & \mu \\ \mu & -\lambda & -\sigma & \nu \\ \lambda & \mu & \nu & \sigma \end{pmatrix} \text{ and } \boldsymbol{T} = \begin{pmatrix} \sigma & -\nu & \mu & \lambda \\ \nu & \sigma & -\lambda & \mu \\ -\mu & \lambda & \sigma & \nu \\ -\lambda & -\mu & -\nu & \sigma \end{pmatrix},$$

which are themselves orthogonal (though $\boldsymbol{S}$ has determinant -1) and which have the property that

$$\boldsymbol{S}^2 = \begin{pmatrix} \boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}$$

so that, for example, if homogeneous coordinates are being employed (Section 3.3.1.1.2)

$$\begin{pmatrix} x' \\ y' \\ z' \\ w \end{pmatrix} = \begin{pmatrix} -\sigma & \nu & -\mu & \lambda \\ -\nu & -\sigma & \lambda & \mu \\ \mu & -\lambda & -\sigma & \nu \\ \lambda & \mu & \nu & \sigma \end{pmatrix}\begin{pmatrix} -\sigma & \nu & -\mu & \lambda \\ -\nu & -\sigma & \lambda & \mu \\ \mu & -\lambda & -\sigma & \nu \\ \lambda & \mu & \nu & \sigma \end{pmatrix}\begin{pmatrix} x \\ y \\ z \\ w \end{pmatrix}$$

is a rotation of (x, y, z, w) through the angle θ about the axis (l, m, n). With suitably pipelined hardware this forms an efficient means of applying rotations since the 'overhead' of establishing $\boldsymbol{S}$ is so trivial.

$\boldsymbol{T}$ has the property that the rotation vector $\boldsymbol{\rho}$ arising from a concatenation of n rotations is

$$\boldsymbol{\rho} = \boldsymbol{T}_n\boldsymbol{T}_{n-1}\ldots\boldsymbol{T}_1\boldsymbol{\rho}_0,$$

in which $\boldsymbol{\rho}_0^T$ is the vector (0, 0, 0, 1) which defines a null rotation. This equation may be used as a basis for factorizing a given rotation into a concatenation of rotations about designated axes (Diamond, 1990*a*).

Finally, an exact rotation of the vector $\mathbf{d}$ may be obtained without using matrices at all by writing

$$\mathbf{d} = \sum_0^\infty \mathbf{d}_n$$

in which

$$\mathbf{d}_n = \frac{1}{n}(\boldsymbol{\theta}\times\mathbf{d}_{n-1})$$

and $\mathbf{d}_0$ is the initial position which is to be rotated. Here $\boldsymbol{\theta}$ is a vector with direction cosines l, m and n, and magnitude equal to

the required rotation angle in radians (Diamond, 1966). This method is particularly efficient when $|\boldsymbol{\theta}| \ll 1$ or when the number of vectors to be transformed is small since the overhead of establishing $\boldsymbol{R}$ is eliminated and the process is simple to program. It is the three-dimensional analogue of the power series for $\sin\theta$ and $\cos\theta$ and has the same convergence properties.

3.3.1.2.2. Measurement of rotations and strains from coordinates

Given the coordinates of a molecular fragment it is often a requirement to relate the fragment to its image in some standard orientation by a transformation which may be required to be a pure rotation, or may be required to be a combination of rotation and strain. Of the methods reviewed in this section all except (iv) are concerned with pure rotation, ignoring any strain that may be present, and give the best rigid-body superposition. In all these methods, unless inhomogeneous strain is being considered, the best possible superposition is obtained if the centroids of the two images are first brought into coincidence by translation and treated as the origin.

Methods (i) to (v) seek transformations which perform the superposition and impose on these, in various ways, the requirements of orthogonality for the rotational part. All these methods therefore need some defence against indeterminacy that arises in the general transformation if one or both of the fragments is planar, and, if improper rotations are to be excluded, need a defence against these also if the fragment and its image are of opposite chirality. Methods (vi) and (vii) pay no attention to the general transformation (which defines the general superposition) and work with variables which are intrinsically rotational in character, and always produce an orthogonal transformation with positive determinant, with no degeneracy arising from planar fragments which need no special attention. Even collinear atoms cause no problem, the superposition being performed correctly but with an arbitrary rotation about the length of the line being present in the result. These methods are therefore to be preferred over the earlier ones unless the purpose of the operation is to detect differences of chirality, although this, too, can be detected with a simple test.

In this review we adopt the same notation for all the methods which, unavoidably, means that symbols are used in ways which differ from the original publications. We use the symbol $\boldsymbol{x}$ for the vector set which is to be rotated and $\boldsymbol{X}$ for the vector set whose orientation is not to be altered, and write the residuals as

$$e_{IA} = D_{Ij}x_{jA} - X_{IA}$$

and, by choice of origin,

$$W_a x_{Ia} = W_a X_{Ia} = 0_I$$

for weights W. The quadratic residual to be minimized is

$$E = W_a e_{ia} e_{ia}$$

and we define the matrix $M_{IJ} = W_a x_{Ia} X_{Ja}$ and use $\mathbf{l}$ for the direction cosines of the rotation axis.

(i) McLachlan's first method (McLachlan, 1972, 1982) is iterative and conceptually the simplest. It sets

$$D_{IJ} = A_{Ik}R_{kJ}$$

in which $\boldsymbol{A}$ and $\boldsymbol{R}$ are both orthogonal with $\boldsymbol{R}$ being a current estimate of $\boldsymbol{D}$ and $\boldsymbol{A}$ being an adjustment which, at the beginning of each cycle, has a zero angle associated with it. One iterative cycle estimates a nontrivial $\boldsymbol{A}$, after which the product $\boldsymbol{AR}$ replaces $\boldsymbol{R}$.

$$A_{IJ} = (1 - \cos\theta)l_I l_J + \delta_{IJ}\cos\theta - \varepsilon_{IJk}l_k \sin\theta$$

and

$$\left(\frac{\partial A_{IJ}}{\partial\theta}\right)_{\theta=0} = -\varepsilon_{IJk}l_k,$$

therefore

$$\left(\frac{\partial E}{\partial\theta}\right)_{\theta=0} = 2W_a\left(\frac{\partial A_{ij}}{\partial\theta}\right)_{\theta=0} R_{jk}x_{ka}(A_{il}R_{lm}x_{ma} - X_{ia})$$
$$= 2\varepsilon_{ijl}R_{jk}M_{ki}l_l.$$

For this to vanish for all possible rotation axes $\mathbf{l}$ the vector

$$g_L = \varepsilon_{ijL}R_{jk}M_{ki}$$

must vanish, *i.e.* at the end of the iteration $\boldsymbol{R}$ must be such that the matrix

$$N_{JI} = R_{Jk}M_{kI}$$

is symmetrical. The vector $\mathbf{g}$ represents the couple exerted on the rotating body by forces $2W_A(R_{Ij}x_{jA} - X_{IA})$ acting at the atoms. Choosing

$$l_L = g_L/|\mathbf{g}|$$

gives the greatest $|\partial E/\partial\theta|_{\theta=0}$ and $(\partial E/\partial\theta)$ vanishes when

$$\tan\theta = \frac{\varepsilon_{ijk}N_{ji}l_k}{N_{pq}(l_p l_q - \delta_{pq})}$$

in which $\boldsymbol{N}$ is constructed from the current $\boldsymbol{R}$ matrix. $\boldsymbol{A}$ is then constructed from $\mathbf{l}$ and this θ and $\boldsymbol{AR}$ replaces $\boldsymbol{R}$. The process is iterative because a couple about some new axis can appear when rotation about $\mathbf{g}$ eliminates the couple about $\mathbf{g}$.

Note that for each rotation axis $\mathbf{l}$ there are two values of θ, differing by π, which reduce $|\mathbf{g}|$ to zero, corresponding to maximum and minimum values of E. The minimum is that which makes

$$\frac{\partial^2 E}{\partial\theta^2} = 2(\text{tr } N - l_i N_{ij} l_j)$$

positive. Adding π to θ alters $\boldsymbol{R}$ and $\boldsymbol{N}$ and negates this quantity.

Note, too, that the process is essentially characterized as that which makes the product $\boldsymbol{RM}$ symmetrical with $\boldsymbol{R}$ orthogonal. We return to this point in (iii).

(ii) Kabsch's method (Kabsch, 1976, 1978) minimizes E with respect to the nine elements of $\boldsymbol{D}$, subject to the six constraints

$$D_{kI}D_{kJ} - \delta_{IJ} = 0_{IJ},$$

by using an auxiliary function

$$F = L_{ij}(D_{ki}D_{kj} - \delta_{ij})$$

in which $\boldsymbol{L}$ is symmetric containing six Lagrange multipliers. The Lagrangian function

$$G = E + F$$

then has minima with respect to the elements of $\boldsymbol{D}$ at locations which are dependent, *inter alia*, on the elements of $\boldsymbol{L}$. By suitably choosing $\boldsymbol{L}$ a minimum of G may be brought into coincidence with the constrained minimum of $\boldsymbol{E}$. A minimum of G occurs where

$$\frac{\partial G}{\partial D_{IJ}} = 2D_{Ik}(S_{Jk} + L_{Jk}) - 2M_{JI} = 0_{IJ}$$

and the 9×9 matrix

$$\frac{\partial^2 G}{\partial D_{MK}\partial D_{IJ}} = 2\delta_{MI}(S_{JK} + L_{JK})$$

is positive definite, block diagonal, and has

$$S_{JK} = W_a x_{Ja} x_{Ka}$$

which is symmetrical. Thus $\boldsymbol{L}$ must be chosen so as to make the symmetric matrix $(\boldsymbol{S}+\boldsymbol{L})$ such that

$$\boldsymbol{D}(\boldsymbol{S}+\boldsymbol{L})^T = \boldsymbol{M}^T$$

with $\boldsymbol{D}$ orthogonal, or $\boldsymbol{RN} = \boldsymbol{M}^T$ with $\boldsymbol{R}$ replacing $\boldsymbol{D}$ since we are now confined to the orthogonal case, and $\boldsymbol{N}$ is symmetric and positive definite.

(iii) Comparison of the Kabsch and McLachlan methods. Using the initials of these authors as subscripts, we have seen that the Kabsch solution involves solving

$$\boldsymbol{R}_{\rm WK}\boldsymbol{N}_{\rm WK} = \boldsymbol{M}^T$$

for an orthogonal matrix $\boldsymbol{R}_{\rm WK}$ given that $\boldsymbol{N}_{\rm WK}$ is symmetrical and positive definite. Thus

$$\boldsymbol{M}\boldsymbol{M}^T = \boldsymbol{N}_{\rm WK}^T\boldsymbol{R}_{\rm WK}^T\boldsymbol{R}_{\rm WK}\boldsymbol{N}_{\rm WK} = \boldsymbol{N}_{\rm WK}^2$$

and

$$\boldsymbol{R}_{\rm WK} = \boldsymbol{M}^T(\boldsymbol{M}\boldsymbol{M}^T)^{-1/2}.$$

By comparison, the McLachlan treatment leads to an orthogonal $\boldsymbol{R}$ matrix satisfying

$$\boldsymbol{R}_{\rm ADM} = \boldsymbol{N}_{\rm ADM}\boldsymbol{M}^{-1}$$

in which $\boldsymbol{N}_{\rm ADM}$ is also symmetric and positive definite, which similarly leads to

$$\boldsymbol{R}_{\rm ADM} = (\boldsymbol{M}^T\boldsymbol{M})^{1/2}\boldsymbol{M}^{-1}.$$

These seemingly different expressions for $\boldsymbol{R}_{\rm WK}$ and $\boldsymbol{R}_{\rm ADM}$ are, in fact, equal, as the following shows

$$\boldsymbol{R}_{\rm WK} = \boldsymbol{R}_{\rm ADM}\boldsymbol{R}_{\rm ADM}^{-1}\boldsymbol{R}_{\rm WK} = \boldsymbol{R}_{\rm ADM}\boldsymbol{M}\boldsymbol{N}_{\rm ADM}^{-1}\boldsymbol{M}^T\boldsymbol{N}_{\rm WK}^{-1},$$

therefore

$$\begin{aligned}\boldsymbol{R}_{\rm WK}^T\boldsymbol{R}_{\rm WK} &= \boldsymbol{I}\\ &= \boldsymbol{N}_{\rm WK}^{-1}\boldsymbol{M}\boldsymbol{N}_{\rm ADM}^{-1}\boldsymbol{M}^T\boldsymbol{R}_{\rm ADM}^T\boldsymbol{R}_{\rm ADM}\boldsymbol{M}\boldsymbol{N}_{\rm ADM}^{-1}\boldsymbol{M}^T\boldsymbol{N}_{\rm WK}^{-1}.\end{aligned}$$

Multiplying on both sides by $\boldsymbol{N}_{\rm WK}$ gives

$$\boldsymbol{N}_{\rm WK}^2 = (\boldsymbol{M}\boldsymbol{N}_{\rm ADM}^{-1}\boldsymbol{M}^T)^2,$$

and since both $\boldsymbol{N}$ matrices are positive definite

$$\boldsymbol{N}_{\rm WK} = \boldsymbol{M}\boldsymbol{N}_{\rm ADM}^{-1}\boldsymbol{M}^T$$

and conversely

$$\boldsymbol{N}_{\rm ADM} = \boldsymbol{M}^T\boldsymbol{N}_{\rm WK}^{-1}\boldsymbol{M},$$

therefore

$$\boldsymbol{R}_{\rm WK} = \boldsymbol{M}^T\boldsymbol{M}^{T-1}\boldsymbol{N}_{\rm ADM}\boldsymbol{M}^{-1} = \boldsymbol{R}_{\rm ADM}.$$

(iv) Diamond's first method. This method (Diamond, 1976*a*) differs from the previous ones in that the transformation $\boldsymbol{D}$ is allowed to be a general transformation which is then factorized into the product of an orthogonal matrix $\boldsymbol{R}$ and a symmetrical matrix $\boldsymbol{T}$. The transformation of $\boldsymbol{x}$ to fit $\boldsymbol{X}$ is thus interpreted as the combination of homogeneous strain and pure rotation in which $\boldsymbol{x}$ is subjected to strain and the result is rotated.

$$\begin{aligned}\boldsymbol{D} &= \boldsymbol{R}\boldsymbol{T}\\ \boldsymbol{T}^2 &= \boldsymbol{D}^T\boldsymbol{D}\\ \boldsymbol{T} &= (\boldsymbol{D}^T\boldsymbol{D})^{1/2}\\ \boldsymbol{R} &= \boldsymbol{D}(\boldsymbol{D}^T\boldsymbol{D})^{-1/2}.\end{aligned}$$

Furthermore, the solution for $\boldsymbol{D}$ is

$$\boldsymbol{D} = \boldsymbol{M}^T\boldsymbol{S}^{-1}$$

(in the notation of Kabsch), so that

$$\boldsymbol{R} = \boldsymbol{M}^T\boldsymbol{S}^{-1}(\boldsymbol{S}^{-1}\boldsymbol{M}\boldsymbol{M}^T\boldsymbol{S}^{-1})^{-1/2}$$

which may be compared with the results of the previous paragraph.

Although this $\boldsymbol{R}$ matrix by itself (*i.e.* applied without $\boldsymbol{T}$) does not produce the best rotational superposition (*i.e.* smallest E), it is the one which *exactly* superposes the only three vectors in $\boldsymbol{x}$ whose mutual dispositions are conserved, on their equivalents in $\boldsymbol{X}$, so that the rotation so found is arguably the best defined one.

Alternatives based on $\boldsymbol{D} = \boldsymbol{T}\boldsymbol{R}$, $\boldsymbol{D}^{-1} = \boldsymbol{R}\boldsymbol{T}$, $\boldsymbol{D}^{-1} = \boldsymbol{T}\boldsymbol{R}$ are all easily developed, and these ideas are developed by Diamond (1976*a*) to include nonhomogeneous strains also.

(v) McLachlan's second method. This method (McLachlan, 1979) is based on the properties of the 6×6 matrix

$$\begin{pmatrix}\boldsymbol{0} & \boldsymbol{M}\\ \boldsymbol{M}^T & \boldsymbol{0}\end{pmatrix}$$

and is immune to singularity of $\boldsymbol{M}$. If $\mathbf{p}$ and $\mathbf{q}$ are three-dimensional vectors such that $(\mathbf{p}^T, \mathbf{q}^T)$ is an eigenvector of this matrix then

$$\begin{pmatrix}\boldsymbol{0} & \boldsymbol{M}\\ \boldsymbol{M}^T & \boldsymbol{0}\end{pmatrix}\begin{pmatrix}\mathbf{p}\\ \mathbf{q}\end{pmatrix} = \begin{pmatrix}\boldsymbol{M}\mathbf{q}\\ \boldsymbol{M}^T\mathbf{p}\end{pmatrix} = \begin{pmatrix}\mathbf{p}\lambda\\ \mathbf{q}\lambda\end{pmatrix}.$$

If $\mathbf{q}$ is negated the second equality is maintained provided λ is also negated. Therefore an orthogonal 6×6 matrix

$$\begin{pmatrix}\boldsymbol{H} & \boldsymbol{H}\\ \boldsymbol{K} & -\boldsymbol{K}\end{pmatrix}$$

(consisting of 3×3 partitions) exists for which

$$\begin{pmatrix}\boldsymbol{H}^T & \boldsymbol{K}^T\\ \boldsymbol{H}^T & -\boldsymbol{K}^T\end{pmatrix}\begin{pmatrix}\boldsymbol{0} & \boldsymbol{M}\\ \boldsymbol{M}^T & \boldsymbol{0}\end{pmatrix}\begin{pmatrix}\boldsymbol{H} & \boldsymbol{H}\\ \boldsymbol{K} & -\boldsymbol{K}\end{pmatrix} = \begin{pmatrix}\boldsymbol{\Lambda} & \boldsymbol{0}\\ \boldsymbol{0} & -\boldsymbol{\Lambda}\end{pmatrix}$$

in which $\boldsymbol{\Lambda}$ is diagonal and contains non-negative eigenvalues. The reverse transformation shows that

$$\boldsymbol{M} = 2\boldsymbol{H}\boldsymbol{\Lambda}\boldsymbol{K}^T$$

and multiplying the eigenvectors together gives

$$\boldsymbol{H}^T\boldsymbol{H} = \boldsymbol{K}^T\boldsymbol{K} = \tfrac{1}{2}\boldsymbol{I} = \boldsymbol{H}\boldsymbol{H}^T = \boldsymbol{K}\boldsymbol{K}^T.$$

Therefore

$$2\boldsymbol{K}\boldsymbol{H}^T\boldsymbol{M} = 4\boldsymbol{K}\boldsymbol{H}^T\boldsymbol{H}\boldsymbol{\Lambda}\boldsymbol{K}^T = 2\boldsymbol{K}\boldsymbol{\Lambda}\boldsymbol{K}^T,$$

but $2\boldsymbol{K}\boldsymbol{H}^T$ is orthogonal and $2\boldsymbol{K}\boldsymbol{\Lambda}\boldsymbol{K}^T$ is symmetrical, therefore [by paragraphs (i) and (iii) above] $2\boldsymbol{K}\boldsymbol{H}^T$ is the required rotation. Similarly, forming

$$\begin{aligned}\boldsymbol{M}^T &= 2\boldsymbol{K}\boldsymbol{\Lambda}\boldsymbol{H}^T\\ 2\boldsymbol{M}^T\boldsymbol{H}\boldsymbol{\Lambda}^{-1}\boldsymbol{H}^T &= 4\boldsymbol{K}\boldsymbol{\Lambda}\boldsymbol{H}^T\boldsymbol{H}\boldsymbol{\Lambda}^{-1}\boldsymbol{H}^T = 2\boldsymbol{K}\boldsymbol{H}^T\end{aligned}$$

corresponds to the Kabsch formulation [paragraphs (ii) and (iii)] since $2\boldsymbol{H}\boldsymbol{\Lambda}^{-1}\boldsymbol{H}^T$ is symmetrical and the same rotation, $2\boldsymbol{K}\boldsymbol{H}^T$, appears.

Note that the determinant of the orthogonal matrix so found is twice the product of the determinants of $\boldsymbol{H}$ and of $\boldsymbol{K}$, and since the positive eigenvalues are collected into $\boldsymbol{\Lambda}$ it follows that the sign of the determinant of $\boldsymbol{M}$ is the same as the sign of the determinant of the resulting orthogonal matrix. If this is negative it means that the best superposition is obtained if one vector set is inverted and that $\boldsymbol{x}$ and $\boldsymbol{X}$ are of opposite chirality.

Expanding the expression for E, the weighted sum of squares of errors, for an orthogonal transformation shows that this is least when the trace of the product $\boldsymbol{RM}$ is greatest. In this treatment

$$\mathrm{tr}(\boldsymbol{RM}) = \mathrm{tr}(2\boldsymbol{KH}^T \cdot 2\boldsymbol{H\Lambda K}^T) = \mathrm{tr}(2\boldsymbol{K\Lambda K}^T) = \mathrm{tr}(\boldsymbol{\Lambda}).$$

Hence, if the eigenvalues in $\boldsymbol{\Lambda}$ and $-\boldsymbol{\Lambda}$ are arranged in decreasing order of modulus, and if the determinant of $\boldsymbol{M}$ is negative, then exchanging the third and sixth columns of

$$\begin{pmatrix} \boldsymbol{H} & \boldsymbol{H} \\ \boldsymbol{K} & -\boldsymbol{K} \end{pmatrix}$$

produces a product $2\boldsymbol{KH}^T$ with positive determinant (*i.e.* a proper rotation) at minimum cost in residual. Similarly, if $\boldsymbol{M}$ is singular and one or more eigenvalues in $\boldsymbol{\Lambda}$ vanishes it is necessary only to complete an orthonormal set of eigenvectors such that the determinants of $\boldsymbol{H}$ and $\boldsymbol{K}$ have the same sign.

(vi) MacKay's method. MacKay (1984) was the first to consider the rotational superposition problem in terms of the vector $\mathbf{r}$ of Section 3.3.1.2.1. Using quaternion algebra he showed that if a vector $\mathbf{x}$ is rotated to $\mathbf{X} = \boldsymbol{R}\mathbf{x}$ then

$$(\mathbf{X} - \mathbf{x}) = \mathbf{r} \times (\mathbf{X} + \mathbf{x}),$$

where $|\mathbf{r}| = \tan(\theta/2)$ and the direction of $\mathbf{r}$ is the axis of rotation, as may also be shown from elementary considerations. MacKay then solves this for the vector $\mathbf{r}$ by least squares given the vector pairs $\mathbf{X}$ and $\mathbf{x}$. The individual errors are

$$e_{IA} = \varepsilon_{Ijk} r_j (X_{kA} + x_{kA}) - (X_{IA} - x_{IA})$$

and

$$E = W_a e_{ia} e_{ia}.$$

Setting $\partial E/\partial r_P = 0_P$ gives

$$\begin{aligned} W_a \varepsilon_{iPk} \varepsilon_{ilm} r_l (X_{ka} + x_{ka})(X_{ma} + x_{ma}) \\ = W_a \varepsilon_{iPk} (X_{ka} + x_{ka})(X_{ia} - x_{ia}) \end{aligned}$$

which reduces to

$$2\mathbf{V} = -(\boldsymbol{Q} + \boldsymbol{Q}_0)\mathbf{r}$$

in which

$$\begin{aligned} \boldsymbol{Q} &= \boldsymbol{M} + \boldsymbol{M}^T - 2\boldsymbol{I}\,\mathrm{tr}\,\boldsymbol{M} \\ \boldsymbol{Q}_0 &= \boldsymbol{S} + \boldsymbol{S}' - \boldsymbol{I}(\mathrm{tr}\,\boldsymbol{S} + \mathrm{tr}\,\boldsymbol{S}') \\ V_I &= \varepsilon_{Ijk} M_{jk} \\ S_{IJ} &= W_a x_{Ia} x_{Ja} \\ S'_{IJ} &= W_a X_{Ia} X_{Ja}. \end{aligned}$$

Thus a direct solution for $\mathbf{r}$ is obtained,

$$\mathbf{r} = -2(\boldsymbol{Q}_0 + \boldsymbol{Q})^{-1}\mathbf{V},$$

the elements of which are u, v and w, and may be used to construct the orthogonal matrix as in Section 3.3.1.2.1. $\boldsymbol{Q} + \boldsymbol{Q}_0$ may be obtained directly from $\boldsymbol{X} + \boldsymbol{x}$.

If the requisite rotation is 180°, $(\boldsymbol{Q}_0 + \boldsymbol{Q})$ is singular and cannot be inverted. In this case any row or column of the adjoint of $(\boldsymbol{Q}_0 + \boldsymbol{Q})$ is a vector in the direction of the axis. Normalizing this vector to unity, giving $\boldsymbol{l}$, gives the requisite orthogonal matrix as

$$\boldsymbol{R} = 2\boldsymbol{ll}^T - \boldsymbol{I}.$$

Note that MacKay's residual E is quadratic in $\mathbf{r}$. E therefore has one minimum and no maximum, and the minimum is reached on the first cycle of least squares. By contrast, the objective function E that is minimized in methods (i), (ii), (v) and (vii) has one minimum, one maximum and two saddle points in the space of the vector $\mathbf{r}$, as shown in (vii).

It may be shown (Diamond, 1989) that if MacKay's solution vector $\mathbf{r}$ is denoted by $\mathbf{r}_\mathrm{M}$ and that given by the other methods [except (iv)] by $\mathbf{r}_\mathrm{O}$ then

$$\mathbf{r}_\mathrm{M} = \mathbf{r}_\mathrm{O} - \boldsymbol{A}^{-1}\boldsymbol{B}\mathbf{r}_\mathrm{O}$$

in which $\boldsymbol{A}$ and $\boldsymbol{B}$ are real symmetric, positive semi-definite. $\boldsymbol{A}$ is positive definite unless all the individual vector sums $(\mathbf{X} + \mathbf{x})$ are parallel, as can happen when the best rotation is 180°. Thus the MacKay method only gives the same result as the other methods if:

(*a*) the initial orientation is optimal, for then $\mathbf{r}_\mathrm{O} = \mathbf{0}$, or

(*b*) perfect fitting is possible, for then $\boldsymbol{B} = \mathbf{0}$, or

(*c*) all the residual vectors (after fitting by $\mathbf{r}_\mathrm{O}$) are parallel to $\mathbf{r}_\mathrm{O}$, for then $\boldsymbol{B}$ is singular such that $\boldsymbol{B}\mathbf{r}_\mathrm{O} = \mathbf{0}$. In general, $|\mathbf{r}_\mathrm{M}| \leq |\mathbf{r}_\mathrm{O}|$. $\mathbf{r}_\mathrm{O}$ may be found by iterating $\mathbf{r}_\mathrm{M}$, but $\boldsymbol{x}$ must be replaced by $\boldsymbol{Rx}$ on each iteration.

(vii) Diamond's second method. This is closely related to MacKay's method, but uses a four-dimensional vector $\boldsymbol{\rho}$ with components λ, μ, ν and σ in which λ, μ and ν are the direction cosines of the rotation axis multiplied by $\sin(\theta/2)$ and σ is $\cos(\theta/2)$. In terms of such a vector Diamond (1988) showed that

$$E = E_0 - 2\boldsymbol{\rho}^T\boldsymbol{P}\boldsymbol{\rho}$$

in which E is the weighted sum of squares of coordinate differences, as before, E_0 is its value before any rotation is applied and $\boldsymbol{P}$ is the matrix

$$\boldsymbol{P} = \begin{pmatrix} \boldsymbol{Q} & \mathbf{V} \\ \mathbf{V}^T & 0 \end{pmatrix}.$$

The rotation matrix $\boldsymbol{R}$ corresponding to the vector $\boldsymbol{\rho}$ is then the last of the forms for $\boldsymbol{R}$ given in Section 3.3.1.2.1.

The minimum E is therefore E_0 minus twice the largest eigenvalue of $\boldsymbol{P}$ since $\boldsymbol{\rho}^T\boldsymbol{\rho} = 1$, and a stationary value of E occurs when $\boldsymbol{\rho}$ is any of the four eigenvectors of $\boldsymbol{P}$. E thus has a maximum, a minimum and two saddle points, in general, and its value may be determined before any coordinates are transformed. Diamond also showed that the orientations giving these stationary values are related by the operations of 222 symmetry. Equivalent results have also been obtained by Kearsley (1989).

As an alternative to solving a 4×4 eigenproblem, Diamond also showed that the vector $\mathbf{r}$, as in MacKay's solution, may be obtained by iterating

$$\begin{aligned} \alpha_0 &= E_0/2 \\ \mathbf{r}_n &= (\alpha_n \boldsymbol{I} - \boldsymbol{Q})^{-1}\mathbf{V} \\ \alpha_{n+1} &= \frac{\mathbf{V} \cdot \mathbf{r}_n + \alpha_n r_n^2}{1 + r_n^2} \end{aligned}$$

which has the property that if $\boldsymbol{X}$ and $\boldsymbol{x}$ are exactly superposable then α_0 is the exact solution and no iteration is necessary. If $\boldsymbol{X}$ and $\boldsymbol{x}$ are similar but not exactly superposable then a small number of iterations may be required to reach a stable $\mathbf{r}$ vector, though the matrix $\boldsymbol{Q}_0$ is not required. As in MacKay's solution, $(\alpha\boldsymbol{I} - \boldsymbol{Q})$ is singular at the end of the iteration if the required rotation is 180°, but the MacKay and Diamond methods both have the advantage that improper rotations are never generated by these means, and methods based on $\boldsymbol{P}$ and $\boldsymbol{\rho}$ rather than $\boldsymbol{Q}$ and $\mathbf{r}$ are trouble-free

for 180° rotations. The iterative loop in this method does not require $\boldsymbol{Rx}$ to be redetermined on each cycle.

Finally, it may be shown that if p_1, p_2, p_3, p_4 are the eigenvalues of $\boldsymbol{P}$ arranged in descending order and

$$p_1 - p_2 - p_3 + p_4$$

is negative, then a closer superposition may be obtained by reversing the chirality of one of the vector sets, and the $\boldsymbol{R}$ matrix constructed from $\boldsymbol{\rho}_4$ optimally superimposes $\boldsymbol{Rx}$ onto $-\boldsymbol{X}$, the enantiomer of $\boldsymbol{X}$ (Diamond, 1990*b*).

These ideas lend themselves to the problem of the multiple simultaneous superposition of many structures, which is a nonlinear problem with the possibility of multiple solutions [Diamond (1992); see also Kearsley (1990) and Shapiro *et al.* (1992)], and they can provide for cluster analysis based on structural similarity to find subsets of similar structures within an ensemble of structures, such as may arise from NMR calculations (Diamond, 1995).

3.3.1.2.3. Orthogonalization of impure rotations

There are several ways of deriving a strictly orthogonal matrix from a given approximately orthogonal matrix, among them the following.

(i) The Gram–Schmidt process. This is probably the simplest and the easiest to compute. If the given matrix consists of three column vectors $\mathbf{v}_1$, $\mathbf{v}_2$ and $\mathbf{v}_3$ (later referred to as primers) which are to be replaced by three column vectors $\mathbf{u}_1$, $\mathbf{u}_2$ and $\mathbf{u}_3$ then the process is

$$\begin{aligned}
\mathbf{u}_1 &= \mathbf{v}_1/|\mathbf{v}_1| \\
\mathbf{u}_2 &= \mathbf{v}_2 - (\mathbf{u}_1 \cdot \mathbf{v}_2)\mathbf{u}_1 \\
\mathbf{u}_2 &= \mathbf{u}_2/|\mathbf{u}_2| \\
\mathbf{u}_3 &= \mathbf{v}_3 - (\mathbf{u}_1 \cdot \mathbf{v}_3)\mathbf{u}_1 - (\mathbf{u}_2 \cdot \mathbf{v}_3)\mathbf{u}_2 \\
\mathbf{u}_3 &= \mathbf{u}_3/|\mathbf{u}_3|.
\end{aligned}$$

As successive vectors are established, each vector $\mathbf{v}$ has subtracted from it its components in the directions of established vectors, and the remainder is normalized. The method will fail at the normalization step if the vectors $\mathbf{v}$ are not linearly independent. Otherwise, the process may be extended to any number of dimensions.

The weakness of the method is that, though $\mathbf{u}_1$ differs from $\mathbf{v}_1$ only in scale, $\mathbf{u}_N$ may differ grossly from $\mathbf{v}_N$ as the various columns are not treated equivalently.

(ii) A preferable method which treats all vectors equivalently is to iteratively replace the matrix $\boldsymbol{M}$ by $\frac{1}{2}(\boldsymbol{M} + \boldsymbol{M}^{T-1})$.

Defining the residual matrix $\boldsymbol{E}$ as

$$\boldsymbol{E} = \boldsymbol{M}\boldsymbol{M}^T - \boldsymbol{I},$$

then on each iteration $\boldsymbol{E}$ is replaced by

$$\boldsymbol{E}^2(\boldsymbol{M}\boldsymbol{M}^T)^{-1}/4$$

and convergence necessarily ensues.

(iii) A third method resolves $\boldsymbol{M}$ into its symmetric and antisymmetric parts

$$\boldsymbol{S} = \tfrac{1}{2}(\boldsymbol{M} + \boldsymbol{M}^T), \quad \boldsymbol{A} = \tfrac{1}{2}(\boldsymbol{M} - \boldsymbol{M}^T), \quad \boldsymbol{M} = \boldsymbol{S} + \boldsymbol{A}$$

and constructs an orthogonal matrix for which only $\boldsymbol{S}$ is altered. $\boldsymbol{A}$ determines l, m, n and θ as shown in Section 3.3.1.2.1, and from these a new $\boldsymbol{S}$ may be constructed.

(iv) A fourth method is to treat the general matrix $\boldsymbol{M}$ as a combination of pure strain and pure rotation. Setting

$$\boldsymbol{M} = \boldsymbol{R}\boldsymbol{T}$$

with $\boldsymbol{R}$ orthogonal and $\boldsymbol{T}$ symmetrical gives

$$\boldsymbol{T} = (\boldsymbol{M}^T\boldsymbol{M})^{1/2}, \quad \boldsymbol{R} = \boldsymbol{M}(\boldsymbol{M}^T\boldsymbol{M})^{-1/2}.$$

The rotation so found is the one which exactly superposes those three mutually perpendicular directions which remain mutually perpendicular under the transformation $\boldsymbol{M}$.

$\boldsymbol{T} - \boldsymbol{I}$ is then the strain tensor of an unrotated body.

Writing $\boldsymbol{M} = \boldsymbol{T}\boldsymbol{R}$, $\boldsymbol{T} = (\boldsymbol{M}\boldsymbol{M}^T)^{1/2}$, $\boldsymbol{R} = (\boldsymbol{M}\boldsymbol{M}^T)^{-1/2}\boldsymbol{M}$ may also be useful, in which $\boldsymbol{T} - \boldsymbol{I}$ is the strain tensor of a rotated body. See also Section 3.3.1.2.2 (iv).

3.3.1.2.4. Eigenvalues and eigenvectors of orthogonal matrices

If $\boldsymbol{R}$ is the orthogonal matrix given in Section 3.3.1.2.1 in terms of the direction cosines l, m and n of the axis of rotation, then it is clear that (l, m, n) is an eigenvector of $\boldsymbol{R}$ with eigenvalue unity because

$$\boldsymbol{R}\begin{pmatrix} l \\ m \\ n \end{pmatrix} = \begin{pmatrix} l \\ m \\ n \end{pmatrix}.$$

Consideration of the determinant $|\boldsymbol{R} - \lambda\boldsymbol{I}| = 0$ shows that the sum of the three eigenvalues is $1 + 2\cos\theta$ and that their product is unity. Hence the three eigenvalues are 1, $e^{i\theta}$ and $e^{-i\theta}$. Since $\boldsymbol{R}$ is real, its product with any real vector is also real, yet its product with an eigenvector must, in general, be complex. Thus the eigenvectors must themselves be complex.

The remaining two eigenvectors $\mathbf{u}$ may be found using the results of Section 3.3.1.2.1 (*q.v.*) according to

$$\boldsymbol{R}\mathbf{u} = \mathbf{u} + \frac{2}{1+t^2}\{(\mathbf{r}\times\mathbf{u}) + [\mathbf{r}\times(\mathbf{r}\times\mathbf{u})]\} = \mathbf{u}e^{\pm i\theta} = \mathbf{u}\frac{1 \pm it}{1 \mp it},$$

which is solved by any vector of the form

$$\mathbf{u} = \mathbf{l}\times\mathbf{v} \mp i\mathbf{l}\times(\mathbf{l}\times\mathbf{v})$$

for any real vector $\mathbf{v}$, where $\mathbf{l}$ is the normalized axis vector, $\mathbf{l}t = \mathbf{r}$, $|\mathbf{l}| = 1$, $t = \tan(\theta/2)$. Eigenvectors for the two eigenvalues may have unrelated $\mathbf{v}$ vectors though the sign choices are coupled. If the vector $\mathbf{v}$ is rotated about $\mathbf{l}$ through an angle φ the corresponding vector $\mathbf{u}$ is multiplied by $e^{-i\varphi}$ and remains an eigenvector. Using superscript signs to denote the sign of θ in the eigenvalue with which each vector is associated, the matrix

$$\boldsymbol{U} = (\mathbf{l},\ \mathbf{u}^+,\ \mathbf{u}^-)$$

has the properties that

$$\boldsymbol{R}\boldsymbol{U} = \boldsymbol{U}\begin{pmatrix} 1 & 0 & 0 \\ 0 & e^{i\theta} & 0 \\ 0 & 0 & e^{-i\theta} \end{pmatrix}$$

and

$$\boldsymbol{U}^{*T}\boldsymbol{U} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2|\mathbf{l}\times\mathbf{v}^+|^2 & 0 \\ 0 & 0 & 2|\mathbf{l}\times\mathbf{v}^-|^2 \end{pmatrix}$$

which places restrictions on $\mathbf{v}$ if this is to be the identity. Note that the 23 element vanishes even in the absence of any relationship between $\mathbf{v}^+$ and $\mathbf{v}^-$.

A convenient form for $\boldsymbol{U}$, symmetrical in the elements of $\mathbf{l}$, is obtained by setting $\mathbf{v}^+ = \mathbf{v}^- = [111]$ and is

$$\boldsymbol{U} = \begin{pmatrix} l & \{(m-n) - i[l(l+m+n)-1]\}/d & \{(m-n) + i[l(l+m+n)-1]\}/d \\ m & \{(n-l) - i[m(l+m+n)-1]\}/d & \{(n-l) + i[m(l+m+n)-1]\}/d \\ n & \{(l-m) - i[n(l+m+n)-1]\}/d & \{(l-m) + i[n(l+m+n)-1]\}/d \end{pmatrix}$$

in which the normalizing denominator is given by

$$d = 2\sqrt{1 - lm - mn - nl}.$$

3.3.1.3. Projection transformations and spaces

In the following section we address the question of the relationship between the coordinates of a molecular model and the corresponding coordinates on the screen of the graphics device. A good introduction to this topic is given by Newman & Sproull (1973), and Foley *et al.* (1990) give a comprehensive account of the field, including recent developments, especially those arising from the development of raster-graphics technologies.

3.3.1.3.1. Definitions

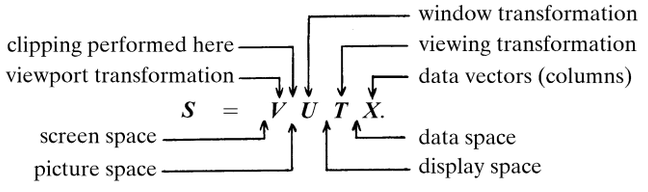
Typically, the coordinates, $\mathbf{X}$, of points in an object to be drawn are held in homogeneous Cartesian form as described in Section 3.3.1.1.2. Such coordinates are said to be in *data space* or world coordinates and this coordinate system is generally a constant aspect of the problem.

In order to view these data in convenient ways such coordinates may be subjected to a 4×4 *viewing transformation* $\boldsymbol{T}$, affecting orientation, scale *etc.*, the resulting coordinates $\boldsymbol{TX}$ being then in *display space*. Here, and throughout what follows, we treat position vectors as columns with transformation matrices as factors on the left, though some writers do the reverse.

In general, only some portion of display space which lies inside a certain frustum of a pyramid is required to fall within the picture. The pyramid may be thought of as having the observer's eye at its vertex, with a rectangular base corresponding to the picture area. This volume is called a *window*. A transformation, $\boldsymbol{U}$, which takes *display-space* coordinates as input and generates vectors (X, Y, Z, W) for which X/W and $Y/W = \pm 1$ for points on the left, right, top and bottom boundaries of the window and for which Z/W takes particular values on the front and back planes of the window, is said to be a *windowing transformation*. In machines for which Z/W controls intensity depth cueing, the range of Z/W corresponding to the window is likely to be 0 to 1 rather than -1 to 1. Coordinates obtained by multiplying display-space coordinates by $\boldsymbol{U}$ are termed *picture-space* coordinates. Mathematically, $\boldsymbol{U}$ is a 4×4 matrix like any other, but functionally it is special. Declaring a transformation to be a windowing transformation implies that only resulting points having $|X|, |Y| < W$ and positive $Z < W$ are to be plotted. Machines with clipping hardware to truncate lines which run out of the picture perform clipping on the output from the windowing transformation.

Finally, the picture has to be drawn in some rectangular portion of the screen which is allocated for the purpose. Such an area is termed a *viewport* and is defined in terms of *screen coordinates* which are defined absolutely for the hardware in question as $\pm n$ for full-screen deflection, where n is declared by the manufacturer. *Screen coordinates* are obtained from picture coordinates with a *viewport transformation*, $\boldsymbol{V}$.[1]

To summarize, screen coordinates, $\mathbf{S}$, are given by



[1] In recent years it has become increasingly common, especially in two-dimensional work, to apply the term 'window' to what is here called a viewport, but in this chapter we use these terms in the manner described in the text.

3.3.1.3.2. Translation

The transformation

$$\begin{pmatrix} N\boldsymbol{I} & \mathbf{V} \\ \mathbf{0}^T & N \end{pmatrix}\begin{pmatrix} \mathbf{X} \\ W \end{pmatrix} = \begin{pmatrix} \mathbf{X}N + \mathbf{V}W \\ NW \end{pmatrix} \simeq \begin{pmatrix} \mathbf{X} + \mathbf{V}W/N \\ W \end{pmatrix} \simeq \begin{pmatrix} \mathbf{X}/W + \mathbf{V}/N \\ 1 \end{pmatrix}$$

evidently corresponds to the addition of the vector $\mathbf{V}W/N$ to the components of $\mathbf{X}$ or of $\mathbf{V}/N$ to the components of $\mathbf{X}/W$. ($\boldsymbol{I}$ is the identity.) Displacements may thus be affected by expressing the required displacement vector in homogeneous coordinates with any suitable choice of N (commonly, $N = W$), with $\mathbf{V}$ scaled to correspond to this choice, and loading the 4×4 transformation matrix as indicated above.

3.3.1.3.3. Rotation

Rotation about the origin is achieved by

$$\begin{pmatrix} N\boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & N \end{pmatrix}\begin{pmatrix} \mathbf{X} \\ W \end{pmatrix} = \begin{pmatrix} N\boldsymbol{R}\mathbf{X} \\ NW \end{pmatrix} \simeq \begin{pmatrix} \boldsymbol{R}\mathbf{X} \\ W \end{pmatrix},$$

in which $\boldsymbol{R}$ is an orthogonal 3×3 matrix. $\boldsymbol{R}$ necessarily has elements not exceeding one in modulus. For machines using integer arithmetic, therefore, N would be chosen large enough (usually half the largest possible integer) for the product $N\boldsymbol{R}$ to be well represented in the available word length. Characteristically, N affects resolution but not scale.

3.3.1.3.4. Scale

The transformation

$$\begin{pmatrix} SN\boldsymbol{I} & \mathbf{0} \\ \mathbf{0}^T & N \end{pmatrix}\begin{pmatrix} \mathbf{X} \\ W \end{pmatrix} = \begin{pmatrix} SN\mathbf{X} \\ NW \end{pmatrix} \simeq \begin{pmatrix} S\mathbf{X} \\ W \end{pmatrix}$$

scales the vector $(\mathbf{X}, W)$ by the factor S. For integer working and $|S| < 1$, N should be set to the largest representable integer. For $|S| > 1$ the product SN should be the largest representable integer, N being reduced accordingly.

3.3.1.3.5. Windowing and perspective

It is necessary at this point to relate the discussion to the axial system inherent in the graphics device employed. One common system adopts X horizontal and to the right when viewing the screen, Y vertically upwards in the plane of the screen, and Z normal to X and Y with $+Z$ into the screen. This is, unfortunately, a left-handed system in that $(\mathbf{X} \times \mathbf{Y}) \cdot \mathbf{Z}$ is negative. Since it is usual in crystallographic work to use right-handed axial systems it is necessary to incorporate a matrix of the form

$$\begin{pmatrix} W & 0 & 0 & 0 \\ 0 & W & 0 & 0 \\ 0 & 0 & -W & 0 \\ 0 & 0 & 0 & W \end{pmatrix}$$

either as the left-most factor in the matrix $\boldsymbol{T}$ or as the right-most factor in the windowing transformation $\boldsymbol{U}$ (see Section 3.3.1.3.1). The latter choice is to be preferred and is adopted here. The former choice leads to complications if transformations in display space will be required. Display-space coordinates are necessarily referred to this axial system.

Let L, R, T, B, N and F be the left, right, top, bottom, near and far boundaries of the windowed volume ($L < R$, $T > B$, $N < F$), S be the Z coordinate of the screen, and C, D and E be the coordinates of the observer's eye position, all ten of these parameters being referred to the origin of display space as origin, which may be anywhere in relation to the hardware. L, R, T and B are to be evaluated in the screen plane. All ten parameters may be referred

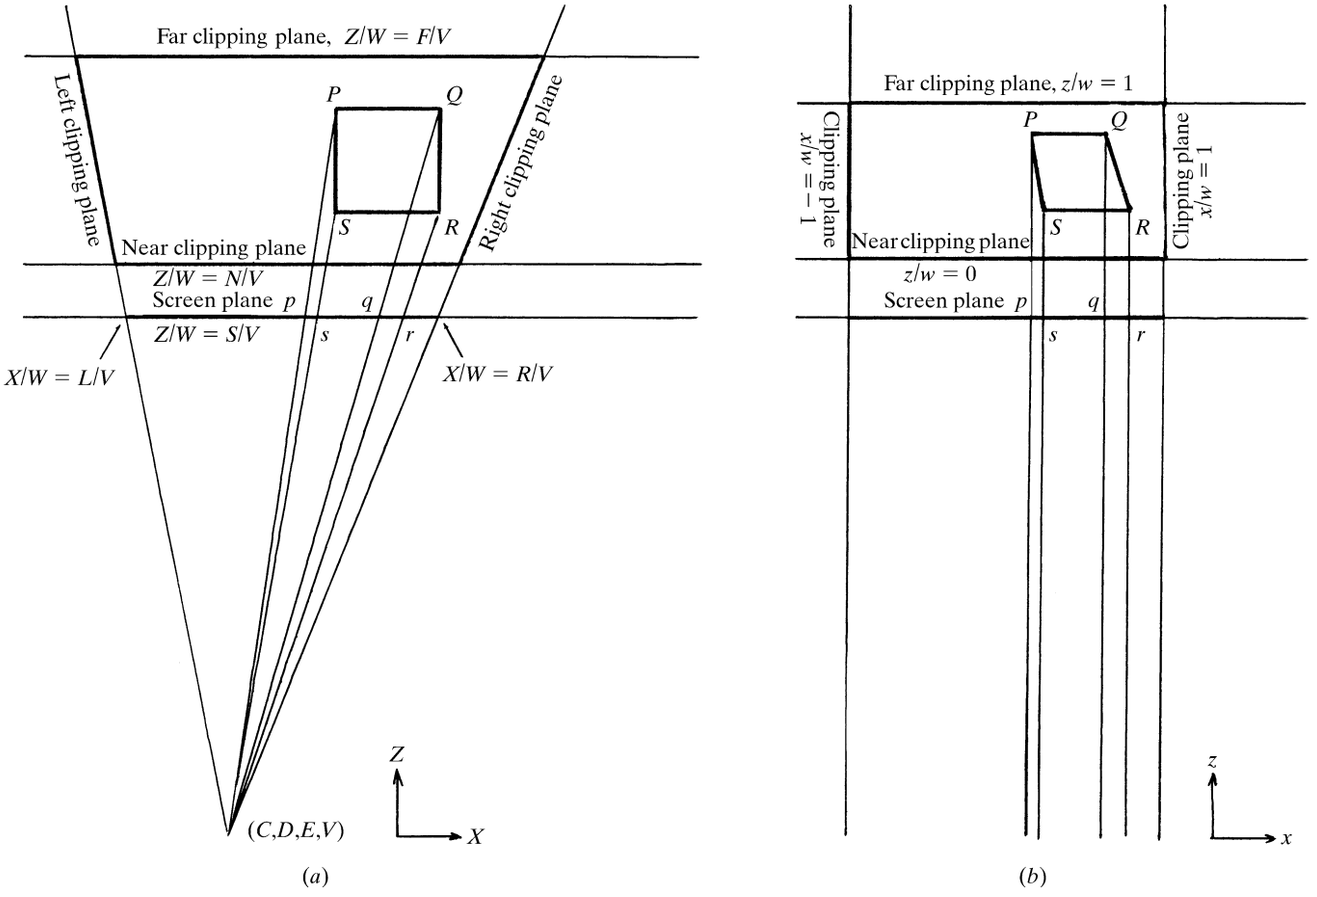


Fig. 3.3.1.1. The relationship between display-space coordinates (X, Y, Z, W) and picture-space coordinates (x, y, z, w) derived from them by the window transformation, $\boldsymbol{U}$. (*a*) Display space (in X, Z projection) showing a square object P, Q, R, S for display viewed from the position (C, D, E, V). The bold trapezium is the window (volume) and the bold line is the viewport portion of the screen. The points P, Q, R and S must be plotted at p, q, r and s to give the correct impression of the object. (*b*) Picture space (in x, z projection). The window is mapped to a rectangle and all sight lines are parallel to the z axis, but the object P, Q, R, S is no longer square. The distribution of p, q, r and s is identical in the two cases. Note that z/w values are not linear on Z/W, and that the origin of picture space arises at the midpoint of the near clipping plane, regardless of the location of the origin of display space. The figure is accurately to scale for coincident viewport positions. The words 'Left clipping plane', if part of the scene in display space, would currently be obscured, but would come into view if the eye moved to the right, increasing C, as the left clipping plane would pivot about the point L/V in the screen plane.

to their own fourth coordinate, V, meaning that the point (X, Y, Z, W) in display space will be on the left boundary of the picture if $X/W = L/V$ when $Z/W = S/V$. V may be freely chosen so that all eleven quantities and all elements of $\boldsymbol{U}$ suit the word length of the machine. These relationships are illustrated in Fig. 3.3.1.1.

Since

$$(X, Y, Z, W) \simeq \left(\frac{XV}{W}, \frac{YV}{W}, \frac{ZV}{W}, V\right),$$

XV/W is a display-space coordinate on the same scale as the window parameters. This must be plotted on the screen at an X coordinate (on the scale of the window parameters) which is the weighted mean of XV/W and C, the weights being $(S - E)$ and $(ZV/W - S)$, respectively. This provides perspective because the weighted mean is at the point where the straight line from (X, Y, Z, W) to the eye intersects the screen. This then has to be mapped into the L-to-R interval, so that picture-space coordinates (x, y, z, w) are given by

$$\begin{pmatrix} x \\ y \\ z \\ w \end{pmatrix} = \begin{pmatrix} \frac{2(S-E)V}{(R-L)} & 0 & \frac{(2C-R-L)V}{(R-L)} & \frac{(R+L)E-2SC}{(R-L)} \\ 0 & \frac{2(S-E)V}{(T-B)} & \frac{(2D-T-B)V}{(T-B)} & \frac{(T+B)E-2SD}{(T-B)} \\ 0 & 0 & \frac{(F-E)V}{(F-N)} & \frac{-N(F-E)}{(F-N)} \\ 0 & 0 & V & -E \end{pmatrix} \begin{pmatrix} X \\ Y \\ Z \\ W \end{pmatrix}$$

which provides for $|x/w|$ and $|y/w|$ to be unity on the picture boundaries, which is usually a requirement of the clipping hardware, and for $0 < z/w < 1$, zero being for the near-plane boundary. Even though z/w is not linear on Z/W, straight lines and planes in display space transform to straight lines and planes in picture space, the nonlinearity affecting only distances. Thus vector-drawing machines are not disadvantaged by the introduction of perspective.

Note that the dimensionality of X/W must equal that of S/V and that this may be regarded as length or as a pure number, but that in either case x/w is dimensionless, consistent with the stipulation that the picture boundaries be defined by the pure number ± 1.

The above matrix is $\boldsymbol{U}$ and is suited to left-handed hardware systems. Note that only the last column of $\boldsymbol{U}$ (the translational part) is sensitive to the location of the origin of display space and that if the eye is on the normal to the picture centre then $C = \frac{1}{2}(R + L)$, $D = \frac{1}{2}(T + B)$ and simplifications result. If C, D and E can be continuously monitored then dynamic parallax as well as perspective may be obtained (Diamond *et al.*, 1982).

If data space is referred to right-handed axes, the viewing transformation $\boldsymbol{T}$ involves only proper rotations and the hardware uses a left-handed axial system then elements in the third column of $\boldsymbol{U}$ should be negated, as explained in the opening paragraph.

To provide for orthographic projection, multiply every element of $\boldsymbol{U}$ by $-K/E$ and then let $E \rightarrow -\infty$, choosing some positive K

to suit the word length of the machine [see Section 3.3.1.1.2 (iii)]. The result is

$$\boldsymbol{U}' \simeq \begin{pmatrix} \dfrac{2KV}{(R-L)} & 0 & 0 & \dfrac{-K(R+L)}{(R-L)} \\ 0 & \dfrac{2KV}{(T-B)} & 0 & \dfrac{-K(T+B)}{(T-B)} \\ 0 & 0 & \dfrac{KV}{(F-N)} & \dfrac{-KN}{(F-N)} \\ 0 & 0 & 0 & K \end{pmatrix},$$

which is the orthographic window.

It may be convenient in some applications to separate the functions of windowing and the application of perspective, and to write

$$\boldsymbol{U} = \boldsymbol{U}'\boldsymbol{P},$$

where $\boldsymbol{U}$ and $\boldsymbol{U}'$ are as above and $\boldsymbol{P}$ is a perspective transformation given by

$$\boldsymbol{P} = (\boldsymbol{U}')^{-1}\boldsymbol{U} \simeq \begin{pmatrix} S-E & 0 & C & -SC/V \\ 0 & S-E & D & -SD/V \\ 0 & 0 & F-E+N & -NF/V \\ 0 & 0 & V & -E \end{pmatrix},$$

which involves F and N but not R, L, T or B. In this form the action of $\boldsymbol{P}$ may be thought of as compressing distant parts of display space prior to an orthographic projection by $\boldsymbol{U}'$ into picture space.

Other factorizations of $\boldsymbol{U}$ are possible, for example

$$\boldsymbol{U} = \boldsymbol{U}''\boldsymbol{P}'$$

with

$$\boldsymbol{U}'' \simeq \begin{pmatrix} \dfrac{2KV}{R-L} & 0 & 0 & \dfrac{-K(R+L)}{(R-L)} \\ 0 & \dfrac{2KV}{T-B} & 0 & \dfrac{-K(T+B)}{(T-B)} \\ 0 & 0 & \dfrac{KV(N-E)(F-E)}{E^2(F-N)} & \dfrac{KN(F-E)}{E(F-N)} \\ 0 & 0 & 0 & K \end{pmatrix}$$

$$\boldsymbol{P}' \simeq \begin{pmatrix} S-E & 0 & C & -SC/V \\ 0 & S-E & D & -SD/V \\ 0 & 0 & -E & 0 \\ 0 & 0 & V & -E \end{pmatrix},$$

which renders $\boldsymbol{P}'$ independent of all six boundary planes, but $\boldsymbol{U}''$ is no longer independent of E. It is not possible to factorize $\boldsymbol{U}$ so that the left factor is a function only of the boundary planes and the right factor a function only of eye and screen positions.

Note that as $E \to -\infty$, $\boldsymbol{U}'' \to \boldsymbol{U}'$, $\boldsymbol{P}$ and $\boldsymbol{P}' \to -\boldsymbol{I}E \simeq \boldsymbol{I}$.

3.3.1.3.6. Stereoviews

Assuming that left- and right-eye views are to be presented through the same viewport (next section) or that their viewports are to be superimposed by an external optical system, *e.g.* Ortony mirrors, then stereopairs are obtained by using appropriate eye coordinates in the $\boldsymbol{U}$ matrix of the previous section. However, $\boldsymbol{U}$ may be factorized according to

$$\boldsymbol{U} = \boldsymbol{U}'''\boldsymbol{S}$$

in which $\boldsymbol{U}'''$ is the matrix $\boldsymbol{U}$ obtained by setting (C, D, E, V) to correspond to the point midway between the viewer's eyes and

$$\boldsymbol{S} = \begin{pmatrix} 1 & 0 & c/(S-E) & -cS/(S-E)V \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

$$\simeq \begin{pmatrix} V & 0 & cV/(S-E) & -cS/(S-E) \\ 0 & V & 0 & 0 \\ 0 & 0 & V & 0 \\ 0 & 0 & 0 & V \end{pmatrix}$$

in which $(c, 0, 0, V)$ is the position of the right eye relative to the mean eye position, and the left-eye view is obtained by negating c.

Stereo is often approximated by introducing a rotation about the Y axis of $\pm\sin^{-1}[c/(S-E)]$ to the views or $\sin^{-1}[2c/(S-E)]$ to one of them. The first corresponds to

$$\boldsymbol{S} = \begin{pmatrix} \sqrt{1-\sigma^2} & 0 & \sigma & 0 \\ 0 & 1 & 0 & 0 \\ -\sigma & 0 & \sqrt{1-\sigma^2} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

with $\sigma = c/(S-E)$. The main difference is in the resulting Z value, which only affects depth cueing and z clipping. The X translation which arises if $S \neq 0$ is also suppressed, but this is not likely to be noticeable. σ is often treated as a constant, such as $\sin 3^\circ$.

The distinction in principle between the true $\boldsymbol{S}$ and the rotational approximation is that with the true $\boldsymbol{S}$ the eye moves relative to the screen and the displayed object, whereas with the approximation the eye and the screen are moved relative to the displayed object, in going from one view to the other.

Strobing of left and right images may conveniently be accomplished with an electro-optic liquid-crystal shutter as described by Harris *et al.* (1985). The shutter is switched by the display itself, thus solving the synchronization problem in a manner free of inertia.

A further discussion of stereopairs may be found in Johnson (1970) and in Thomas (1993), the second of which generalizes the treatment to allow for the possible presence of an optical system.

3.3.1.3.7. Viewports

The window transformation of the previous two sections has been constructed to yield picture coordinates (X, Y, Z, W) (formerly called x, y, z, w) such that a point having X/W or $Y/W = \pm 1$ is on the boundary of the picture, and the clipping hardware operates on this basis. However, the edges of the picture need not be at the edges of the screen and a viewport transformation, $\boldsymbol{V}$, is therefore needed to position the picture in the requisite part of the screen.

$$\boldsymbol{V} = \begin{pmatrix} (r-l)/2 & 0 & 0 & (r+l)/2 \\ 0 & (t-b)/2 & 0 & (t+b)/2 \\ 0 & 0 & n & 0 \\ 0 & 0 & 0 & n \end{pmatrix},$$

where r, l, t and b are now the right, left, top and bottom boundaries of the picture area, or viewport, expressed in screen coordinates, and n is the full-screen deflection value. Thus a point with $X/W = 1$ in picture space plots on the screen with an X coordinate which is a fraction r/n of full-screen deflection to the

right. Z/W is unchanged by $\boldsymbol{V}$ and is used only to control intensity in a technique known as depth cueing.

It is necessary, of course, to arrange for the aspect ratio of the viewport, $(r-l)/(t-b)$, to equal that of the window otherwise distortions are introduced.

3.3.1.3.8. Compound transformations

In this section we consider the viewing transformation $\boldsymbol{T}$ of Section 3.3.1.3.1 and its construction in terms of translation, rotation and scaling, Sections 3.3.1.3.2–4. We use $\boldsymbol{T}'$ to denote a new transformation in terms of the prevailing transformation $\boldsymbol{T}$.

We note first that any 4×4 matrix of the form

$$\begin{pmatrix} U\boldsymbol{R} & \mathbf{V} \\ \mathbf{0}^T & W \end{pmatrix},$$

with U a scalar, may be factorized according to

$$\begin{pmatrix} U\boldsymbol{R} & \mathbf{V} \\ \mathbf{0}^T & W \end{pmatrix} \simeq \begin{pmatrix} U\boldsymbol{I} & \mathbf{0} \\ \mathbf{0}^T & W \end{pmatrix}\begin{pmatrix} U\boldsymbol{I} & \mathbf{V} \\ \mathbf{0}^T & U \end{pmatrix}\begin{pmatrix} U\boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & U \end{pmatrix}$$

and also that multiplying

$$\begin{pmatrix} U\boldsymbol{R} & \mathbf{V} \\ \mathbf{0}^T & W \end{pmatrix}$$

by an isotropic scaling matrix, a rotation, or a translation, either on the left or on the right, yields a product matrix of the same form, and its inverse

$$\begin{pmatrix} W\boldsymbol{R}^T & -\boldsymbol{R}^T\mathbf{V} \\ \mathbf{0}^T & U \end{pmatrix}$$

is also of this form, *i.e.* any combination of these three operations in any order may be reduced by the above factorization to a rotation about the original origin, a translation (which defines a new origin) and an expansion or contraction about the new origin, applied in that order.

If

$$\begin{pmatrix} N\boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & N \end{pmatrix}$$

is a rotation matrix as in Section 3.3.1.3.3, its application produces a rotation about an axis through the origin defined only in the space in which it is applied. For example, if

$$\boldsymbol{R} = \begin{pmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

$$\boldsymbol{T}'\begin{pmatrix} \mathbf{X} \\ W \end{pmatrix} = \boldsymbol{T}\begin{pmatrix} N\boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & N \end{pmatrix}\begin{pmatrix} \mathbf{X} \\ W \end{pmatrix}$$

rotates the image about the z axis of data space, whatever the prevailing viewing transformation, $\boldsymbol{T}$.

Forming

$$\begin{pmatrix} N\boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & N \end{pmatrix}\boldsymbol{T}\begin{pmatrix} \mathbf{X} \\ W \end{pmatrix}$$

rotates the image about the z axis of display space, *i.e.* the normal to the tube face under the usual conventions, whatever the prevailing $\boldsymbol{T}$. Furthermore, if this rotation is to appear to be about some chosen position in the picture, *e.g.* the centre, then the window transformation $\boldsymbol{U}$, Section 3.3.1.3.5, must place the origin of display space there by setting $F > S = R + L = T + B = 0 > N$, in the notation of that section.

If a rotation is to be about a point

$$\begin{pmatrix} \mathbf{V} \\ N \end{pmatrix}$$

then

$$\begin{aligned} \boldsymbol{T}' &= \begin{pmatrix} N\mathbf{I} & \mathbf{V} \\ \mathbf{0}^T & N \end{pmatrix}\begin{pmatrix} N'\boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & N' \end{pmatrix}\begin{pmatrix} N\boldsymbol{I} & -\mathbf{V} \\ \mathbf{0}^T & N \end{pmatrix}\boldsymbol{T} \\ &\simeq \begin{pmatrix} N\boldsymbol{R} & \mathbf{V} - \boldsymbol{R}\mathbf{V} \\ \mathbf{0}^T & N \end{pmatrix}\boldsymbol{T} \end{aligned}$$

or

$$\begin{aligned} \boldsymbol{T}' &= \boldsymbol{T}\begin{pmatrix} N\boldsymbol{I} & \mathbf{V} \\ \mathbf{0}^T & N \end{pmatrix}\begin{pmatrix} N'\boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^T & N' \end{pmatrix}\begin{pmatrix} N\boldsymbol{I} & -\mathbf{V} \\ \mathbf{0}^T & N \end{pmatrix} \\ &\simeq \boldsymbol{T}\begin{pmatrix} N\boldsymbol{R} & \mathbf{V} - \boldsymbol{R}\mathbf{V} \\ \mathbf{0}^T & N \end{pmatrix} \end{aligned}$$

according to whether $\boldsymbol{R}$ and $\mathbf{V}$ are both defined in display space or both in data space. If the rotation is defined in display space and the position of the centre of rotation is defined in data space, then the first form of $\boldsymbol{T}'$ must be used, in which $\mathbf{V}$ is first computed from

$$\begin{pmatrix} \mathbf{V} \\ N \end{pmatrix} = \boldsymbol{T}\begin{pmatrix} \mathbf{U} \\ W \end{pmatrix}$$

for a rotation centre at

$$\begin{pmatrix} \mathbf{U} \\ W \end{pmatrix}$$

in data space.

For continuous rotations defined in display space it is usually worthwhile to bring the centre of rotation to the origin of display space and leave it there, *i.e.* to omit the left-most factor in the first expression for $\boldsymbol{T}'$. Incremental rotations can then be made by further rotational factors on the left without further attention to $\mathbf{V}$. When continuous rotations are implemented by repeated multiplication of $\boldsymbol{T}$ by a rotation matrix, say thirty times a second for a minute or so, the orthogonality of the top-left partition of $\boldsymbol{T}$ may become degraded by accumulation of round-off error and this should be corrected occasionally by one of the methods of Section 3.3.1.2.3.

It is sometimes a requirement, depending on hardware capabilities, to effect a transformation in display space when access to data space is all that is readily available. In such a case

$$\boldsymbol{T}' = \boldsymbol{T}_1\boldsymbol{T} = \boldsymbol{T}\boldsymbol{T}_2,$$

where $\boldsymbol{T}_1$ is the required alteration to the prevailing viewing transformation $\boldsymbol{T}$ and $\boldsymbol{T}_2$ is the data-space equivalent,

$$\begin{aligned} \boldsymbol{T}_2 = \boldsymbol{T}^{-1}\boldsymbol{T}_1\boldsymbol{T} &= \begin{pmatrix} U\boldsymbol{R} & \mathbf{V} \\ \mathbf{0}^T & W \end{pmatrix}^{-1}\begin{pmatrix} U_1\boldsymbol{R}_1 & \mathbf{V}_1 \\ \mathbf{0}^T & W_1 \end{pmatrix}\begin{pmatrix} U\boldsymbol{R} & \mathbf{V} \\ \mathbf{0}^T & W \end{pmatrix} \\ &\simeq \begin{pmatrix} UU_1\boldsymbol{R}^T\boldsymbol{R}_1\boldsymbol{R} & \boldsymbol{R}^T(U_1\boldsymbol{R}_1\mathbf{V} + W\mathbf{V}_1 - \boldsymbol{W}_1\mathbf{V}) \\ \mathbf{0}^T & UW_1 \end{pmatrix}. \end{aligned}$$

An important special case is when $\boldsymbol{T}_1$ is to effect a rotation about the origin of display space without change of scale, so that $\mathbf{V}_1 = 0$, $U_1 = W_1 = W$, for then

$$\boldsymbol{T}_2 \simeq \begin{pmatrix} U\boldsymbol{R}^T\boldsymbol{R}_1\boldsymbol{R} & \boldsymbol{R}^T(\boldsymbol{R}_1 - \boldsymbol{I})\mathbf{V} \\ \mathbf{0}^T & U \end{pmatrix}.$$

If $\mathbf{r}$ is the required axis of rotation of $\boldsymbol{R}_1$ in display space then the axis of rotation of $\boldsymbol{R}^T\boldsymbol{R}_1\boldsymbol{R}$ in data space is $\mathbf{s} = \boldsymbol{R}^T\mathbf{r}$ since $\boldsymbol{R}^T\boldsymbol{R}_1\boldsymbol{R}\mathbf{s} = \mathbf{s}$. This gives a particularly simple result if $\boldsymbol{R}_1$ is to be a

primitive rotation for then **s** is the relevant row of $\boldsymbol{R}$, and $\boldsymbol{R}^T\boldsymbol{R}_1\boldsymbol{R}$ can be constructed directly from this and the required angle of rotation.

3.3.1.3.9. Inverse transformations

It is frequently a requirement to be able to identify a feature or position in data space from its position on the screen. Facilities for identifying an existing feature on the screen are in many instances provided by the manufacturer as a 'hit' function which correlates the position indicated on the screen by the user (with a tablet or light pen) with the action of drawing and flags the corresponding item in the drawing internally as having been hit. In other instances it may be necessary to be able to indicate a position in data space independently of any drawn feature and this may be done by setting two or more nonparallel sight lines through the displayed volume and finding their best point of intersection in data space.

In Section 3.3.1.3.1 the relationship between data-space coordinates and screen-space coordinates was given as

$$\mathbf{S} = \boldsymbol{VUTX};$$

hence data-space coordinates are given by

$$\mathbf{X} = \boldsymbol{T}^{-1}\boldsymbol{U}^{-1}\boldsymbol{V}^{-1}\mathbf{S}.$$

A line of sight through the displayed volume passing through the point

$$\begin{pmatrix} x \\ y \end{pmatrix}$$

on the screen is the line joining the two position vectors

$$\boldsymbol{S} = \begin{pmatrix} x & x \\ y & y \\ o & n \\ n & n \end{pmatrix}$$

in screen-space coordinates, as in Section 3.3.1.3.7, from which the corresponding two points in data space may be obtained using

$$\boldsymbol{V}^{-1} \simeq \begin{pmatrix} \dfrac{2n}{r-l} & 0 & 0 & \dfrac{-(r+l)}{(r-l)} \\ 0 & \dfrac{2n}{t-b} & 0 & \dfrac{-(t+b)}{(t-b)} \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

and

$$\boldsymbol{U}^{-1} \simeq \begin{pmatrix} \dfrac{R-L}{2(S-E)} & 0 & \dfrac{-C(F-N)}{(F-E)(N-E)} & \dfrac{(R+L)(N-E)-2C(N-S)}{2(N-E)(S-E)} \\ 0 & \dfrac{T-B}{2(S-E)} & \dfrac{-D(F-N)}{(F-E)(N-E)} & \dfrac{(T+B)(N-E)-2D(N-S)}{2(N-E)(S-E)} \\ 0 & 0 & \dfrac{-E(F-N)}{(F-E)(N-E)} & \dfrac{N}{(N-E)} \\ 0 & 0 & \dfrac{-V(F-N)}{(F-E)(N-E)} & \dfrac{V}{(N-E)} \end{pmatrix}$$

in the notation of Section 3.3.1.3.5, and $\boldsymbol{T}^{-1}$ was given in Section 3.3.1.3.8. If orthographic projection is being used ($E = -\infty$) then $\boldsymbol{U}^{-1}$ simplifies to

$$\boldsymbol{U'}^{-1} \simeq \begin{pmatrix} \dfrac{R-L}{2} & 0 & 0 & \dfrac{R+L}{2} \\ 0 & \dfrac{T-B}{2} & 0 & \dfrac{T+B}{2} \\ 0 & 0 & F-N & N \\ 0 & 0 & 0 & V \end{pmatrix}.$$

Each of these inverse matrices may be suitably scaled to suit the word length of the machine [Section 3.3.1.1.2 (iii)].

Having determined the end points of one sight line in data space the viewing transformation $\boldsymbol{T}$ may then be changed and the required position marked again through the screen in the new orientation. Each such operation generates a pair of points in data space, expressed in homogeneous form, with a variety of values for the fourth coordinate. Each such point must then be converted to three dimensions in the form (X/W, Y/W, Z/W), and for each sight line any (three-dimensional) point $\mathbf{p}_A$ on the line and the direction $\mathbf{q}_A$ of the line are established. For each sight line a rank 2 projector matrix $\boldsymbol{M}_A$ of order 3 is formed as

$$\boldsymbol{M}_A = \boldsymbol{I} - \mathbf{q}_A\mathbf{q}_A^T/\mathbf{q}_A^T\mathbf{q}_A$$

and the best point of intersection of the sight lines is given by

$$\left(\sum_a \boldsymbol{M}_a\right)^{-1}\left(\sum_a \boldsymbol{M}_a\mathbf{p}_a\right),$$

to which three-vector a fourth coordinate of unity may be applied.

3.3.1.3.10. The three-axis joystick

The three-axis joystick is a device which depends on compound transformations for its exploitation. As it is usually mounted it consists of a vertical shaft, mounted at its lower end, which can rotate about its own length (the Y axis of display space, Section 3.3.1.3.1), its angular setting, φ, being measured by a shaft encoder in its mounting. At the top of this shaft is a knee-joint coupling to a second shaft. The first angle φ is set to zero when the second shaft is in some selected direction, *e.g.* normal to the screen and towards the viewer, and goes positive if the second shaft is moved clockwise when seen from above. The knee joint itself contains a shaft encoder, providing an angle, ψ, which may be set to zero when the second shaft is horizontal and goes positive when its free end is raised. A knob on the tip of the second shaft can then rotate about an axis along the second shaft, driving a third shaft encoder providing an angle θ. The device may then be used to produce a rotation of the object on the screen about an axis parallel to the second shaft through an angle given by the knob. The necessary transformation is then

$$\begin{aligned} \boldsymbol{R} = &\begin{pmatrix} \cos\varphi & 0 & -\sin\varphi \\ 0 & 1 & 0 \\ \sin\varphi & 0 & \cos\varphi \end{pmatrix}\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\psi & \sin\psi \\ 0 & -\sin\psi & \cos\psi \end{pmatrix} \\ &\times \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\psi & -\sin\psi \\ 0 & \sin\psi & \cos\psi \end{pmatrix} \\ &\times \begin{pmatrix} \cos\varphi & 0 & \sin\varphi \\ 0 & 1 & 0 \\ -\sin\varphi & 0 & \cos\varphi \end{pmatrix} \end{aligned}$$

which is

$$\begin{pmatrix} c^2\psi s^2\varphi + (1 - c^2\psi s^2\varphi)c\theta & -s\psi c\psi s\varphi(1 - c\theta) - c\psi c\varphi s\theta & -c^2\psi s\varphi c\varphi(1 - c\theta) + s\psi s\theta \\ -s\psi c\psi s\varphi(1 - c\theta) + c\psi c\varphi s\theta & s^2\psi + c^2\psi c\theta & s\psi c\psi c\varphi(1 - c\theta) + c\psi s\varphi s\theta \\ -c^2\psi s\varphi c\varphi(1 - c\theta) - s\psi s\theta & s\psi c\psi c\varphi(1 - c\theta) - c\psi s\varphi s\theta & c^2\psi c^2\varphi + (1 - c^2\psi c^2\varphi)c\theta \end{pmatrix}$$

in which cos and sin are abbreviated to c and s, which is the standard form with $l = -\cos\psi\sin\varphi$, $m = \sin\psi$, $n = \cos\psi\cos\varphi$.

3.3.1.3.11. Other useful rotations

If rotations in display space are to be controlled by trackerball or tablet then there are two measures available, an x and a y, which can define an axis of rotation in the plane of the screen and an angle θ. If x and y are suitably scaled coordinates of a pen on a tablet then the rotation

$$\begin{pmatrix} \dfrac{y^2 + x^2c}{x^2 + y^2} & \dfrac{-xy(1 - c)}{x^2 + y^2} & x\sqrt{x^2 + y^2} \\ \dfrac{-xy(1 - c)}{x^2 + y^2} & \dfrac{x^2 + y^2c}{x^2 + y^2} & y\sqrt{x^2 + y^2} \\ -x\sqrt{x^2 + y^2} & -y\sqrt{x^2 + y^2} & c \end{pmatrix}$$

with $c = \sqrt{1 - (x^2 + y^2)^2}$ is about an axis in the xy plane (*i.e.* the screen face) normal to (x, y) and with $\sin\theta = x^2 + y^2$. Applied repetitively this gives a quadratic velocity characteristic. Similarly, if an atom at (x, y, z, w) in display space is to be brought onto the z axis by a rotation with its axis in the xy plane the necessary matrix, in homogeneous form, is

$$\begin{pmatrix} \dfrac{x^2z + y^2r}{x^2 + y^2} & \dfrac{-xy(r - z)}{x^2 + y^2} & -x & 0 \\ \dfrac{-xy(r - z)}{x^2 + y^2} & \dfrac{x^2r + y^2z}{x^2 + y^2} & -y & 0 \\ x & y & z & 0 \\ 0 & 0 & 0 & r \end{pmatrix}$$

with $r = \sqrt{x^2 + y^2 + z^2}$.

3.3.1.3.12. Symmetry

In Section 3.3.1.1.1 it was pointed out that it is usual to express coordinates for graphical purposes in Cartesian coordinates in ångström units or nanometres. Symmetry, however, is best expressed in crystallographic fractional coordinates. If a molecule, with Cartesian coordinates, is being displayed, and a symmetry-related neighbour is also to be displayed, then the data-space coordinates must be multiplied by

$$\begin{pmatrix} \boldsymbol{W} & \mathbf{T} \\ \mathbf{0}^T & W \end{pmatrix}\begin{pmatrix} \boldsymbol{M} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}\mathscr{S}\begin{pmatrix} \boldsymbol{M}^{-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}\begin{pmatrix} \boldsymbol{W} & -\mathbf{T} \\ \mathbf{0}^T & W \end{pmatrix},$$

where

$$\begin{pmatrix} \mathbf{T} \\ W \end{pmatrix}$$

are the data-space coordinates of the crystallographic origin, $\boldsymbol{M}$ and $\boldsymbol{M}^{-1}$ are as in Section 3.3.1.1.1 and $\mathscr{S}$ is a crystallographic symmetry operator in homogeneous coordinates, expressed relative to the same crystallographic origin.

For example, in $P2_1$ with the origin on the screw dyad along **b**,

$$\mathscr{S} = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & \frac{1}{2} \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

and

$$\begin{pmatrix} \boldsymbol{M} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}\mathscr{S}\begin{pmatrix} \boldsymbol{M}^{-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix} = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & \frac{1}{2}b \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

$\mathscr{S}$ comprises a proper or improper rotational partition, $\boldsymbol{S}$, in the upper-left 3×3 in the sense that $\boldsymbol{MSM}^{-1}$ is orthogonal, and with the associated fractional lattice translation in the last column, with the last row always consisting of three zeros and 1 at the 4, 4 position. See *IT* A (2005, Chapters 5.2 and 8.1) for a fuller discussion of symmetry using augmented (*i.e.* 4×4) matrices.

3.3.1.4. Modelling transformations

The two sections under this heading are concerned only with the graphical aspects of conformational changes. Determination of such changes is considered under Section 3.3.2.2.

3.3.1.4.1. Rotation about a bond

It is a common requirement in molecular modelling to be able to rotate part of a molecule relative to the remainder about a bond between two atoms.

If four atoms are bonded 1–2–3–4 then the dihedral angle in the bond 2–3 is zero if the four atoms are *cis* planar, and a rotation in the 2–3 bond is, by convention (IUPAC–IUB Commission on Biochemical Nomenclature, 1970), positive if, when looking along the 2–3 bond, the far end rotates clockwise relative to the near end. This is valid for either viewing direction. This sign convention, when applied to the $\boldsymbol{R}$ matrix of Section 3.3.1.2.1, leads to the following statement.

If one of the two atoms is selected as the near atom and the direction cosines are those of the vector from the near atom to the far atom, and if the matrix is to rotate material attached to the far atom (with the reference axes fixed), then a positive rotation in the foregoing sense is generated by a positive θ.

Rotation about a bond normally involves compounding $\boldsymbol{R}$ with translations in the manner of Section 3.3.1.3.8.

3.3.1.4.2. Stacked transformations

A flexible molecule may require to be drawn in any of a number of conformations which are related to one another by, for example, rotations about single bonds, changes of bond angles or changes of bond lengths, all of which changes may be brought about by the application of suitable homogeneous transformations during the drawing of the molecule (Section 3.3.1.3.8). With suitable organization, this may be done without necessarily altering the coordinates of the atoms in the coordinate list, only the transformations being manipulated during drawing.

The use of transformations in the manner shown below is straightforward for simply connected structures or structures containing only rigid rings. Flexible rings may be similarly handled provided that the matrices employed are consistent with the consequential constraints as described in Section 3.3.2.2.1, though this requirement may make real-time folding of flexible rings difficult.

Any simply connected structure may be organized as a tree with a node at each branch point and with an arbitrary number of sites of conformational change between one node and the next. We shall call such sites and their associated matrices 'conformons'. The technique then depends on the stacking technique in which matrices are stored and later recovered in the reverse order of their storage.

One begins at some reference point deemed to be fixed in data space and at this point one stacks the prevailing viewing transformation. From this reference point one advances through the molecule along the structural tree and as each conformon is encountered its matrix is calculated. The product of the prevailing matrix with the conformon matrix is formed and stacked, and this product becomes the prevailing matrix. This product is constructed with the conformon matrix as a factor on the right, *i.e.* in data space as defined in Section 3.3.1.3.1, and is calculated using the coordinates of the molecule in their unmodified form, *i.e.* before any shape changes are brought about.

This progression leads eventually to an extremity of the tree. At this point drawing is commenced using the prevailing matrix and working backwards towards the fixed root, unstacking (or 'popping') a matrix as each conformon is passed until a node is reached, which, in general, will occur only part way back to the root. On reaching such a node drawing is suspended and one advances along the newly found branch as before, stacking matrices, until another extremity is reached when drawing towards the root is resumed. This alternation of stacking matrices while moving away from the root and drawing and unstacking matrices while moving towards the root is continued until the whole tree is traversed.

This process is illustrated schematically in Fig. 3.3.1.2 for a simple tree with one node, numbered 1, and three conformons at *a*, *b* and *c*. One enters the tree with a current viewing transformation $\boldsymbol{T}$ and progresses upwards from the fixed lower extremity. When the conformon at *a* is encountered, $\boldsymbol{T}$ is stacked and the product $\boldsymbol{TM}_a$ is formed. Continuing up the tree, at node 1 either branch may be chosen; we choose the left and, on reaching *b*, $\boldsymbol{TM}_a$ is stacked and $\boldsymbol{TM}_a\boldsymbol{M}_b$ is formed. On reaching the tip drawing down to *b* is done with this transformation, $\boldsymbol{TM}_a$ is then unstacked and drawing continues with this matrix until node 1 is reached. The other branch is then followed to *c* whereupon $\boldsymbol{TM}_a$ is again stacked and the product $\boldsymbol{TM}_a\boldsymbol{M}_c$ is formed. From the tip down as far as *c* is drawn with this matrix, whereupon $\boldsymbol{TM}_a$ is unstacked and drawing continues down to *a*, where $\boldsymbol{T}$ is unstacked before drawing the section nearest the root.

With this organization the matrices associated with *b* and *c* are unaffected by changes in the conformation at *a*, notwithstanding the fact that changes at *a* alter the direction of the axis of rotation at *b* or *c*.

Two other approaches are also possible. One of these is to start at the tip of the left branch, replace the coordinates of atoms between *b* and the tip by $\boldsymbol{M}_b\mathbf{X}$, and later replace all coordinates between the tip and *a* by $\boldsymbol{M}_a\mathbf{X}$, with a similar treatment for the other branch. The advantage of this is that no storage is required for stacked matrices, but the disadvantage is that atoms near the tips of the tree have to be reprocessed for every conformon. It also modifies the stored coordinates, which may or may not be desirable.

The second alternative is to draw upwards from the root using $\boldsymbol{T}$ until *a* is reached, then using $\boldsymbol{TM}_a$ until *b* is reached, then using $\boldsymbol{TM}'_b\boldsymbol{M}_a$ to the tip, but in this formulation $\boldsymbol{M}'_b$ must be based on the geometry that exists at *b* after the transformation $\boldsymbol{M}_a$ has been applied to this region of the molecule, *i.e.* $\boldsymbol{M}'_b$ is characteristic of the final conformation rather than the initial one.

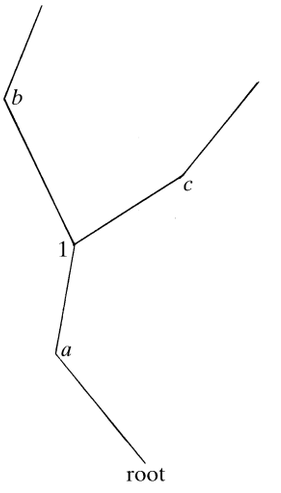

Fig. 3.3.1.2. Schematic representation of a simple branched-chain molecule with a stationary root and two extremities. The positions marked *a*, *b* and *c* are the loci of possible conformational change, here called conformons, and there is a single, numbered branch point.

3.3.1.5. Drawing techniques

3.3.1.5.1. Types of hardware

There are two main types of graphical hardware in use for interactive work, in addition to plotters used for batch work. These main types are raster and vector. In raster equipment the screen is scanned as in television, with a grid of points, called pixels, addressed sequentially as the scan proceeds. Associated with each pixel is a word of memory, usually containing something in the range of 1 to 24 bits per pixel, which controls the colour and intensity to be displayed. Many computer terminals have one bit per pixel (said to be 'single-plane' systems) and these are essentially monochrome and have no grey scale. Four-plane systems are cheap and popular and commonly provide 4-bit by 4-bit look-up tables between the pixel memory and the monitor with one such table for each of the colours red, green and blue. If these tables are each loaded identically then 16 levels of monochrome grey scale are available, but if they are loaded differently 16 different colours are available simultaneously chosen from a total of 4096 possibilities. Four-plane systems are adequate for many applications where colour is used for coding, but are inadequate if colour is intended also to provide realism, where brilliance and saturation must be varied as well as hue. For these applications eight-plane systems are commonly used which permit 256 colours chosen from 16 million using three look-up tables, though the limitations of these can also be felt and full colour is only regarded as being available in 24-plane systems.

Raster-graphics devices are ideal for drawing objects represented by opaque surfaces which can be endowed with realistic reflecting properties (Max, 1984) and they have been successfully used to give effects of transparency. They are also capable of representing shadows, though these are generally difficult to calculate (see Section 3.3.1.5.5). Many devices of this type provide vectorization, area fill and anti-aliasing. Vectorization provides automatically for the loading of relevant pixels on a straight line between specified points. Area fill automatically fills any irregular pre-defined polygon on the screen with a uniform colour with the user specifying only the colour and one point within the polygon. Anti-aliasing is the term used for a technique which softens the staircase effect that may be seen on a line which runs at a small angle to a vertical or horizontal row of pixels.

The main drawback with this type of equipment is that it is slow compared to vector machines. Only relatively simple objects can be displayed with smooth rotation in real time as transformed coordinates have to be converted to pixel addresses and the previous frame needs to be deleted with each new frame unless it is known that each new frame will specify every pixel. However, the technology is advancing rapidly and these restrictions are already disappearing.

Vector machines, on the other hand, are specialized to drawing straight lines between specified points by driving the electron beam along such lines. No time is wasted on blank areas of the screen. Dots may be drawn with arbitrary coordinates, in any order, but areas, if they are to be filled, must be done with a ruling technique which is very seldom done. Images produced by vector

machines are naturally transparent in that foreground does not obscure background, which makes them ideal for seeing into representations of molecular structure.

3.3.1.5.2. Optimization of line drawings

A line drawing consisting of n line segments may be specified by anything from $(n+1)$ to $2n$ position vectors depending on whether the lines are end-to-end connected or independent. Appreciable gains in both processing time and storage requirements may be made in complicated drawings by arranging for line segments to be end-to-end connected as far as possible, and an algorithm for doing this is outlined below. For further details see Diamond (1984*a*).

Supposing that a list of nodal points (atoms if a covalent skeleton is being drawn) exists within a computer with each node appearing only once and that the line segments to be drawn between them are already determined, then at each node there are, generally, both forward and backward connections, forward connections being those to nodes further down the list. A quantity D is calculated at each node which is the number of forward connections minus the number of backward connections. At the commencement of drawing, the first connected node in the list must have a positive D, the last must have a negative D, the sum of all D values must be zero and the sum of the positive ones is the number of strokes required to draw the drawing, a 'stroke' being a sequence of end-to-end connected line segments drawn without interruption. The total number of position vectors required to specify the drawing is then the number of nodes plus the number of strokes plus the number of rings minus one.

Drawing should then be done by scanning the list of nodes from the top looking for a positive D (usually found at the first node), commencing a stroke at this node and decrementing its D value by 1. This stroke is continued from node to node using the specified connections until a negative D is encountered, at which point the stroke is terminated and the D value at the terminating node is incremented by 1. This is done even though this terminating node may also possess some forward connections, as the total number of strokes required is not minimized by keeping a stroke going as far as possible, but by terminating a stroke as soon as it reaches a node at which *some* stroke is bound to terminate.

The next stroke is initiated by resuming the scan for positive D values at the point in the node list where the previous stroke began. If this scan encounters a zero D value at a node which has not hitherto been drawn to, or drawn from, then the node concerned is isolated and not connected to any other, and such nodes may require to be drawn with some special symbol. The expression already given for the number of vectors required is valid in the presence of isolated nodes if drawing an isolated node is allowed one position vector, this vector not being counted as a stroke.

The number of strokes generated by this algorithm is sensitive to the order in which the nodes are listed, but if this resembles a natural order then the number of strokes generated is usually close to the minimum, which is half the number of nodes having an odd number of connections. For example, the letter E has six nodes, four of which have an odd number of connections, so it may be drawn with two strokes.

3.3.1.5.3. Representation of surfaces by lines

The commonest means of representing surfaces, especially contour surfaces, is to consider evenly spaced serial sections and to perform two-dimensional contouring on each section. Repeating this on serial sections in two other orientations then provides a good representation of the surface in three dimensions when all such contours are displayed. The density is normally cited on a grid with submultiples of **a**, **b** and **c** as grid vectors, inverse linear interpolation being used between adjacent grid points to locate points on the contour. For vector-graphics applications it is expedient to connect such points with straight lines; some equipment may be capable of connecting them with splines though this is burdensome or impossible if real-time rotation of the scene is required. Precalculation of splines stored as short vectors is always possible if the proliferation of vectors is acceptable. For efficient drawing it is necessary for the line segments of a contour to be end-to-end connected, which means that it is necessary to contour by following contours wherever they go and not by scanning the grid. Algorithms which function in this way have been given by Heap & Pink (1969) and Diamond (1982*a*). Contouring by grid scanning followed by line connection by the methods of the previous section would be possible but less efficient. Further contouring methods are described by Sutcliffe (1980) and Cockrell (1983).

For raster-graphics devices there is little disadvantage in using curved contours though many raster devices now have vectorizing hardware for loading a line of pixels given only the end points. For these devices well shaped contours may be computed readily, using only linear arithmetic and a grid-scanning approach (Gossling, 1967). Others have colour-coded each pixel according to the density, which provides a contoured visual impression without performing contouring (Hubbard, 1983).

3.3.1.5.4. Representation of surfaces by dots

Connolly (Langridge *et al.*, 1981; Connolly, 1983*a*,*b*) represents surfaces by placing dots on the surface with an approximately uniform superficial density. Connolly's algorithm was developed to display solvent-accessible surfaces of macromolecules and provides for curved concave portions where surface atoms meet. Pearl & Honegger (1983) have developed a similar algorithm, based on a grid, which generates only convex portions which meet in cusps, but is faster to compute than the Connolly surface. Bash *et al.* (1983) have produced a van der Waals surface algorithm fast enough to permit real-time changes to the structure without tearing the surface.

It has become customary to use a dot representation to display computed surfaces, such as the surface at a van der Waals radius from atomic centres, and to use lines to represent experimentally determined surfaces, especially density contours.

3.3.1.5.5. Representation of surfaces by shading

Many techniques have been developed, mainly for raster-graphics devices, for representing molecular surfaces and these have been very well reviewed by Max (1984).

The simplest technique in this class consists in representing each atom by a uniform disc, or high polygon, which can be colour-coded and area-filled by the firmware of the device. If such atoms are sorted on their z coordinate and drawn in order, furthest ones first, so that nearer ones partly or completely overwrite the further ones then the result is a simple representation of the molecule as seen from the front. This technique is fast and has its uses when a rapid schematic is all that is required. In one sense it is wasteful to process distant atoms when they are going to be overwritten by foreground atoms, but front-to-back processing requires the boundaries of visible parts of partially obscured atoms near the front to be determined before they can be painted or, alternatively, every pixel must be tested before loading to see if it is already loaded. Not only does this approach give a uniform rendering over the whole area of one atom, it also gives a boundary between overlapping atoms with almost equal z values which completes the circle of the nearer atom, though it should be an arc of an ellipse when the atoms are drawn with radii exceeding their covalent radii.

Greater realism is achieved by establishing a z buffer, which is an additional area of memory with one word per pixel, in which is stored the z value of the currently loaded feature in each pixel.

Treatments which take account of the sphericity are then possible and correct arcs of intersection for interpenetrating spheres and more complicated entities arise naturally through loading a colour value into a pixel only if the z coordinate is less than that of the currently loaded value. This z buffer and the associated x, y coordinates should be in picture space or screen space rather than display space since only after the application of perspective can points with the same x/w and y/w coordinates obscure one another.

It is usual in such systems to vary the intensity of colour within one atom by darkening it towards the circumference on the basis of the z coordinate. Some systems augment this impression of sphericity by highlighting. The simplest form of highlighting is an extension of the uniform disc treatment in which additional, brighter discs, possibly off centre, are associated with each atom. More general highlighting (Phong, 1975) is computed from four unit vectors, these being the normal to the surface, the direction to a light source, the direction to the viewer and the normalized vector sum of these last two. Intensity levels may then be set as the sum of three terms: a constant, a term proportional to the scalar product of the first two vectors (if positive) and a term proportional to a high power of the scalar product of the first and last vectors; the higher the power the glossier the surface appears to be. This final term normally adds a white term, rather than the surface colour, supposing the light source to be white.

Shadows may also be rendered to give even greater realism. In addition to the z buffer and (x, y) frame buffer a second z buffer for z' values associated with x' and y' is also required. These coordinates are then related by $x' = x + \alpha z$, $y' = y + \beta z$, $z' = z$. The second buffer is a ray buffer since x' y' are the coordinates with which an illuminating ray passing through (xyz) passes through the $z = 0$ plane, and z', stored at x', y', records the depth at which this ray encounters material. Thus any two pixels $(x_1y_1z_1)$ and $(x_2y_2z_2)$ are on the same illuminating ray if their x' and y' values are equal and the one with smaller z' shadows the other. Processing a pixel at $(x_1y_1z_1)$ therefore involves first determining its visibility on the basis of the z buffer, as before, then, whether or not it is visible, setting $z'_1 = z_1$ and considering the value of z' currently stored at $x'y'$, which we call z'_2.

If $z'_1 < z'_2$ then $x_1y_1z_1$ is in light and must be loaded accordingly. From z'_2 we find the previously processed pixel $(x_2y_2z_2)$ which is now in shade and which was in light when originally processed, so that the colour value stored at x_2y_2 needs to be altered *unless* the pixel at x_2y_2 is now $(x_2y_2z_3)$ with $z_3 < z_2$, in which case the pixel $(x_2y_2z_2)$ which has now become shadowed by $(x_1y_1z_1)$ has, in the meantime, been obscured by $(x_2y_2z_3)$ which is not shadowed by $(x_1y_1z_1)$ and no change is therefore needed. In either event z'_1 then replaces z'_2.

If $z'_1 > z'_2$ then $(x_1y_1z_1)$, if visible, is in shade and must be coloured accordingly, and in this case z'_2 is not superseded.

This shadowing scheme corresponds to illumination by a light source at infinity in picture space or, equivalently, with a z coordinate equal to that of the eye in display space. For its implementation x, y and z may be in any convenient coordinate system, *e.g.* pixel addresses, but if x and y are expressed with the range -1 to 1 and z with the range 0 to 1 corresponding to the window then they may be identified as the quantities x/w, y/w and z/w of picture space (Section 3.3.1.3.1).

If, in the notation of Section 3.3.1.3.5, the light source is placed at (P, Q, E, V) in display space and a ray leaves it in the direction (p, q, r, V) then

$$x' = \frac{p}{r} \cdot \frac{2(S-E)}{(R-L)} + \frac{2(S-E)(P-C)}{(N-E)(R-L)} + \frac{2C-R-L}{R-L},$$

which varies only with beam direction,

$$\alpha = \frac{2(S-E)(F-N)(P-C)}{(F-E)(N-E)(R-L)}$$

and similarly for y' and β.

3.3.1.5.6. Advanced hidden-line and hidden-surface algorithms

Hidden surfaces may be handled quite generally with the z-buffer technique described in the previous section but this technique becomes very inefficient with very complicated scenes. Faster techniques have been developed to handle computations in real time (*e.g.* 25 frames s^{-1}) on raster machines when both the viewpoint and parts of the environment are moving and substantial complexity is required. These techniques generally represent surfaces by a number of points in the surface, connected by lines to form panels. Many algorithms require these panels to be planar and some require them to be triangular. Of those that permit polygonal panels, most require the polygons to be convex with no re-entrant angles. Yet others are limited to cases where the objects themselves are convex. Some can handle interpenetrating surfaces, others exclude these. Some make enormous gains in efficiency if the objects in the scene are separable by the insertion of planes between them and degrade to lower efficiency if required, for example, to draw a chain. Some are especially suited to vector machines and others to raster machines, the latter capitalizing on the finite resolution of such systems. In all of these the basic entities for consideration are entire panels or edges, and in some cases vertices, point-by-point treatment of the entire surface being avoided until after all decisions are made concerning what is or is not visible.

All of these algorithms strive to derive economies from the notion of 'coherence'. The fact that, in a cine context, one frame is likely to be similar to the previous frame is referred to as 'frame coherence'. In raster scans line coherence also exists, and other kinds of coherence can also be identified. The presence of any form of coherence may enable the computation to be concerned primarily with changes in the situation, rather than with the totality of the situation so that, for example, computation is required where one edge crosses in front of another, but only trivial actions are involved so long as scan lines encounter the projections of edges in the same order.

The choice of technique from among many possibilities may even depend on the viewpoint if the scene has a statistical anisotropy. For example, the depiction of a city seen from a viewpoint near ground level involves many hidden surfaces. Distant buildings may be hidden many times over. The same scene depicted from an aerial viewpoint shows many more surfaces and fewer overlaps. This difference may swing the balance of advantage between an algorithm which sorts first on z or one which leaves that till last.

These advanced techniques have, so far, found little application in crystallography, but this may change. Ten such techniques are critically reviewed and compared by Sutherland *et al.* (1974), and three of these are described in detail by Newman & Sproull (1973).

3.3.2. Molecular modelling, problems and approaches

By R. Diamond

This section is concerned with software techniques which permit a set of atomic coordinates for a molecule to be generated *ab initio*, or to be modified, by reference to some chosen criterion, usually the electron density. Software that can change the shape of a molecule must be cognizant of the connectivity of the molecule and the bonding characteristics of atom types. It must also have means of regaining good stereochemistry if current coordinates are poor in this respect, or of performing its

manipulations in ways which conserve essential stereochemical features. Approaches to some of these problems are outlined below. Many of the issues involved, including the topics outlined in Section 3.3.1.4 above, have been excellently reviewed by Hermans (1985), though with little reference to graphical aspects, and a comprehensive treatment of modelling methods based on energies is given by Burkert & Allinger (1982).

3.3.2.1. Connectivity

It is necessary to distinguish three different kinds of connectivity, namely structural, logical and drawing connectivities. Structural connectivity consists of the specification of the chemical bonding of the molecule and, as such, is an absolute property of the molecule. Logical connectivity consists of the specification of what part or parts of a molecule are moved, and in what way, if some stereochemical feature is altered. Logical and structural connectivity are closely related and in simple cases coincide, but the distinction is apparent, for example, if the puckering of a five-membered ring is being modelled by permitting folding of the pentagon about a line connecting nonadjacent corners. This line is then a logical connection between two moving parts, but it is not a feature of the structural connectivity.

Drawing connectivity consists of a specification of the lines to be drawn to represent the molecule and often coincides with the structural connectivity. However, stylized drawings, such as those showing the α-carbon atoms of a protein, require to be drawn with lines which are features neither of the logical nor of the structural connectivity.

3.3.2.1.1. Connectivity tables

The simplest means of storing connectivity information is by means of tables in which, for each atom, a list of indices of other atoms to which it is connected is stored. This approach is quite general; it may serve any type of molecular structure and permits structures to be traversed in a variety of ways. In this form, however, it is extravagant on storage because every connection is stored twice, once at each of the nodes it connects. It may, however, provide the starting material for the algorithm of Section 3.3.1.5.2 and its generality may justify its expense.

From such a list, lists of bonds, bond angles and dihedral angles may readily be derived in which each entry points to two, three or four atoms in the atom list. Lists of these three types form the basis of procedures which adjust the shape of a molecule to reduce its estimated potential energy (Levitt & Lifson, 1969; Levitt, 1974), and of search-and-retrieval techniques (Allen *et al.,* 1979).

Katz & Levinthal (1972) discuss the explicit specification of structural connectivity in terms of a tree structure in which, for each atom, is stored a single pointer to the connected atom nearer to the root, virtual atoms being used to allow ring structures to be treated as trees. An algorithm is also presented which allows such a tree specification to be redetermined if an atom in the tree is newly chosen as the root atom or if the tree itself is modified.

Cohen *et al.* (1981) have developed methods of handling connectivity in complicated fused- and bridged-ring systems.

3.3.2.1.2. Implied connectivity

In cases where software is required to deal only with a certain class of molecule, it may be possible to exploit the characteristics of that class to define an ordering for lists of atoms such that connectivity is implied by the ordering of items in the list. Such an ordering may successfully define one of the three types of connectivity defined in Section 3.3.2.1 but it is unlikely to be able to meet the needs of all three simultaneously. It may also be at a disadvantage when required to deal with structures not part of the class for which it is designed. Within these limitations, however, it may be exceedingly efficient. Both proteins and nucleic acids are of a class which permits their logical connectivity to be specified entirely by list ordering, and the software described in Section 3.3.3.2.6 uses no connectivity tables for this purpose. The ordering rules concerned are given by Diamond (1976*b*).

Drawing connectivity needs explicit specification in such a case; this may be done using only one 16-bit integer per atom, which may be stored as part of the atom list without the need of a separate table. This integer consists of two signed bytes which act as relative pointers in the list, positive pointers implying draw-to, negative pointers implying move-to. As each atom is encountered during drawing the right byte is read and utilized, and the two bytes are swapped before proceeding. This allows up to two bonds drawn to an atom and two bonds drawn from it, four in all, with a minimum of storage (Diamond, 1984*a*).

Brandenburg *et al.* (1981) handle drawing connectivity by enlarging the molecular list with duplicate atoms such that each is connected to the next in the list, but moves and draws still need to be distinguished.

Levitt (1971) has developed a syntax for specifying structural connectivity implicitly from a list structure which is very general, though designed with biopolymers in mind, and the work of Katz & Levinthal (1972) includes something similar.

3.3.2.2. Modelling methods

Fundamental to the design of any software for molecular modelling are the choices of modelling criteria, and of parameterization. Criteria which may be adopted might include the fitting of electron density, the minimization of an energy estimate or the matching of complementary surfaces between a pair of molecules. Parameterizations which may be adopted include the use of Cartesian coordinates of atoms as independent variables, or of internal coordinates, such as dihedral angles, as independent variables with atomic positions being dependent on these. Systems designed to suit energetic criteria usually use Cartesian coordinates since all aspects of the structure, including bond lengths, must be treated as variables and be allowed to contribute to the energy estimate. Systems designed to fit a model to observed electron density, however, may adequately meet the stereochemical requirements of modelling on either parameterization, and examples of both types appear below.

Inputs to modelling systems vary widely. Systems intended for use mainly with proteins or other polymeric structures usually work with a library of monomers which the software may develop into a polymer. Systems intended for smaller molecules usually develop the molecular structure atom-by-atom rather than a residue at a time, and systems of this kind require a very general form of input. They may accept a list of atom types and coordinates if measurement and display of a known molecule is the objective, or they may accept 'sketch-pad' input in the form of a hand-drawn two-dimensional sketch of the type conventional in chemistry, if the objective is the design of a molecule. Sketch-pad input is a feature of some systems with quantum-mechanical capabilities.

3.3.2.2.1. Methods based on conformational variables

Suppose that $\mathbf{t}$ represents a vector from the current position of an atom in the model to a target position then (see Section 3.3.1.1.3), to first order, the observational equations are

$$t_{IA} = D_{IpA}\theta_p + v_{IA}$$

in which $\boldsymbol{\theta}$ represents changes to conformational variables which may include dihedral angles, bond angles, bond lengths, and parameters determining overall position and orientation of the molecule as a whole. If every such parameter is included the model acquires $3n$ degrees of freedom for n atoms, in which case

the methods of the next section are more appropriate, but if bond lengths and some or all bond angles are being treated as constants then the above equation becomes the basis of the treatment.

$$D_{IPA} = \frac{\partial r_{IA}}{\partial \theta_P} = \varepsilon_{Ijk} n_{jP} (r_{kA} - r_{kP})$$

in which $\mathbf{n}_P$ is a unit vector defining the axis of rotation for an angular variable θ_P, $\mathbf{r}_A$ and $\mathbf{r}_P$ are position vectors of the atom A and the site of the parameter P, and $\mathbf{v}_A$ represents a residual vector.

$\sigma = v_{ia} v_{ia}$ is minimized by

$$\boldsymbol{\theta} = \boldsymbol{M}^{-1}\mathbf{V}$$

in which

$$M_{PQ} = D_{iPa} D_{iQa}$$
$$V_P = D_{iPa} t_{ia}.$$

More generally, if σ represents any scalar quantity which is to be minimized, *e.g.* an energy, then

$$V_P = -\frac{1}{2}\frac{\partial \sigma}{\partial \theta_P}$$
$$M_{PQ} = \frac{1}{2}\frac{\partial^2 \sigma}{\partial \theta_P \partial \theta_Q}.$$

It is beyond the scope of this chapter to review the methods available for evaluating $\boldsymbol{\theta}$ from these equations. Difficulties may arise from two sources:

(i) Inversion of $\boldsymbol{M}$ may be difficult if $\boldsymbol{M}$ is large or ill conditioned and impossible if $\boldsymbol{M}$ is singular.

(ii) Successful evaluation of $\boldsymbol{M}^{-1}\mathbf{V}$ will not minimize σ in one step if $\mathbf{t}$ is not linearly dependent on $\boldsymbol{\theta}$ or, equivalently, $\partial^2\sigma/\partial\theta_P\partial\theta_Q$ is not constant, and substantial changes $\boldsymbol{\theta}$ are involved. Iteration is then necessary.

Difficulties of the first kind may be overcome by gradient methods, for example the conjugate gradient method without searches if $\boldsymbol{M}$ is available or with searches if it is not available, or they may be overcome by methods based on eigenvalue decompositions. If nonlinearity is serious less dependence should be placed on $\boldsymbol{M}$ and gradient methods using searches are more valuable. In this connection Diamond (1966) introduced a sliding filter technique which produced rapid convergence in extreme conditions of nonlinearity. These topics have been reviewed elsewhere (Diamond, 1981*b*, 1984*b*) and are the subject of many textbooks (Walsh, 1975; Gill *et al.*, 1981; Luenberger, 1984).

Warme *et al.* (1972) have developed a similar system using dihedral angles as variables and a variety of alternative optimization algorithms.

The modelling of flexible rings or lengths of chain with two or more fixed parts is sometimes held to be a difficulty in methods using conformational variables, although a simple two-stage solution does exist. The principle involved is the sectioning of the space of the variables into two orthogonal subspaces of which the first is used to satisfy the constraints and the second is used to perform the optimization subject to those constraints.

The algebra of the method may be outlined as follows, and is given in more detail by Diamond (1971, 1980*a*, 1981*a*). Parametric shifts $\boldsymbol{\theta}_1$ which satisfy the constraints are solutions of

$$\mathbf{V}_1 = \boldsymbol{M}_1 \boldsymbol{\theta}_1$$

in which $\mathbf{V}_1$ and $\boldsymbol{M}_1$ depend only on the target vectors, $\mathbf{t}_1$, of the atoms with constrained positions and on the corresponding derivatives. We then find a partitioned orthogonal matrix $(\boldsymbol{A}_1\boldsymbol{B}_1)$ satisfying

$$(\boldsymbol{A}_1\boldsymbol{B}_1) = (\boldsymbol{E}_\lambda \boldsymbol{E}_0)\begin{pmatrix} \boldsymbol{R}_\lambda & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{R}_0 \end{pmatrix}$$

in which $\boldsymbol{E}_\lambda$ are the eigenvectors of $\boldsymbol{M}_1$ having positive eigenvalues, $\boldsymbol{E}_0$ are those having zero eigenvalues, and $\boldsymbol{R}_\lambda$ and $\boldsymbol{R}_0$ are arbitrary orthogonal matrices. Then

$$\begin{pmatrix} \boldsymbol{A}_1^T \\ \boldsymbol{B}_1^T \end{pmatrix}\mathbf{V}_1 = \begin{pmatrix} \boldsymbol{A}_1^T \\ \boldsymbol{B}_1^T \end{pmatrix}\boldsymbol{M}_1(\boldsymbol{A}_1\boldsymbol{B}_1)\begin{pmatrix} \boldsymbol{A}_1^T \\ \boldsymbol{B}_1^T \end{pmatrix}\boldsymbol{\theta}_1$$
$$= \begin{pmatrix} \boldsymbol{A}_1^T\boldsymbol{M}_1\boldsymbol{A}_1 & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} \end{pmatrix}\begin{pmatrix} \boldsymbol{A}_1^T \\ \boldsymbol{B}_1^T \end{pmatrix}\boldsymbol{\theta}_1$$
$$\boldsymbol{A}_1^T\boldsymbol{\theta}_1 = (\boldsymbol{A}_1^T\boldsymbol{M}_1\boldsymbol{A}_1)^{-1}\boldsymbol{A}_1^T\mathbf{V}_1$$

in which the matrix to be inverted is positive definite. $\boldsymbol{A}_1$, however, is rectangular so that multiplying on the left by $\boldsymbol{A}_1$ does not necessarily serve to determine $\boldsymbol{\theta}_1$, but we may write

$$\boldsymbol{\theta}_1 = (\boldsymbol{A}_1\boldsymbol{B}_1)\begin{pmatrix} \boldsymbol{\varphi}_1 \\ \boldsymbol{\psi}_1 \end{pmatrix}$$

giving

$$\begin{pmatrix} \boldsymbol{A}_1^T \\ \boldsymbol{B}_1^T \end{pmatrix}\mathbf{V}_1 = \begin{pmatrix} \boldsymbol{A}_1^T\boldsymbol{M}_1\boldsymbol{A}_1 & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} \end{pmatrix}\begin{pmatrix} \boldsymbol{\varphi}_1 \\ \boldsymbol{\psi}_1 \end{pmatrix}$$
$$\boldsymbol{\varphi}_1 = (\boldsymbol{A}_1^T\boldsymbol{M}_1\boldsymbol{A}_1)^{-1}\boldsymbol{A}_1^T\mathbf{V}_1$$

and $\boldsymbol{\psi}_1$ is indeterminate and free to adopt any value. We therefore adopt

$$\boldsymbol{\theta}_1 = \boldsymbol{A}_1\boldsymbol{\varphi}_1 = \boldsymbol{A}_1(\boldsymbol{A}_1^T\boldsymbol{M}_1\boldsymbol{A}_1)^{-1}\boldsymbol{A}_1^T\mathbf{V},$$

which is the smallest vector of parametric shifts which will satisfy the constraints, and allow $\boldsymbol{\psi}_1$ to be determined by the remaining observational equations in which the target vectors, $\mathbf{t}$, are now modified to $\mathbf{t}_2$ according to

$$\mathbf{t}_2 = \mathbf{t} - \boldsymbol{D}_2\boldsymbol{\theta}_1,$$

$\boldsymbol{D}_2$ and $\mathbf{t}_2$ being the derivatives and effective target vectors for the unconstrained atoms. We then solve

$$\mathbf{V}_2 = \boldsymbol{M}_2\boldsymbol{\theta}_2$$

in which $\boldsymbol{\theta}_2$ is required to be of the form

$$\boldsymbol{\theta}_2 = \boldsymbol{B}_1\boldsymbol{\psi}_1$$

giving

$$\boldsymbol{\theta}_2 = \boldsymbol{B}_1(\boldsymbol{B}_1^T\boldsymbol{M}_2\boldsymbol{B}_1)^{-1}\boldsymbol{B}_1^T\mathbf{V}_2$$

and apply the total shifts

$$\boldsymbol{\Theta} = \boldsymbol{\theta}_1 + \boldsymbol{\theta}_2$$

to obtain a structure which is optimized within the restrictions imposed by the constraints.

It may happen that $\boldsymbol{B}_1^T\boldsymbol{M}_2\boldsymbol{B}_1$ is itself singular because there are insufficient data in the vector $\mathbf{t}_2$ to control the structure and the parametric shifts contained in $\boldsymbol{\theta}_2$ fully. In this event the same process may be applied again, basing the solution for $\boldsymbol{\theta}_2$ on

$$\begin{pmatrix} \boldsymbol{A}_2^T \\ \boldsymbol{B}_2^T \end{pmatrix}\boldsymbol{B}_1^T\boldsymbol{M}_2\boldsymbol{B}_1(\boldsymbol{A}_2\boldsymbol{B}_2)$$

so that the vectors in $\boldsymbol{B}_2$ represent the degrees of freedom which remain uncommitted. This method of application of constraints by subspace sectioning may be nested to any depth and is completely general.

A valid matrix $\boldsymbol{A}_1$ may be found from $\boldsymbol{M}_1$ by using the fact that the columns of $\boldsymbol{M}_1$ are all linear combinations of the columns of

$\boldsymbol{E}_\lambda$ and are void of any contribution from $\boldsymbol{E}_0$. It follows that $\boldsymbol{A}_1$ may be found by using the columns of $\boldsymbol{M}_1$ as priming vectors in the Gram–Schmidt process [Section 3.3.1.2.3 (i)] until the normalizing step involves division by zero. $\boldsymbol{A}_1$ is then complete if all the columns of $\boldsymbol{M}_1$ have been tried. $(\boldsymbol{A}_1\boldsymbol{B}_1)$ may then be completed by using arbitrary vectors as primers.

Manipulation of a ring of n atoms may be achieved by treating it as a chain of $(n+2)$ atoms [having $(n+1)$ bond lengths, n bond angles and $(n-1)$ dihedral angles] in which atom 1 is required to coincide with atom $(n+1)$ and atom 2 with $(n+2)$. $\mathbf{t}_1$ then contains two vectors, namely the lack-of-closure vectors at these points, and is typically zero. $\boldsymbol{A}_1$ is then found to have five columns corresponding to the five degrees of freedom of two points of fixed separation; $\boldsymbol{\theta}_1$ contains only zeros if the ring is initially closed, and contains ring-closure corrections if, through non-linearity or otherwise, the ring has opened. $\boldsymbol{B}_1$ contains $(p-5)$ columns if the chain of $(n+2)$ points has p variable parameters. It follows, if bond lengths and bond angles are treated as constants, that the seven-membered ring is the smallest ring which is flexible, that the six-membered ring (if it can be closed with the given bond angles) has no flexibility (though it may have discrete alternatives) and that it may be impossible to close a five-membered ring. Therefore some variation of bond angles and/or bond lengths is essential for the modelling of flexible five- and six-membered rings. Treating the ring as a chain of $(n+1)$ atoms is less satisfactory as there is then no control over the bond angle at the point of ring closure.

A useful concept for the modelling of flexible five-membered rings with near-constant bond angles is the concept of the pseudorotation angle P, and amplitude θ_m, for which the jth dihedral angle is given by

$$\theta_j = \theta_m \cos\left(P + \frac{4\pi j}{5}\right).$$

This formulation has the property $\sum_{j=0}^{4}\theta_j = 0$, which is not exactly true; nevertheless, θ_j values measured from observed conformations comply with this formulation within a degree or so (Altona & Sundaralingam, 1972).

Software specialized to the handling of condensed ring systems has been developed by van der Lieth *et al.* (1984) (Section 3.3.3.3.1) and by Cohen *et al.* (1981) (Section 3.3.3.3.2).

3.3.2.2.2. Methods based on positional coordinates

Modelling methods in which atomic coordinates are the independent variables are mathematically simpler than those using angular variables especially if the function to be minimized is a quadratic function of interatomic distances or of distances between atoms and fixed points. The method of Dodson *et al.* (1976) is representative of this class and it may be outlined as follows. If **d** is a column vector containing ideal values of the scalar distances from atoms to fixed target points or to other atoms, and if **l** is a column vector containing the prevailing values of these quantities obtained from the model, then

$$\mathbf{d} = \mathbf{l} + \boldsymbol{D}\boldsymbol{\delta}\mathbf{x} + \boldsymbol{\varepsilon}$$

in which the column matrix $\boldsymbol{\delta}\mathbf{x}$ contains alterations to the atomic coordinates, $\boldsymbol{\varepsilon}$ contains residual discrepancies and $\boldsymbol{D}$ is a large sparse rectangular matrix containing values of $\partial l/\partial x$, of which there are not more than six nonzero values on any row, consisting of direction cosines of the line of which **l** is the length. $\boldsymbol{\varepsilon}^T\boldsymbol{W}\boldsymbol{\varepsilon}$ is then minimized by setting

$$\boldsymbol{D}^T\boldsymbol{W}(\mathbf{d}-\mathbf{l}) = \boldsymbol{D}^T\boldsymbol{W}\boldsymbol{D}\boldsymbol{\delta}\mathbf{x},$$

which they solve by the method of conjugate gradients without searches. This places reliance on the linearity of the observational equations (Diamond, 1984*b*). It also works entirely with the sparse matrix $\boldsymbol{W}^{1/2}\boldsymbol{D}$, the dense matrix $\boldsymbol{D}^T\boldsymbol{W}\boldsymbol{D}$, and its inverse, being never calculated.

The method is extremely efficient in annealing a model structure for which an initial position for every atom is available, especially if the required shifts are within the quasi-linear region, but is less effective when large dihedral-angle changes are involved or when many atoms are to be placed purely by interpolation between a few others for which target positions are available. Interbond angles are controlled by assigning d values to second-nearest-neighbour distances; this is effective except for bond angles near 180° so that, in particular, planar groups require an out-of-plane dummy atom to be included which has no target position of its own but does have target values of distances between itself and atoms in the planar group. The method requires a d value to be supplied for every type of nearest- and next-nearest-neighbour distance in the structure, of which there are many, together with W values which are the inverse variances of the distances concerned as assessed by surveys of the corresponding distances in small-molecule structures, or from estimates of their accuracy, or from estimates of accuracy of the target positions.

Hermans & McQueen (1974) published a similar method which differs in that it moves only one atom at a time, in the environment of its neighbours, these being considered fixed while the central atom is under consideration. This is inefficient in the sense that in any one cycle one atom moves only a small fraction (∼3%) of the distance it will ultimately be required to move, but individual atom cycles are so cheap and simple that many cycles can be afforded. The method was selected for inclusion in *Frodo* by Jones (1978) (Section 3.3.3.2.7) and is an integral part of the *GRIP* system (Tsernoglou *et al.*, 1977; Girling *et al.*, 1980) (Section 3.3.3.2.2) for which it was designed.

3.3.2.2.3. Approaches to the problem of multiple minima

Modelling methods which operate by minimizing an objective function of the coordinates (whether conformational or positional) suffer from the fact that any realistic objective function representing the potential energy of the structure is likely to have many minima in the space of the variables for any but the simplest problems. No general system has yet been devised that can ensure that the global minimum is always found in such cases, but we indicate here two approaches to this problem.

The first approach uses dynamics to escape from potential-energy minima. Molecular-mechanics simulations allow each atom to possess momentum as well as position and integrate the equations of motion, conserving the total energy. By progressively removing energy from the simulation by scaling down the momentum vectors some potential-energy minimum may be found. Conversely, a minimization of potential energy which has led to a minimum thought not to be the global minimum may be continued by introducing atomic momenta sufficient to overcome potential-energy barriers between minima, and subsequently attenuate the momenta again. In this way a number of minima may be found (Levitt & Warshel, 1975). It is equivalent to initializing a potential-energy minimization from a number of different conformations but it has the property that the minima so found are separated by energy barriers for which an upper limit is known so that the possibility exists of exploring transition pathways.

A second approach is described by Purisima & Scheraga (1986). If the objective function to be minimized can be expressed in terms of interatomic distances, and if each atom is given coordinates in a space of $n-1$ dimensions for n atoms, then a starting structure may be postulated for which the interatomic distances *all* take their ideal values and the objective function is then necessarily at an absolute minimum. This multidimensional structure is then projected into a space of fewer dimensions, within which it is again optimized with respect to the

objective function. The dimensionality of the model is thus progressively reduced until a three-dimensional model is attained at a low energy. This means that the minimum so attained in three dimensions is approached *from beneath*, having previously possessed a lower value in a higher-dimensional space. This, in itself, does not guarantee that the three-dimensional minimum-energy structure so found is at the global minimum, but it is not affected by energy barriers between minima in the same way, and it does appear to reach very low minima, and frequently the global one. Because it is formulated entirely in terms of inter-atomic distances it offers great promise for modelling molecules on the basis of data from nuclear magnetic resonance.

3.3.3. Implementations

By R. Diamond

In this section the salient characteristics of a number of systems are described. Regrettably, it cannot claim to be a complete guide to all existing systems, but it probably describes a fairly representative sample. Some of these systems have arisen in academia and these are freely described. Some have arisen in or been adopted by companies which now market them, and these are described by reference to the original publications. Other marketed systems for which originators' published descriptions have not been found are not described. Yet other systems have been developed, for example, by companies within the chemical and pharmaceutical industries for their own use, and these have generally not been described in what follows since it is assumed that they are not generally available, even where published descriptions exist.

Software concerned especially with molecular dynamics has not been included unless it also provides static modelling capability, since this is a rapidly growing field and it has been considered to be beyond the intended scope of this chapter. Systems for which outline descriptions have already been given (Levitt & Lifson, 1969; Levitt, 1974; Diamond, 1966; Warme *et al.*, 1972; Dodson *et al.*, 1976; Hermans & McQueen, 1974) are not discussed further.

For some of the earliest work Levinthal (1966) still makes interesting reading and Feldmann (1976) is still an excellent review of the technical issues involved. The issues have not changed, the algorithms there described are still valuable, only the manner of their implementation has moved on as hardware has developed. A further review of the computer generation of illustrations has been given by Johnson (1980). Excellent bibliographies relating to these sections have been given by Morffew (1983, 1984), which together contain over 250 references including their titles.

The following material is divided into three sections. The first is concerned primarily with display rather than modelling though some of these systems can modify a model, the second is concerned with molecular modelling with reference to electron density and can develop a model *ab initio*, and the third is concerned with modelling with reference to other criteria.

Where software names are known to be acronyms constructed from initial letters, or where the original authors have used capitals, the names are capitalized here. Otherwise names are lower case with an initial capital.

While it is recognised that many of the systems here described are now of mainly historical interest, most were retained for the second edition, some were updated and some new paragraphs were added.

For the third edition a whole new section, Section 3.3.4, has been added, which provides an overview of recent developments relevant in particular to small and medium-sized structures. Recent developments in the macromolecular field of model building and computer graphics are now covered by Chapters 17.1 and 17.2 in *International Tables for Crystallography* Volume F (2001).

3.3.3.1. Systems for the display and modification of retrieved data

One of the earliest systems designed for information retrieval and display was that described by Meyer (1970, 1971) which used television raster technology and enabled the contents of the Brookhaven Protein Data Bank (Meyer, 1974; Bernstein *et al.*, 1977) to be studied visually by remote users. It also enabled a rigid two-ring molecule to be solved from packing considerations alone (Hass *et al.*, 1975; Willoughby *et al.*, 1974). Frames for display were written digitally on a disk and the display rate was synchronized to the disk rotation. With the reduction in the cost of core storage, contemporary systems use large frame buffer memories thus avoiding synchronization problems and permitting much richer detail than was possible in 1970. A majority of the systems in this section use raster techniques which preclude real-time rotation except for relatively simple drawings, though *GRAMPS* is an exception (O'Donnell & Olson, 1981; Olson, 1982) (Section 3.3.3.1.4).

3.3.3.1.1. ORTEP

This program, the Oak Ridge Thermal Ellipsoid Program, due to Johnson (1970, 1976) was developed originally for the preparation of line drawings on paper though versions have since been developed to suit raster devices with interactive capability.

The program draws molecules in correct perspective with each atom represented by an ellipsoid which is the equi-probability surface for the atomic centre, as determined by anisotropic temperature factor refinement, the principal axes of which are displayed. Bonds are represented by cylindrical rods connecting the atoms which in the drawing are tapered by the perspective.

In line-drawing versions the problem of hidden-line suppression is solved analytically, whereas the later versions for raster devices draw the furthest elements of the picture first and either overwrite these with nearer features of the scene if area painting is being done or use the nearer features as erase templates if line drawings are being made.

3.3.3.1.2. Feldmann's system

R. J. Feldmann and co-workers (Feldmann, 1983) at the National Institutes of Health, Bethesda, Maryland, USA, were among the first to develop a suite of programs to display molecular structure using colour raster-graphics techniques. Their system draws with coloured shaded spheres, usually with one sphere to represent each atom, but alternatively the spheres may represent larger moieties like amino acids or whole proteins if lower-resolution representations are required. These workers have made very effective use of colour. Conventionally, oxygens have been modelled in red, but this system allows charged oxygens to be red and uncharged ones to be pink, with a similar treatment in blue for charged and uncharged nitrogens. By such means they have been able to give immediacy to the hydrophobic and electrostatic properties of molecular surfaces, and have used these characteristics effectively in studies of the binding possibilities of benzamidine derivatives to trypsin (Feldmann *et al.*, 1978).

The algorithm developed by Porter (1978) for shading spheres to be darkened near their peripheries also computes the proper appearance of the line of intersection of two spheres wherever interpenetration occurs, in contrast to some simpler systems which draw a complete disc for whichever sphere is forward of the other. Provided that all opaque spheres are drawn first, the system is also capable of representing transparent spheres by darkening the colour of the existing background inside, and especially near the edge of, discs representing transparent foreground spheres.

Other systems that produce space-filling pictures of a similar general character have been produced by Motherwell (1978), by Sundaram & Radhakrishnan (1979) and by Lesk (next section).

3.3.3.1.3. Lesk & Hardman software

The complexity of macromolecules is a formidable obstacle to perceiving the basic features of their construction. Stylized drawings to facilitate this perception were pioneered by A. Rossmann and B. Furugren, and developed further by Richardson (1977, 1981, 1985) and by Lesk and Hardman, whose software is capable of mixing several styles of representation, among them the style of cylinders for α-helices, arrows for β-strands and ribbons for less-organized regions, or the creased-ribbon technique for the whole chain, or a ball-and-stick representation of atoms and bonds, or space-filling spheres. All these styles are available simultaneously in a single picture with depth cueing, colour and shading, and hidden-feature suppression as appropriate. It is also able to show a stylized drawing of a complete molecule together with a magnified part of it in a more detailed style. See Lesk & Hardman (1982, 1985) and Lesk (1991).

3.3.3.1.4. GRAMPS

This system, due to O'Donnell & Olson (O'Donnell & Olson, 1981; Olson, 1982) provides a high-level graphics language and its associated interpretive software. It provides a general means of defining objects, drawable by line drawings, in such a way that these may be logically connected in groups or trees using a simple command language. Such a system may, for example, define a subunit protein of an icosahedral virus and define icosahedral symmetry, in such a way that modification of one subunit is expressed simultaneously in all subunits whilst preserving the symmetry, and simultaneously allowing the entire virus particle to be rotated. Such logical and functional relationships are established by the user through the medium of the *GRAMPS* language at run time, and a great diversity of such relationships may be created. The system is thus not limited to any particular type of structure, such as linear polymers, and has proved extremely effective as a means of providing animation for the production of cine film depicting viral and other structures. *GRAMPS* runs on all Silicon Graphics workstations under IRIX 4.0 or above.

3.3.3.1.5. Takenaka & Sasada's system

Takenaka & Sasada (1980) have described a system for the manipulation and display of molecular structures, including packing environments in the crystal, using a minicomputer loosely coupled to a mainframe. Their system is also capable of model building by the addition of groups of one or more atoms with a facility for monitoring interaction distances while doing so.

3.3.3.1.6. MIDAS

This system, due to Langridge and co-workers (Gallo *et al.*, 1983; Ferrin *et al.*, 1984) is primarily concerned with the display of existing structures rather than with the establishment of new ones, but it may modify such structures by bond rotations under manual control. It is of particular value in the study of molecular interactions since two or more molecules may be manipulated simultaneously and independently. Visual docking of molecules is greatly facilitated by the display of van der Waals surfaces, which may be computed in real time so that the turning of a bond in the underlying structure does not tear the surface (Bash *et al.*, 1983).

3.3.3.1.7. Insight

This system, originally due to Dayringer *et al.* (1986), has a functionality similar to *MIDAS*. It has been replaced by *Insight* II (version 2.3.5 or later). It appears to be well suited to the study of intermolecular relationships in docking and in structural comparisons, and it is able to make modifications to structures. Objects for display may be molecular or nonmolecular, the former having an atomic substructure and the latter consisting of a vector list which may not be subdivided into referrable components. Map fitting with the current version has been reported.

3.3.3.1.8. PLUTO

PLUTO was developed by Motherwell (1978) at the Cambridge Crystallographic Data Centre (CCDC) for the display of molecular structures and crystal-packing diagrams, including an option for space-filling model style with shadowing. The emphasis was on a free format command and data structure, and the ability to produce ball-and-spoke drawings with line shadowing suitable for reproduction in journal publication. Many variant versions have been produced, with essentially the 1978 functionality, its popularity deriving from its ease of use and the provision of default options for establishing connectivity using standard bonding radii. It was distributed as part of the CCDC software associated with the Cambridge Structural Database, with an interface for reading entries from the database.

In 1993 Motherwell and others at the CCDC added an interactive menu and introduced colour and PostScript output. New features were introduced to allow interactive examination of intermolecular contacts, particularly hydrogen-bonded networks, and sections through packing diagrams (Cambridge Structural Database, 1994).

3.3.3.1.9. MDKINO

This system, due to Swanson *et al.* (1989), provides for the extraction and visualization of selected regions from molecular-dynamics simulations. It permits stereo viewing, interactive geometric interrogation and both forwards and backwards display of motion.

3.3.3.2. Molecular-modelling systems based on electron density

Systems described in this section require real-time rotation of complicated transparent scenes and all used vector-graphics technology in their original implementations for that reason, though many are now available for raster machines. In every case the graphics are the means of communication between the user and software possessing high functionality, capable of building a representation of a molecule *ab initio* and to alter it, change its shape and position it optimally in relation to an electron-density map, with due attention being paid to stereochemical considerations, by one or more of several approaches.

3.3.3.2.1. CHEMGRAF

Katz & Levinthal (1972) have developed a powerful modelling and display system for macromolecules known as *CHEMGRAF*. This system permits the definition of many atom types which includes bonding specifications, so that, for example, four types of carbon atom are included in the basic list and others may be added. A molecular fragment with an unsatisfied valency (by which it might later be attached to another such group) would have that feature represented by a 'vanishing virtual' atom which removes the need for any organizational distinction between such fragments and complete molecules. Fragments, such as amino-acid residues, may be assembled from atoms, and molecules may be assembled from atoms and/or from such fragments invoked by name, by the superposition and elimination of the relevant vanishing virtuals. The assembly process includes the development of a connectivity tree for the molecule and provision is made for the 'turning' or reconstruction of such trees if the combination of such fragments redefines the root atom of one or more of the fragments. The system also provides for ring closure. Model building initially uses fixed bond lengths and angles,

varying only the dihedral angles in single bonds, but has a library of preformed rings which could not otherwise be modelled on the simple basis. The results of such modelling may then be subjected to an energy-minimization routine using a steepest-descent method in the space of the dihedral angles and referring to the Lennard–Jones potential for nonbonded atom pairs. Atoms are first sorted into contiguous cubes so that all neighbours of any atom may be found by searching not more than 27 cubes.

The system is also capable of modelling by reference to electron density either by the translation and rotation of molecular fragments and the rotation of rotatable bonds within them or by the automatic linking of peaks in an electron-density map which are separated by less than, say, 1.8 Å, which is an important aid to interpretation when the resolution is sufficiently high.

3.3.3.2.2. GRIP

This system, developed by Professor F. P. Brooks, Dr W. V. Wright and associates at the University of North Carolina, Chapel Hill, NC, USA, was designed for biopolymers and was the first to enable a protein electron-density map to be interpreted *ab initio* without the aid of mechanical models (Tsernoglou *et al.*, 1977). Girling *et al.* (1980) give a more recent example of its use.

In its 1975 version *GRIP* is a three-machine system. Centrally there is a minicomputer which receives inputs from the user and controls a vector display with high-speed matrix-multiplication capability. The third machine is a mainframe computer with high-speed communication with the minicomputer.

The system develops a polymer chain from a library of monomers and manipulates it through bond rotations or free rotations of fragments explicitly specified by the user, with the aid of dials which may be coupled to bonds for the purpose. Bond rotations in the main chain either rotate part of the molecule relative to the remainder, which may have undesirable long-range effects, or the scope of the rotation is artificially limited with consequential discontinuities arising in the chain. Such discontinuities are removed or alleviated by the mainframe computer using the method of Hermans & McQueen (1974), which treats atomic position vectors, rather than bond rotations, as independent variables.

The system made pioneering use of a two-axis joystick to control orientation and a three-translation joystick to control position.

3.3.3.2.3. Barry, Denson & North's systems

These systems (Barry & North, 1971; North *et al.*, 1981; North, 1982) are examples of pioneering work done with minicomputers before purpose-built graphics installations became widespread; examples of their use are given by Ford *et al.* (1974), Potterton *et al.* (1983) and Dodson *et al.* (1982). They have the ability to develop a polymer chain in sections of several residues, each of which may subsequently be adjusted to remove any misfit errors where the sections overlap. Manipulations are by rotation and translation of sections and by bond rotations within sections. These movements are directly controlled by the user, who may simultaneously observe on the screen the agreement with electron density, or calculated estimates of potential or interaction energy, or a volume integral of the product of observed and model densities, or predicted shifts of proton magnetic resonance spectra. Thus models which are optimal by various criteria may be constructed, but there is no optimizer directly controlling the rotational adjustments which are determined by the user.

One of the earliest applications of them (Beddell, 1970) was in the fitting of substrate molecules to the active site of lysozyme using difference electron densities; however, the systems also permitted the enzyme–substrate interaction to be studied simultaneously and to be taken into account in adjusting the model.

3.3.3.2.4. MMS-X

The Molecular Modelling System-X (*MMS-X*) is a system of purpose-built hardware developed by Barry, Marshall and others at Washington University, St Louis. Associated with it are several sets of software. The St Louis software consists of a suite of programs rather than one large one and provides for the construction of a polymer chain in helical segments which may be adjusted bodily to fit the electron density, and internally also if the map requires this too. Nonhelical segments are built helically initially and unwound by user-controlled rotations in single bonds. The fitting is done to visual criteria. An example of the use of this system is given by Lederer *et al.* (1981).

Miller *et al.* (1981) have described an alternative software system for the same equipment. Functions invoked from a keyboard allow dials to be coupled to dihedral angles in the structure. Their system communicates with a mainframe computer which can deliver small blocks of electron density to be contoured and stored locally by the graphics system; this provides freedom of choice of contour level at run time. An example of the use of this system is given by Abad-Zapatero *et al.* (1980).

3.3.3.2.5. Texas A&M University system

This system (Morimoto & Meyer, 1976), a development of Meyer's earlier system (Section 3.3.3.1), uses vector-graphics technology and a minicomputer and is free of the timing restrictions of the earlier system. The system allows control dials to be dynamically coupled by software to rotations or translations of parts of the structure, thus permitting the reshaping or repositioning of the model to suit an electron-density map which may be contoured and managed by the minicomputer host. The system may be used to impose idealized geometry, such as planar peptides in proteins, or it may work with nonidealized coordinates.

The system was successfully applied to the structures of rubredoxin and the extracellular nuclease of *Staphylococcus aureus* (Collins *et al.*, 1975) and to binding studies of sulfonamides to carbonic anhydrase (Vedani & Meyer, 1984). In addition, two of the first proteins to be constructed without the aid of a 'Richards' Box' were modelled on this system: monoclinic lysozyme in 1976 (Hogle *et al.*, 1981) and arabinose binding protein in 1978 (Gilliland & Quiocho, 1981).

3.3.3.2.6. Bilder

This system (Diamond, 1980*b*, 1981*a*, 1982*b*) runs on a minicomputer independent of any mainframe. It builds a polymer chain from a library of residues and adapts it by internal rotations and overall positioning in much the same way as previous systems described in this section. Like them, it can provide user-controlled bond rotations, but its distinctive feature is that it has an optimizer within the minicomputer which will determine optimal combinations of bond rotations needed to meet the user's declared objectives. Such objectives are normally target positions for atoms set by the user by visual reference to the density, using the method of Section 3.3.1.3.9, but they may include target values for angles. These latter may either declare a required shape that is to take precedence over positional requirements, which are then achieved as closely as the declared shape allows, or they may be in least-squares competition with the positional requests. The optimizer also recognizes the constraints imposed by chain continuity and enables an internal section of the main chain to be modified without breaking its connection to the rest of the molecule. Similar techniques also allow ring systems to adopt various conformations, by bond rotation, without breaking the ring, simultaneously permitting the ring to have target positions. The optimizer is unperturbed by underdetermined situations, providing a minimum-disturbance result in such cases. All these properties of the optimizer are generated without recourse to any 'special cases' by a general-

ization of the subspace section technique which was used to maintain chain continuity in a 'real-space-refinement' program (Diamond, 1971). This is based entirely on the rank of the normal matrix that arises during optimization, which may serve to satisfy a constraint such as chain continuity or ring closure and simultaneously to establish what degrees of freedom remain to be controlled by other criteria. In *Bilder* this is achieved without establishing eigenvalues or eigenvectors. The method is described in outline in Section 3.3.2.2.1 and in detail by Diamond (1980*a*, 1981*a*).

The angular variables used normally comprise all single bonds but may include others, such as the peptide bond with or without a target of 180°. Thus this bond may be completely rigid, elastic, or completely free. Any interbond angles may also be parameterized but at some cost in storage. The normal mode of working is to develop a single chain for the entire length of the molecule, but if cumulative error makes fitting difficult a fresh chain may be started at any stage. *Bilder* may itself reconnect such chains at a later stage.

Construction and manipulation operates on a few residues at a time within the context of a polymer chain, but any or all of the rest of the molecule, or other molecules, may be displayed simultaneously.

Contouring is done in advance to produce a directoried file of contoured bricks of space, each brick containing up to 20 independently switchable elements which need not all be from the same map. Choice of contour level and displayed volume is thus instantaneous within the choices prepared.

The system is menu driven from a tablet, only file assignments and the like requiring the keyboard, and it offers dynamic parallax as an aid to 3D perception (Diamond *et al.*, 1982). Bloomer *et al.* (1978), Phillips (1980) and Evans *et al.* (1981) give examples of its use.

3.3.3.2.7. Frodo

This system, due to Jones (Jones, 1978, 1982, 1985; Jones & Liljas, 1984), in its original implementation was a three-machine system comprising graphics display, minicomputer and mainframe, though more recent implementations combine the last two functions in a 'midi'. Its capabilities are similar to those of *Bilder* described above, but its approach to stereochemical questions is very different. Where *Bilder* does not allow an atom to be moved out of context (unless it comprises a 'chain' of one atom) *Frodo* will permit an atom or group belonging to a chain to be moved independently of the other members of the chain and then offers regularization procedures based on the method of Hermans & McQueen (1974) to regain good stereochemistry. During this regularization, selected atoms may be fixed, remaining atoms then adjusting to these. A peptide, for example, may be inverted by moving the carbonyl oxygen across the peptide and fixing it, relying on the remaining atoms to rearrange themselves. (*Bilder* would do the equivalent operation by cutting the chain nearby, turning the peptide explicitly, reconnecting the chain and optimizing to regain chain continuity.) The *Frodo* approach is easy to use especially when large displacements of an existing structure are called for, but requires that ideal values be specified for all bond lengths, angles and fixed dihedrals since the system may need to regain such values in a distorted situation. *Bilder*, in contrast, never changes such features and so need not know their ideal values.

Frodo may work either with consecutive residues of a polymer chain, useful for initial building, or with a volume centred on a chosen position, which is ideal for adjusting interacting side chains which are close in space but remote in sequence.

In recent implementations *Frodo* can handle maps both in density grid form and in contour form and permits online contouring. It has also been developed (Jones & Liljas, 1984) to allow the automatic adjustment of the position and orientation of small rigid groupings by direct reference to electron density in the manner of Diamond (1971) but without the maintenance of chain continuity, which is subsequently reintroduced by regularization.

Horjales and Cambillau (Cambillau & Horjales, 1987; Cambillau *et al.*, 1984) have also provided a development of *Frodo* which allows the optimization of the interaction of a ligand and a substrate with both molecules being treated as flexible.

3.3.3.2.8. Guide

Brandenburg *et al.* (1981) have described a system which enables representations of macromolecules to be modified with reference to electron density. Such modifications include rotation about single bonds under manual control, or the movement with six degrees of freedom, also under manual control, of any part or parts of the molecule relative to the remainder. The latter operation may necessitate subsequent regularization of the structure if the moved and unmoved parts are chemically connected, and this is done as a separate operation on a different machine. The system also has the capability of displaying several molecules and of manually superimposing these on each other for comparison purposes.

3.3.3.2.9. HYDRA

This program, due to Hubbard (1985) (and, more recently, to Molecular Simulations) has several functional parts, referred to as 'heads', which all use the same data structure. The addition of further heads may be accomplished, knowing the data structure, without the need to know anything of the internal workings of existing heads.

The program contains extensive features for the display, analysis and modelling of molecular structure with particular emphasis on proteins. Display options include dotted surfaces, molecular skeletons, protein cartoons and a variety of van der Waals, ball-and-stick, and other raster-graphics display techniques such as ray tracing and shaded molecular surfaces. Protein analysis features include the analysis of hydrogen bonding, and of secondary and domain structure, as well as computational assessment of deviations from accepted protein structural characteristics such as abnormal main-chain or side-chain conformations and solvent exposure of hydrophobic amino acids. A full set of protein modelling facilities are provided including homology modelling and the 'docking' of substrate molecules. The program contains extensive tools for interactive modelling of structures from NMR or X-ray crystallographic data, and provides interfaces to molecular-mechanics and dynamics calculations. There are also database searching facilities to analyse and compare features of protein structure, and it is well suited to the making of cine films.

3.3.3.2.10. O

Jones *et al.* (1991) have developed a modelling system for proteins with a radically different approach to any of the foregoing, in that they begin by reducing the available electron-density map to a skeletal representation (Greer, 1974; Williams, 1982) which consists of a line running through the density close to its maximal values, this being the basis of a chain trace. Provisional α-carbon positions are also estimated at this stage. A database of known structures is then scanned for pentapeptides which may be superimposed on five successive positions in the chain trace, the best fit so found being taken to provide coordinates for the three central residues of the developing model. The process advances by three residues at each step, the first and last residues of the pentapeptide being used only to ensure that the central residues are built in a manner compatible with what precedes and follows.

The process ensures that conformations so built are free from improbable conformations, and the whole forms an adequate

starting structure for molecular-dynamics procedures, even though some imperfect geometry is to be expected where each tripeptide joins the next.

3.3.3.3. Molecular-modelling systems based on other criteria

Systems described within this section mostly have some form of energy minimization as their objective but some are purely geometrical. The optimization of molecules through empirical force fields has been reviewed by Allinger (1976), Burkert & Allinger (1982) and Boyd & Lipkowitz (1982). Some of these systems are in the academic domain, others are commercial. Most have capabilities exceeding the features referred to here and, of necessity, the list cannot be complete. No attempt at comparative evaluations is attempted or implied.

3.3.3.3.1. Molbuild, Rings, PRXBLD and MM2/MMP2

Liljefors (1983) has described a system for constructing representations of organic molecules. The system develops the molecule with plausible geometry and satisfied valencies at all stages of the development with explicit recognition of lone pairs and the various possible hybridization states. Growth is generally by substitution in which a substituent and the atom it is to replace are both nominated from the screen. The bond which is reconstructed in a substitution is generally a single bond. Double and triple bonds are introduced by the substitution of moieties containing them. Atom types may be changed after incorporation in the growing molecule, so that although the menu of substituents includes $-CH_3$ but not $-NH_2$ the latter may be obtained by incorporating $-CH_3$, then changing C to N and one of the hydrogens to a lone pair. Facilities are also provided for cyclization and acyclization.

van der Lieth *et al.* (1984) have described an extension to this that is specialized to the construction of fused-ring systems. It permits the joining of rings by fusion of a bond, in which two adjacent atoms in one ring are superposed on two in another. It also permits the construction of spiro links in which one atom is common to two rings, or the construction of bridges, or the polymerization of ring systems to form, for example, oligosaccharides. Again the satisfaction of valencies is maintained during building and the geometry of the result is governed by superposition of relevant atoms in the moieties involved.

PRXBLD is a molecular-model-building program which accepts two-dimensional molecular drawings in a manner similar to *Script* (Section 3.3.3.3.2) and constructs approximate three-dimensional coordinates from these. It is the model-building component of *SECS* (Simulation and Evaluation of Chemical Synthesis) (Wipke *et al.*, 1977; Wipke & Dyott, 1974; Wipke, 1974). See also Anderson (1984).

All three of these programs produce output which is acceptable as input to *MM*2(82)/*MMP*2 which are developments of Allinger's geometrical optimization based on molecular mechanics (Allinger, 1976).

3.3.3.3.2. Script

This system, described by Cohen *et al.* (1981), is specialized for fused-ring systems, especially steroids, but is not limited to these classes. The system allows the user to draw on the screen (with a light pen or equivalent) a two-dimensional representation of a molecule using single lines for single bonds, double lines for double bonds, and wedges to indicate out-of-plane substituents. The software can then enumerate the possible distinct conformers, each of which is expected to be near an energy minimum on the conformational potential surface. Each conformer may then be annealed to reach an energy minimum using an energy estimate based on bond lengths, bond angles, torsion angles and van der Waals, electrostatic and hydrogen-bonding terms. An example is given of the identification of an unusual conformer as the most stable one from twelve possibilities for a four-ring system.

The program is a development of similar work by Cohen (1971) in which the molecule was defined in terms of a tree structure and an optimizer based on search techniques rather than gradient vectors was used. The method included van der Waals terms and hence estimated energy differences between stereoisomers in condensed ring systems arising from steric hindrance.

3.3.3.3.3. CHARMM

This system, due to Brooks *et al.* (1983), is primarily concerned with molecular dynamics but it includes the capability of model-building proteins and nucleic acids from sequence information and values of internal coordinates (bond lengths, bond angles and dihedral angles). The resulting structure (or a given structure) may then be optimized by minimizing an empirical energy function which may include electrostatic and hydrogen-bonding terms as well as the usual van der Waals energy and a Hookean treatment of the covalent skeleton. Hydrogen atoms need not be handled explicitly, groups such as $-CH_2-$ being treated as single pseudo atoms, and this may be advisable for large structures. For small or medium proteins hydrogens may be treated explicitly and their initial positions may be determined by *CHARMM* if they are not otherwise known.

3.3.3.3.4. Commercial systems

A number of very powerful molecular-modelling systems are now available commercially and we mention a few of these here. Typically, each consists of a suite of programs sharing a common data structure so that the components of a system may be acquired selectively.

The *Chem-X* system, from Chemical Design Ltd, enables models to be developed from sketch-pad input, provides for their geometrical optimization and interfaces the result to *Gaussian*80 for quantum-mechanical calculations.

MACCS, from Molecular Design Ltd, and related software (Allinger, 1976; Wipke *et al.*, 1977; Potenzone *et al.*, 1977) has similar features and also has extensive database-maintenance facilities including data on chemical reactions.

Sybyl, from Tripos Associates (van Opdenbosch *et al.*, 1985), also builds from sketches with a standard fragment library, and provides interfaces to quantum-mechanical routines, to various databases and to *MACCS*.

Insight II (Section 3.3.3.1.7) is available from Biosym and *GRAMPS* (Section 3.3.3.1.4) is available from T. J. O'Donnell Associates.

3.3.4. Graphics software for the display of small and medium-sized molecules

By L. M. D. Cranswick

3.3.4.1. Introduction

In the age of the Internet, a wide variety of software can be easily obtained for the display of small and medium-sized molecules. An obvious question to ask is 'which software is the best?'. It can be 'best' to try all the relevant available software quickly before settling on two to three programs that are found to be most suitable. Not relying on just a single program can be important for visual and numeric cross validation of the resulting structural plot, as bugs (if present) can be quite subtle in their effect, but moderately easy to find by comparing plots made by different programs.

Most software can import crystallographic data in some format. The IUCr CIF format [see *International Tables for*

Table 3.3.4.1. *Functionality of software for crystal structure display*

Crystallography Volume G (2005)] is slowly becoming a standard in this regard, displacing the single-crystal *SHELX* INS format, which has been a *de-facto* standard file format for much crystallographic data exchange. Entering crystallographic data by hand is slow and often introduces errors *via* typographical mistakes. Such mistakes can be minimized by importing structures using a known file type, or reformatting using a text editor or spreadsheet program into a known file type. A variety of software programs can be used for translating crystallographic structure files; however, the output (especially the handling of the symmetry operators and the space group) should be carefully checked. The CCP14 website (Cockroft & Stephenson, 2005) lists a variety of programs that can be used for this, of which a specialist program is *Cryscon* (Dowty, 2005).

3.3.4.2. Types of crystal structure display and functionality

The following information was current at the time of writing, but most software is continually changing with the insertion of new features. Thus occasional checks for updated functionality can be useful. Most software distributions include an 'updates' file containing new features and bug fixes. Detailed information on the software referred to in this section, including functionality, authorship, source and availability, is given in Tables 3.3.4.1 and 3.3.4.2.

3.3.4.2.1. Ball and stick

This is one of the most fundamental methods of displaying a crystal structure and almost all software supports this. The exceptions are *STRUVIR* and *STRUPLO for Windows* [a port of *STRUVIR* incorporating a graphical user interface (GUI)], which are both optimized for the polyhedral display of crystal structures.

3.3.4.2.2. Anisotropic displacement parameters

A subset of the programs that display ball-and-stick structures can also display surfaces related to anisotropic displacement parameters (ADPs) (also known colloquially as 'thermals', 'anisotropic thermal ellipsoids' or 'ORTEPS'). By default, most programs display the ellipsoid surfaces at a probability of 50% and normally allow this value to be changed to values between 1 and 99%. Programs that can draw ADPs include *ATOMS*, *Cameron*, *Crystallographica*, *CrystalMaker*, *Crystal Studio*, *CrystMol*, *Diamond*, *DrawXTL*, *FpStudio*, *GRETEP*, *MolXtl*, *ORTEP-III*, *ORTEP-3 for Windows*, *ORTEX*, *PEANUT*, *Platon*, *VENUS*, *XmLmctep*, *X-Seed* and *XtalDraw*.

3.3.4.2.3. Mean-square displacement amplitude

When a more thorough investigation of the ADPs would be informative (Hummel, Raselli & Bürgi, 1990), *PEANUT* can be used for plotting the mean-square displacement amplitude (MSDA), root-mean-square displacements (RMSDs) and difference surfaces. MSDA 'peanuts' can be displayed where the ADPs are non-positive-definite and the ellipsoids cannot be drawn. *ORTEP-3 for Windows* also has an option for plotting MSDAs. Care should be taken to ensure the resulting display is correct.

3.3.4.2.4. Polyhedral display

A method for understanding inorganic and intermetallic structures is the use of coordination polyhedra. The faces defined by the outer coordinated atoms generate a polyhedral object that is displayed instead of the individual atoms. This can aid in understanding the structures of polymeric inorganic materials involving both simple and complex tilt systems, and distorted

coordination structures. Polyhedral display is provided by the programs *ATOMS*, *Balls&Sticks*, *CaRIne*, *Crystallographica*, *CrystalMaker*, *Crystal Studio*, *Diamond*, *DrawXTL*, *STRUPLO*, *STRUPLO for Windows* (a port of *STRUVIR* incorporating a GUI), *STRUVIR*, *VENUS*, *Xtal-3D* and *XtalDraw*. Nearly all the programs display polyhedra automatically after the user has defined (i) a central atom, (ii) the coordinated atoms and (iii) minimum (often a default of near zero) and maximum bond distances. One exception is *Balls&Sticks*, where graphical point and click of the mouse is used to define the polyhedra.

3.3.4.2.5. Cartesian coordinates

Importing Cartesian coordinates can allow the display of incommensurate and quasicrystal structures if the refinement software has this as an output option. Using Cartesian coordinates can sometimes be more convenient for the slight modification of structures for the display of distortions or individual molecules. A structure defined as triclinic with space group *P*1 and a cubic cell with edges of unit length would also work for importing a structure or molecule originally defined in a Cartesian frame of reference.

3.3.4.2.6. Comparing or overlaying crystal structures

The graphical comparison of crystallographic structures can be useful and time-saving for comparison of polymorphs or a chemically similar series of small-molecule structures. One program that can perform this function is *CrystMol*, where multiple molecular structures can be compared using a point and click menu or *via* the *CrystMol* scripting system. RMS differences are also listed. Superposition of structures is discussed in Section 3.3.1.2.2.

3.3.4.2.7. Extended structures and topology analysis

Currently, the only available program that rigorously analyses extended structures (involving overlapping or interpenetrating molecules) is *OLEX*. For graphical viewing of extended structures *OLEX* displays particular fragments in a single colour. *GRETEP* also has this display functionality, making it useful for viewing extended structures.

3.3.4.2.8. Magnetic crystal structure display

The software listed in Tables 3.3.4.1 and 3.3.4.2 includes programs that can display graphics representing magnetic vectors without necessarily having the ability to understand magnetic symmetry. Programs that can display magnetic structures include *ATOMS*, *CrystalMaker*, *Diamond*, *DrawXTL*, *FpStudio*, *VENUS* and *Xtal-3D*.

3.3.4.2.9. Incommensurate crystal structures

PRJMS and *FpStudio* are currently the only programs that can plot modulated structures in three-dimensional space; *FpStudio* is currently restricted to incommensurate magnetic structures. However, importing Cartesian coordinates can be used to display incommensurate structures when incommensurate refinement software can output coordinates in this format. *BALSAC* provides a good example of software which by default uses Cartesian coordinates, from which plots of incommensurate and quasicrystal structures can be generated.

3.4. Accelerated convergence treatment of R^{-n} lattice sums

By D. E. Williams†

3.4.1. Introduction

The electrostatic energy of an ionic crystal is often represented by taking a pairwise sum between charge sites interacting *via* Coulomb's law (the $n = 1$ sum). The individual terms may be positive or negative, depending on whether the pair of sites have charges of the same or different signs. The Coulombic energy is very long-range, and it is well known that convergence of the Coulombic lattice-energy sum is extremely slow. For simple structure types Madelung constants have been calculated which represent the Coulombic energy in terms of the cubic lattice constant or a nearest-neighbour distance. Glasser & Zucker (1980) give tables of Madelung constants and review the subject giving references dating back to 1884. If the ionic crystal structure is not of a simple type usually no Madelung constant will be available and the Coulombic energy must be obtained for the specific crystal structure being considered. In carrying out this calculation, accelerated-convergence treatment of the Coulombic lattice sum is indispensable to achieve accuracy with a reasonable amount of computational effort. A model of a molecular crystal may include partial net atomic charges or other charge sites such as lone-pair electrons. The $(n = 1)$ sum also applies between these site charges.

The dispersion energy of ionic or molecular crystals may be represented by an $(n = 6)$ sum over atomic sites, with possible inclusion of $(n = 8, 10, \ldots)$ terms for higher accuracy. The dispersion-energy sum has somewhat better convergence properties than the Coulombic sum. Nevertheless, accelerated-convergence treatment of the dispersion sum is strongly recommended since its use can yield at least an order of magnitude improvement in accuracy for a given calculation effort. The repulsion energy between nonbonded atoms in a crystal may be represented by an exponential function of short range, or possibly by an $(n = 12)$ function of short range. The convergence of the repulsion energy is fast and no accelerated-convergence treatment is normally required.

3.4.2. Definition and behaviour of the direct-space sum

This pairwise sum is taken between atoms (or sites) in the reference unit cell and all other atoms (or sites) in the crystal, excluding the self terms. Thus, the second atom (or site) is taken to range over the entire crystal, with elimination of self-energy terms. If V_n represents an energy, each atom is assigned one half of the pair energy. Therefore, the energy per unit cell is

$$V_n = (1/2) \sum_{j}^{\text{one cell}} \sum_{k}^{\prime\ \text{all cells}} Q_{jk} R_{jk}^{-n},$$

where Q_{jk} is a given coefficient, R_{jk} is an interatomic distance, and the prime on the second sum indicates that self terms are omitted. In the case of the Coulombic sum, $n = 1$ and $Q_{jk} = q_j q_k$ is the product of the site charges.

Table 3.4.2.1 gives an example of the convergence behaviour of the untreated $(n = 1)$ Coulombic sum for sodium chloride. Even at the rather large summation limit of 20 Å the Coulombic lattice sum has not converged and is incorrect by about 8%. The 20 Å sum included 832 molecules and 2494 individual distances. At various smaller summation limits the truncation error fluctuates wildly and can be either positive or negative. Note that the results shown in the table always refer to summation over whole molecules, that is, over neutral charge units.

If the Coulombic summation is not carried out over neutral charge units the truncation error is even larger. These considerations support the conclusion that accelerated-convergence treatment of the Coulombic lattice sum should be regarded as mandatory. Table 3.4.2.2 gives an example of the convergence behaviour of the untreated $(n = 6)$ dispersion sum for benzene. In obtaining this sum it is not necessary to consider whole molecules as in the Coulombic case. The exclusion of atoms (or sites) in the portions of molecules outside the summation limit greatly reduces the number of terms to be considered. At the summation limit of 20 Å, 439 benzene molecules and 22 049 individual distances are considered; the dispersion-sum truncation error is 0.4%. Thus, if sufficient computer time is available it may be possible to obtain a moderately accurate dispersion sum without the use of accelerated convergence. However, as shown below, the use of accelerated convergence will greatly speed up the calculation, and is in practice necessary if higher accuracy is required.

3.4.3. Preliminary description of the method

Ewald (1921) developed a method which modified the mathematical representation of the Coulombic lattice sum to improve the rate of convergence. This method was based on partially transforming the lattice sum into reciprocal space. Bertaut (1952) presented another method for derivation of the Ewald result which used the concept of the crystallographic structure factor. His formula extended the Ewald treatment to a composite lattice with more than one atom per lattice point. Nijboer & DeWette (1957) developed a general Fourier transform method for the evaluation of R^{-n} sums in simple lattices. Williams (1971) extended this treatment to a composite lattice and gave general formulae for the R^{-n} sums for any crystal. A review article, on which this chapter is based, appeared later (Williams, 1989*a*,*b*).

Consider a function, $W(R)$, which is unity at $R = 0$ and smoothly declines to zero as R approaches infinity. If each term of the lattice sum is multiplied by $W(R)$, the rate of convergence is increased. However, the rate of convergence of the remainder of

the original sum, which contains the difference terms, is not increased.

$$V_n = (1/2) \sum_{j}^{\text{one cell}} \sum_{k}^{\prime\ \text{all cells}} Q_{jk} R_{jk}^{-n} W(R) + (1/2) \sum_{j}^{\text{one cell}} \sum_{k}^{\prime\ \text{all cells}} Q_{jk} R_{jk}^{-n} [1 - W(R)].$$

In the accelerated-convergence method the difference terms are expressed as an integral of the product of two functions. According to Parseval's theorem (described below) this integral is equal to an integral of the product of the two Fourier transforms of the functions. Finally, the integral over the Fourier transforms of the functions is converted to a sum in reciprocal (or Fourier-transform) space. The choice of the convergence function $W(R)$ is not unique; an obvious requirement is that the relevant Fourier transforms must exist and have correct limiting behaviour. Nijboer and DeWette suggested using the incomplete gamma function for $W(R)$. More recently, Fortuin (1977) showed that this choice of convergence function leads to optimal convergence of the sums in both direct and reciprocal space:

$$W(R) = \Gamma(n/2, \pi w^2 R^2)/\Gamma(n/2),$$

where $\Gamma(n/2)$ and $\Gamma(n/2, \pi w^2 R^2)$ are the gamma function and the incomplete gamma function, respectively:

$$\Gamma(n/2, \pi w^2 R^2) = \int_{\pi w^2 R^2}^{\infty} t^{(n/2)-1} \exp(-t)\, \mathrm{d}t$$

and

$$\Gamma(n/2) = \Gamma(n/2, 0).$$

The complement of the incomplete gamma function is

$$\gamma(n/2, \pi w^2 R^2) = \Gamma(n/2) - \Gamma(n/2, \pi w^2 R^2).$$

3.4.4. Preliminary derivation to obtain a formula which accelerates the convergence of an R^{-n} sum over lattice points X(d)

The three-dimensional direct-space crystal lattice is specified by the origin vectors $\mathbf{a}_1$, $\mathbf{a}_2$ and $\mathbf{a}_3$. A general vector in direct space is defined as

$$\mathbf{X}(\mathbf{x}) = x_1\mathbf{a}_1 + x_2\mathbf{a}_2 + x_3\mathbf{a}_3,$$

where x_1, x_2, x_3 are the fractional cell coordinates of $\mathbf{X}$. A lattice vector in direct space is defined as

$$\mathbf{X}(\mathbf{d}) = d_1\mathbf{a}_1 + d_2\mathbf{a}_2 + d_3\mathbf{a}_3,$$

where d_1, d_2, d_3 are integers (specifying particular values of x_1, x_2, x_3) designating a lattice point. V_d is the direct-cell volume which is equal to $\mathbf{a}_1 \cdot \mathbf{a}_2 \times \mathbf{a}_3$. A general point in the direct lattice is $\mathbf{X}(\mathbf{x})$; the contents of the lattice are by definition identical as the components of $\mathbf{x}$ are increased or decreased by integer amounts.

The reciprocal-lattice vectors are defined by the relations

$$\mathbf{a}_j \cdot \mathbf{b}_k = 1 \qquad j = k$$
$$= 0 \qquad j \neq k.$$

A general vector in reciprocal space $\mathbf{H}(\mathbf{r})$ is defined as

$$\mathbf{H}(\mathbf{r}) = r_1\mathbf{b}_1 + r_2\mathbf{b}_2 + r_3\mathbf{b}_3.$$

A reciprocal-lattice vector $\mathbf{H}(\mathbf{h})$ is defined by the integer triplet h_1, h_2, h_3 (specifying particular values of r_1, r_2, r_3) so that

$$\mathbf{H}(\mathbf{h}) = h_1\mathbf{b}_1 + h_2\mathbf{b}_2 + h_3\mathbf{b}_3.$$

In other sections of this volume a shortened notation $\mathbf{h}$ is used for the reciprocal-lattice vector. In this section the symbol $\mathbf{H}(\mathbf{h})$ is used to indicate that it is a particular value of $\mathbf{H}(\mathbf{r})$.

The three-dimensional Fourier transform $g(\mathbf{t})$ of a function $f(\mathbf{x})$ is defined by

$$g(\mathbf{t}) = FT_3[f(\mathbf{x})] = \int f(\mathbf{x}) \exp(2\pi i \mathbf{x} \cdot \mathbf{t})\, \mathrm{d}\mathbf{x}.$$

The Fourier transform of the set of points defining the direct lattice is the set of points defining the reciprocal lattice, scaled by the direct-cell volume. It is useful for our purpose to express the lattice transform in terms of the Dirac delta function $\delta(x - x_\mathrm{o})$ which is defined so that for any function $f(\mathbf{x})$

$$f(\mathbf{x}_\mathrm{o}) = \int \delta(\mathbf{x} - \mathbf{x}_\mathrm{o}) f(\mathbf{x})\, \mathrm{d}\mathbf{x}.$$

We then write

$$FT_3\{\sum_{\mathbf{d}} \delta[\mathbf{X}(\mathbf{x}) - \mathbf{X}(\mathbf{d})]\} = V_\mathrm{d}^{-1} \sum_{\mathbf{h}} \delta[\mathbf{H}(\mathbf{r}) - \mathbf{H}(\mathbf{h})].$$

First consider the lattice sum over the direct-lattice points $\mathbf{X}(\mathbf{d})$, relative to a particular point $\mathbf{X}(\mathbf{x}) = \mathbf{R}$, with omission of the origin lattice point.

$$S'(n, \mathbf{R}) = \sum_{\mathbf{d} \neq 0} |\mathbf{X}(\mathbf{d}) - \mathbf{R}|^{-n}.$$

The special case with $\mathbf{R} = 0$ will also be needed:

$$S'(n, 0) = \sum_{\mathbf{d} \neq 0} |\mathbf{X}(\mathbf{d})|^{-n}.$$

Now define a sum of Dirac delta functions

$$f'[\mathbf{X}(\mathbf{d})] = \sum_{d\neq 0}\delta[\mathbf{X}(\mathbf{x}) - \mathbf{X}(\mathbf{d})].$$

Then S' can be represented as an integral

$$S'(n, \mathbf{R}) = \int f'[\mathbf{X}(\mathbf{d})]|\mathbf{X} - \mathbf{R}|^{-n}\,\mathrm{d}\mathbf{X},$$

in which a term is contributed to S' whenever the direct-space vector $\mathbf{X}$ coincides with the lattice vector $\mathbf{X}(\mathbf{d})$, except for $\mathbf{d} = 0$. Now apply the convergence function to S':

$$\begin{aligned} S'(n, \mathbf{R}) = {} & [\Gamma(n/2)]^{-1}\int f'[\mathbf{X}(\mathbf{d})]|\mathbf{X} - \mathbf{R}|^{-n} \\ & \times \Gamma(n/2, \pi w^2|\mathbf{X} - \mathbf{R}|^2)\,\mathrm{d}\mathbf{X} \\ & + [\Gamma(n/2)]^{-1}\int f'[\mathbf{X}(\mathbf{d})]|\mathbf{X} - \mathbf{R}|^{-n} \\ & \times \gamma(n/2, \pi w^2|\mathbf{X} - \mathbf{R}|^2)\,\mathrm{d}\mathbf{X}. \end{aligned}$$

The first integral is shown here only for the purpose of giving a consistent representation of S'; in fact, the first integral will be reconverted back into a sum and evaluated in direct space. The second integral will be transformed to reciprocal space using Parseval's theorem [see, for example, Arfken (1970)], which states that

$$\int f(\mathbf{X})g^*(\mathbf{X})\,\mathrm{d}\mathbf{X} = \int FT_3[f(\mathbf{X})]FT_3[g^*(\mathbf{X})]\,\mathrm{d}\mathbf{H}.$$

Considering only the second integral in the formula for S' and explicitly introducing the $\mathbf{d} = 0$ term we have

$$\begin{aligned} & [\Gamma(n/2)]^{-1}\int f[\mathbf{X}(\mathbf{d})]|\mathbf{X}(\mathbf{d}) - \mathbf{R}|^{-n}\gamma(n/2, \pi w^2|\mathbf{X} - \mathbf{R}|^2)\,\mathrm{d}\mathbf{X} \\ & - [\Gamma(n/2)]^{-1}\int \delta(\mathbf{X})|\mathbf{R}|^{-n}\gamma(n/2, \pi w^2|\mathbf{R}|^2)\,\mathrm{d}\mathbf{X}, \end{aligned}$$

where the unprimed f includes the $\mathbf{h} = 0$ term which was earlier omitted from f':

$$f(\mathbf{X}) = \sum_{\mathbf{d}}\delta[\mathbf{X}(\mathbf{x}) - \mathbf{X}(\mathbf{d})].$$

Using Parseval's theorem, and evaluating the origin term, we have

$$\begin{aligned} & [\Gamma(n/2)]^{-1}\int FT_3\{f[\mathbf{X}(\mathbf{d})]\}FT_3 \\ & \quad \times [|\mathbf{X}(\mathbf{d}) - \mathbf{R}|^{-n}\gamma(n/2, \pi w^2|\mathbf{X} - \mathbf{R}|^2)]\,\mathrm{d}\mathbf{H} \\ & \quad - [\Gamma(n/2)]^{-1}|\mathbf{R}|^{-n}\gamma(n/2, \pi w^2|\mathbf{R}|^2). \end{aligned}$$

The Fourier transform of the complement of the incomplete gamma function divided by $|\mathbf{X}|^n$ is (Nijboer & DeWette, 1957)

$$\begin{aligned} & FT_3[\gamma(n/2, \pi w^2|\mathbf{X}|^2)|\mathbf{X}|^{-n}] \\ & \quad = \pi^{n-(3/2)}|\mathbf{H}|^{n-3}\Gamma[(-n/2) + (3/2), \pi w^{-2}|\mathbf{H}|^2]. \end{aligned}$$

If there is a change of origin and the point $(\mathbf{X} - \mathbf{R})$ is used instead of $\mathbf{X}$ the transform is

$$\begin{aligned} & FT_3[\gamma(n/2, \pi w^2|\mathbf{X} - \mathbf{R}|^2)|\mathbf{X} - \mathbf{R}|^{-n}] \\ & \quad = \pi^{n-(3/2)}|\mathbf{H}|^{n-3}\Gamma[(-n/2) \\ & \qquad + (3/2), \pi w^{-2}|\mathbf{H}|^2]\exp(2\pi i\mathbf{H}\cdot\mathbf{R}). \end{aligned}$$

Evaluation of the two Fourier transforms in the first term gives

$$\begin{aligned} & [\Gamma(n/2)]^{-1}\int V_{\mathrm{d}}^{-1}\sum_{\mathbf{h}}\delta[\mathbf{H}(\mathbf{h}) - \mathbf{H}]\pi^{n-(3/2)}|\mathbf{H}|^{n-3} \\ & \quad \times \Gamma[(-n/2) + (3/2), \pi w^{-2}|\mathbf{H}|^2]\exp(2\pi i\mathbf{H}\cdot\mathbf{R})\,\mathrm{d}\mathbf{H}. \end{aligned}$$

Because of the presence of the Dirac delta function in each integral, we can convert the integrals with $\mathbf{h}$ unequal to zero into a sum

$$\begin{aligned} & [\Gamma(n/2)]^{-1}V_{\mathrm{d}}^{-1}\pi^{n-(3/2)}\sum_{h\neq 0}|\mathbf{H}(\mathbf{h})|^{n-3} \\ & \quad \times \Gamma[(-n/2) + (3/2), \pi w^{-2}|\mathbf{H}(\mathbf{h})|^2]\exp[2\pi i\mathbf{H}(\mathbf{h})\cdot\mathbf{R}]. \end{aligned}$$

The $\mathbf{h} = 0$ term needs to be evaluated in the limit. Clearly, the complex exponential goes to unity. If n is greater than 3 the limit of the indeterminate form infinity/infinity is needed:

$$\begin{aligned} & \lim_{|\mathbf{H}|\to 0}\frac{\Gamma[(-n/2) + (3/2), \pi w^{-2}|\mathbf{H}|^2]}{|\mathbf{H}|^{3-n}} \\ & \quad = \lim_{|\mathbf{H}|\to 0}\frac{\int_{\pi w^{-2}|\mathbf{H}|^2}^{\infty} t^{(-n/2)+(1/2)}\exp(-t)\,\mathrm{d}t}{|\mathbf{H}|^{3-n}}. \end{aligned}$$

The limit can be found by L'Hospital's rule [see, for example, Widder (1961)] which states that if $f(x)$ and $g(x)$ both approach infinity as x approaches a constant, c, and the limit of the ratio of the first derivatives $f'(x)$ and $g'(x)$ exists, that limit is also true for the limit of the ratio of the functions:

$$\lim_{x\to c}\frac{f(x)}{g(x)} = \lim_{x\to c}\frac{f'(x)}{g'(x)}.$$

To differentiate the definite integral function, Leibnitz's formula may be used [see, for example, Arfken (1970)]. This formula states that

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}x}\int_{g(x)}^{h(x)} f(t, x)\,\mathrm{d}t = {} & \int_{g(x)}^{h(x)}\frac{\mathrm{d}f(t, x)}{\mathrm{d}x}\,\mathrm{d}t \\ & + f[h(x)]\frac{\mathrm{d}h(x)}{\mathrm{d}x} - f[g(x)]\frac{\mathrm{d}g(x)}{\mathrm{d}x}. \end{aligned}$$

In our case, x becomes $|\mathbf{H}|$; f becomes $t^{(-n/2)+(1/2)}\exp(-t)$ which is independent of $|\mathbf{H}|$; g becomes $\pi w^{-2}|\mathbf{H}|^2$; and h is infinite. Thus only the last term of Leibnitz's formula is nonzero and we obtain for the ratio of the first derivatives

$$\begin{aligned} & \lim_{|\mathbf{H}|\to 0}\frac{-(\pi w^{-2}|\mathbf{H}|^2)^{(-n/2)+(1/2)}\exp(-\pi w^2|\mathbf{H}|^2)2\pi w^{-2}|\mathbf{H}|}{(3-n)|\mathbf{H}|^{2-n}} \\ & \quad = \pi^{(-n/2)+(3/2)}w^{n-3}[2/(n-3)], \end{aligned}$$

so that the limiting value for the $\mathbf{h} = 0$ term for n greater than 3 is

$$+[\Gamma(n/2)]^{-1}V_{\rm d}^{-1}\pi^{n/2}w^{n-3}[2/(n-3)].$$

The final result for S' is

$$\begin{aligned}S'(n,\mathbf{R}) &= [\Gamma(n/2)]^{-1}\sum_{\mathbf{d}\neq 0}|\mathbf{X}(\mathbf{d})-\mathbf{R}|^{-n}\\ &\times\Gamma(n/2,\pi w^2|\mathbf{X}(\mathbf{d})-\mathbf{R}|^2)\\ &-[\Gamma(n/2)]^{-1}|\mathbf{R}|^{-n}\gamma(n/2,\pi w^2|\mathbf{R}|^2)\\ &+[\Gamma(n/2)]^{-1}V_{\rm d}^{-1}\pi^{n-(3/2)}\sum_{\mathbf{h}\neq 0}|\mathbf{H}(\mathbf{h})|^{n-3}\\ &\times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2]\\ &\times\exp[2\pi i\mathbf{H}(\mathbf{h})\cdot\mathbf{R}]\\ &+[\Gamma(n/2)]^{-1}V_{\rm d}^{-1}\pi^{n/2}w^{n-3}2(n-3)^{-1}.\end{aligned}$$

The significance of the terms is as follows. The first term represents the convergence-accelerated direct sum, which does not include the origin term; the next term, also in direct space, corrects for the remainder resulting from the subtraction of the origin term; the third term comes from Parseval's theorem and is a sum over the nonzero **h** reciprocal-lattice points; and the last term is the reciprocal-lattice $\mathbf{h}=0$ term.

If $\mathbf{R}=0$ the second term becomes an indeterminate form 0/0. The limit can be found with use of L'Hospital's rule again, this time for the 0/0 form. We need the limit of $f(x)/g(x)$, where $f(R)=\gamma(n/2,\pi w^2R^2)$ and $g(R)=R^n$. To differentiate the incomplete gamma function, we can again use Leibnitz's formula. In this case only the second term of the formula is nonzero and we obtain for the ratio of the first derivatives

$$\frac{2\pi^{n/2}w^n|\mathbf{R}|^{n-1}\exp(-\pi w^2|\mathbf{R}|^2)}{n|\mathbf{R}|^{n-1}},$$

so that the limiting value for this term as $|\mathbf{R}|$ approaches zero is

$$-[\Gamma(n/2)]^{-1}2\pi^{n/2}w^n n^{-1}.$$

Therefore, the value of the sum when $\mathbf{R}=0$ is

$$\begin{aligned}S'(n,0) &= [\Gamma(n/2)]^{-1}\sum_{\mathbf{d}\neq 0}|\mathbf{X}(\mathbf{d})|^{-n}\Gamma(n/2,\pi w^2|\mathbf{X}(\mathbf{d})|^2)\\ &-[\Gamma(n/2)]^{-1}2\pi^{n/2}w^n n^{-1}\\ &+[\Gamma(n/2)]^{-1}V_{\rm d}^{-1}\pi^{n-(3/2)}\sum_{\mathbf{h}\neq 0}|\mathbf{H}(\mathbf{h})|^{n-3}\\ &\times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2]\\ &+[\Gamma(n/2)]^{-1}V_{\rm d}^{-1}\pi^{n/2}w^{n-3}2(n-3)^{-1}.\end{aligned}$$

3.4.5. Extension of the method to a composite lattice

Define a general lattice sum over direct-space points $\mathbf{R}_j$ which interact with pairwise coefficients Q_{jk}, where $Q_{jk}=Q_{kj}$:

$$V(n,\mathbf{R}_j)=(1/2)\sum_j{\sum_k}'\,Q_{jk}\sum_{\mathbf{d}}|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^{-n},$$

where the prime indicates that when $\mathbf{d}=0$ the self-terms with $j=k$ are omitted. For convenience the terms may be divided into three groups: the first group of terms has $\mathbf{d}=0$, where j is unequal to k; the second group has **d** not zero and j not equal to k; and the third group had **d** not zero and $j=k$. (A possible fourth group with $\mathbf{d}=0$ and $j=k$ is omitted, as defined.)

$$\begin{aligned}V(n,\mathbf{R}_j) &= (1/2)\sum_{j\neq k}Q_{jk}|\mathbf{R}_k-\mathbf{R}_j|^{-n}\\ &+(1/2)\sum_{j\neq k}Q_{jk}S'(n,|\mathbf{R}_j-\mathbf{R}_k|)+(1/2)\sum_j Q_{jj}S'(n,0).\end{aligned}$$

By expanding this expression we obtain

$$\begin{aligned}V(n,\mathbf{R}_j) &= (1/2)\sum_{j\neq k}Q_{jk}|\mathbf{R}_k-\mathbf{R}_j|^{-n} &(1)\\ &+\Big\{[1/2\Gamma(n/2)]\sum_{j\neq k}Q_{jk}\sum_{\mathbf{d}\neq 0}|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^{-n}\\ &\times\Gamma(n/2,\pi w^2|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^2)\Big\} &(2)\\ &-\Big\{[1/2\Gamma(n/2)]\sum_{j\neq k}Q_{jk}|\mathbf{R}_k-\mathbf{R}_j|^{-n}\\ &\times\gamma(n/2,\pi w^2|\mathbf{R}_k-\mathbf{R}_j|^2)\Big\} &(3)\\ &+\Big\{[1/2\Gamma(n/2)]V_{\rm d}^{-1}\pi^{n-(3/2)}\sum_{j\neq k}Q_{jk}\sum_{\mathbf{h}\neq 0}|\mathbf{H}(\mathbf{h})|^{n-3}\\ &\times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2]\\ &\times\exp[2\pi i\mathbf{H}(\mathbf{h})\cdot(\mathbf{R}_k-\mathbf{R}_j)]\Big\} &(4)\\ &+[1/2\Gamma(n/2)]V_{\rm d}^{-1}\pi^{n/2}w^{n-3}2(n-3)^{-1}\sum_{j\neq k}Q_{jk} &(5)\\ &+\Big\{[1/2\Gamma(n/2)]\sum_j Q_{jj}\sum_{\mathbf{d}\neq 0}|\mathbf{X}(\mathbf{d})|^{-n}\\ &\times\Gamma(n/2,\pi w^2|\mathbf{X}(\mathbf{d})|^2)\Big\} &(6)\\ &-[1/\Gamma(n/2)]\pi^{n/2}w^n n^{-1}\sum_j Q_{jj} &(7)\\ &+\Big\{[1/2\Gamma(n/2)]V_{\rm d}^{-1}\pi^{n-(3/2)}\sum_j Q_{jj}\sum_{\mathbf{h}\neq 0}|\mathbf{H}(\mathbf{h})|^{n-3}\\ &\times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2]\Big\} &(8)\\ &+[1/2\Gamma(n/2)]V_{\rm d}^{-1}\pi^{n/2}w^{n-3}2(n-3)^{-1}\sum_j Q_{jj}. &(9)\end{aligned}$$

This expression for V has nine terms, which are numbered on the right-hand side. Term (3) can be expressed in terms of Γ rather than γ:

$$\begin{aligned}(3) &= -(1/2)\sum_{j\neq k}Q_{jk}|\mathbf{R}_k-\mathbf{R}_j|^{-n}\\ &+[1/\Gamma(n/2)]\sum_{j\neq k}Q_{jk}|\mathbf{R}_k-\mathbf{R}_j|^{-n}\Gamma(n/2,\pi w^2|\mathbf{R}_k-\mathbf{R}_j|^2).\end{aligned}$$

It is seen that cancellation occurs with term (1) so that

$$(1)+(3)=[1/\Gamma(n/2)]\sum_{j\neq k} Q_{jk}|\mathbf{R}_k-\mathbf{R}_j|^{-n} \times \Gamma(n/2,\pi w^2|\mathbf{R}_k-\mathbf{R}_j|^2),$$

which is the $\mathbf{d}=0$, j unequal to k portion of the treated direct-lattice sum. The $\mathbf{d}$ unequal to 0, j unequal to k portion corresponds to term (2) and the $\mathbf{d}$ unequal to 0, $j=k$ portion corresponds to term (6). The direct-lattice terms may be consolidated as

$$(1)+(2)+(3)+(6)=[1/2\Gamma(n/2)]\sum_j{\sum_k}' Q_{jk}\sum_{\mathbf{d}}|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^{-n} \times \Gamma[n/2,\pi w^2|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^2].$$

Now let us combine terms (4) and (8), carrying out the $\mathbf{h}$ summation first:

$$(4)+(8)=[1/2\Gamma(n/2)]V_{\mathrm{d}}^{-1}\pi^{n-(3/2)}\sum_{\mathbf{h}}|\mathbf{H}(\mathbf{h})|^{n-3} \times \Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2] \times \sum_j\sum_k Q_{jk}\exp[2\pi i\mathbf{H}(\mathbf{h})\cdot(\mathbf{R}_k-\mathbf{R}_j)].$$

Terms (5) and (9) may be combined:

$$(5)+(9)=[\Gamma(n/2)]^{-1}V_{\mathrm{d}}^{-1}\pi^{n/2}w^{n-3}(n-3)^{-1}\left(\sum_j Q_{ij}+\sum_{j\neq k} Q_{jk}\right).$$

The final formula is shown below. The significance of the four terms is: (1) the treated direct-lattice sum; (2) a correction for the difference resulting from the removal of the origin term in direct space; (3) the reciprocal-lattice sum, except $\mathbf{h}=0$; and (4) the $\mathbf{h}=0$ term of the reciprocal-lattice sum.

$$\begin{aligned}
&V(n,\mathbf{R}_j)\\
&\quad=[1/2\Gamma(n/2)]\sum_j{\sum_k}' Q_{jk}\sum_{\mathbf{d}}|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^{-n}\\
&\qquad\times\Gamma(n/2,\pi w^2|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^2) \qquad (1)\\
&\qquad-[1/\Gamma(n/2)]\pi^{n/2}w^n n^{-1}\sum_j Q_{jj} \qquad (2)\\
&\qquad+[1/2\Gamma(n/2)]V_{\mathrm{d}}^{-1}\pi^{n-(3/2)}\sum_{\mathbf{h}}|\mathbf{H}(\mathbf{h})|^{n-3}\\
&\qquad\times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2]\\
&\qquad\times\sum_j\sum_k Q_{jk}\exp[2\pi i\mathbf{H}(\mathbf{h})\cdot(\mathbf{R}_k-\mathbf{R}_j)] \qquad (3)\\
&\qquad+[\Gamma(n/2)]^{-1}V_{\mathrm{d}}^{-1}\pi^{n/2}w^{n-3}(n-3)^{-1}\left(\sum_j\sum_k Q_{jk}\right). \qquad (4)
\end{aligned}$$

3.4.6. The case of $n=1$ (Coulombic lattice energy)

As taken above, the limit of the reciprocal-lattice $\mathbf{h}=0$ term of $S'(n,\mathbf{R})$ or $S'(n,0)$ existed only if n was greater than 3. The corresponding contributions to $V(n,\mathbf{R}_j)$ were terms (5) and (9) of Section 3.4.5. To extend the method to $n=1$ we will show in this section that these $\mathbf{h}=0$ terms vanish if conditions of unit-cell neutrality and zero dipole moment are satisfied.

The integral representation of the term (5) is

$$[1/2\Gamma(n/2)]V_{\mathrm{d}}^{-1}\pi^{n-(3/2)}\sum_{j\neq k} Q_{jk}\int\delta(0)|\mathbf{H}|^{n-3} \times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}|^2] \times\exp[2\pi i\mathbf{H}\cdot(\mathbf{R}_k-\mathbf{R}_j)]\,\mathrm{d}\mathbf{H}$$

and for term (9) is

$$[1/2\Gamma(n/2)]V_{\mathrm{d}}^{-1}\pi^{n-(3/2)}\sum_j Q_{jj}\int\delta(0)|\mathbf{H}|^{n-3} \times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}|^2]\,\mathrm{d}\mathbf{H}.$$

Combining these two sums of integrals into one integral sum gives

$$[1/2\Gamma(n/2)]V_{\mathrm{d}}^{-1}\pi^{n-(3/2)}\int\delta(0)|\mathbf{H}|^{n-3} \times\Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}|^2]\sum_j{\sum_k} Q_{jk} \times\exp[2\pi i\mathbf{H}\cdot(\mathbf{R}_k-\mathbf{R}_j)]\,\mathrm{d}\mathbf{H}.$$

For $n=1$, suppose q_j are net atomic charges so that the geometric combining law holds for $Q_{jk}=q_jq_k$. Then the double sum over j and k can be factored so that the limit that needs to be considered is

$$\lim_{|\mathbf{H}|\to 0}\frac{\left[\sum_k q_k\exp(2\pi i\mathbf{H}\cdot\mathbf{R}_k)\right]\left[\sum_j q_j\exp(-2\pi i\mathbf{H}\cdot\mathbf{R}_j)\right]}{|\mathbf{H}|^2}.$$

If the unit cell does not have a net charge, the sum over the q's goes to zero in the limit and this is a 0/0 indeterminate form. Let $|\mathbf{H}|$ approach zero along the polar axis so that $\mathbf{H}\cdot\mathbf{R}_k=H_3R_{3k}$, where subscript 3 indicates components along the polar axis. To find the limit with L'Hospital's rule the numerator and denominator are differentiated twice with respect to H_3. Represent the numerator of the limit by the product (uv) and note that

$$\frac{\mathrm{d}^2(uv)}{\mathrm{d}x^2}=u\frac{\mathrm{d}^2v}{\mathrm{d}x^2}+v\frac{\mathrm{d}^2u}{\mathrm{d}x^2}+2\frac{\mathrm{d}u}{\mathrm{d}x}\frac{\mathrm{d}v}{\mathrm{d}x}.$$

It is seen that in addition to cell neutrality the product of the first derivatives of the sums must exist. These sums are

$$\left[2\pi i\sum_k q_kR_{3k}\exp(2\pi iH_3R_{3k})\right]$$

and

$$\left[-2\pi i\sum_j q_jR_{3j}\exp(-2\pi iH_3R_{3j})\right],$$

which vanish if the unit cell has no dipole moment in the polar direction, that is, if $\sum q_jR_{3j}=0$. Since the second derivative of the denominator is a constant, the desired limit is zero under the specified conditions. Now the polar direction can be chosen arbitrarily, so the unit cell must not have a dipole moment in any direction for the limit of the numerator to be zero. Thus we have the formula for the Coulombic lattice sum

$$\begin{aligned} V(1,\mathbf{R}_j) = {} & [1/2\Gamma(1/2)]\sum_j{\sum_k}' Q_{jk}\sum_{\mathbf{d}}|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^{-1} \\ & \times \Gamma(1/2,\pi w^2|\mathbf{R}_k+\mathbf{X}(\mathbf{d})-\mathbf{R}_j|^2) \\ & + [1/2\Gamma(1/2)V_{\rm d}^{-1}\pi^{-1/2}\sum_{\mathbf{h}}|\mathbf{H}(\mathbf{h})|^{-2} \\ & \times \Gamma(1/2,\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2)\sum_j\sum_k Q_{jk} \\ & \times \exp[2\pi i\mathbf{H}(\mathbf{h})\cdot(\mathbf{R}_k-\mathbf{R}_j)] \\ & - [1/\Gamma(1/2)]\pi^{1/2}w\sum_j q_j^2, \end{aligned}$$

which holds on conditions that the unit cell be electrically neutral and have no dipole moment. If the unit cell has a dipole moment, the limiting value discussed above depends on the direction of **H**. For methods of obtaining the Coulombic lattice sum where the unit cell does have a dipole moment, the reader is referred to the literature (DeWette & Schacher, 1964; Cummins *et al.*, 1976; Bertaut, 1978; Massidda, 1978).

3.4.7. The cases of $n = 2$ and $n = 3$

If $n = 2$ the denominator considered for the limit in the preceding section is linear in $|\mathbf{H}|$ so that only one differentiation is needed to obtain the limit by L'Hospital's method. Since a term of the type $\sum q_j \exp(2\pi i\mathbf{H}\cdot\mathbf{R}_j)$ is always a factor, the requirement that the unit cell have no dipole moment can be relaxed. For $n = 2$ the zero-charge condition is still required: $\sum q_j = 0$. When $n = 3$ the expression becomes determinate and no differentiation is required to obtain a limit. In addition, factoring the Q_{jk} sums into q_j sums is not necessary so that the only remaining requirement for this term to be zero is $\sum\sum Q_{jk} = 0$, which is a further relaxation beyond the requirement of cell neutrality.

3.4.8. Derivation of the accelerated convergence formula *via* the Patterson function

The structure factor with generalized coefficients q_j is defined by

$$F[\mathbf{H}(\mathbf{h})] = \sum_j q_j \exp[2\pi i\mathbf{H}(\mathbf{h})\cdot\mathbf{R}_j].$$

The corresponding Patterson function is defined by

$$P(\mathbf{X}) = V_{\rm d}^{-1}\sum_{\mathbf{h}}|F[\mathbf{H}(\mathbf{h})]|^2\exp[2\pi i\mathbf{H}(\mathbf{h})\cdot\mathbf{X}].$$

The physical interpretation of the Patterson function is that it is nonzero only at the intersite vector points $\mathbf{R}_k+\mathbf{X}(\mathbf{h})-\mathbf{R}_j$. If the origin point is removed, the lattice sum may be expressed as an integral over the Patterson function. This origin point in the Patterson function corresponds to intersite vectors with $j = k$ and $\mathbf{H}(\mathbf{h}) = 0$:

$$S_n = (1/2V_{\rm d})\int|\mathbf{X}|^{-n}[P(\mathbf{X})-P(\mathbf{X})\delta(\mathbf{X})]\,{\rm d}\mathbf{X}.$$

Using the incomplete gamma function as a convergence function, this formula expands into two integrals

$$\begin{aligned} S_n = {} & [1/2V_{\rm d}\Gamma(n/2)]\int|\mathbf{X}|^{-n} \\ & \times [P(\mathbf{X})-P(\mathbf{X})\delta(\mathbf{X})]\Gamma(n/2,\pi w^2|\mathbf{X}|^2)\,{\rm d}\mathbf{X} \\ & + [1/2V_{\rm d}\Gamma(n/2)]\int|\mathbf{X}|^{-n} \\ & \times [P(\mathbf{X})-P(\mathbf{X})\delta(\mathbf{X})]\gamma(n/2,\pi w^2|\mathbf{X}|^2)\,{\rm d}\mathbf{X}. \end{aligned}$$

The first integral is shown only for a consistent representation; actually it will be reconverted to a sum and evaluated in direct space. The first part of the second integral will be evaluated with Parseval's theorem and the second part in the limit as $|\mathbf{X}|$ approaches zero:

$$\begin{aligned} & [1/2V_{\rm d}\Gamma(n/2)]\int FT_3[P(\mathbf{X})] \\ & \quad \times FT_3[|\mathbf{X}|^{-n}\gamma(n/2,\pi w^2|\mathbf{X}|^2)]\,{\rm d}\mathbf{H} \\ & \quad - \lim_{\mathbf{X}\to 0}[1/2V_{\rm d}\Gamma(n/2)][P(0)|\mathbf{X}|^{-n}\gamma(n/2,\pi w^2|\mathbf{X}|^2)]. \end{aligned}$$

The first Fourier transform (of the Patterson function) is the set of amplitudes of the structure factors and the second Fourier transform has already been discussed above; the method for obtaining the limit (for n equal to or greater than 1) was also discussed above. The result obtained is

$$\begin{aligned} & [1/2V_{\rm d}\Gamma(n/2)]\pi^{n-(3/2)}\int|F[\mathbf{H}(\mathbf{h})]|^2|\mathbf{H}|^{n-3} \\ & \quad \times \Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}|^2]\,{\rm d}\mathbf{H} \\ & \quad - [1/2V_{\rm d}\Gamma(n/2)]|F(0)|^2 2\pi^{n/2}w^n n^{-1}. \end{aligned}$$

The integral can be converted into a sum, since $|F[\mathbf{H}(\mathbf{h})]|$ is nonzero only at the reciprocal-lattice points:

$$\begin{aligned} & [1/2V_{\rm d}\Gamma(n/2)]\pi^{n-(3/2)}\sum_{\mathbf{h}}|F[\mathbf{H}(\mathbf{h})]|^2|\mathbf{H}(\mathbf{h})|^{n-3} \\ & \quad \times \Gamma[(-n/2)+(3/2),\pi w^{-2}|\mathbf{H}(\mathbf{h})|^2]. \end{aligned}$$

The term with $\mathbf{H}(\mathbf{h}) = 0$ is evaluated in the limit, for n greater than 3, as

$$[\Gamma(n/2)]^{-1}V_{\rm d}^{-1}\pi^{n/2}w^{n-3}(n-3)^{-1}|F(0)|^2.$$

Since $|F(0)|^2 = \sum\sum q_j q_k$, this term is identical with the third term of $V(n,\mathbf{R}_j)$ as derived earlier. The case of $n = 1$ is handled in the same way as previously discussed, where the limit of this term is zero provided the unit cell has no net charge or dipole moment.

3.4.9. Evaluation of the incomplete gamma function

The incomplete gamma function may be expressed in terms of commonly available functions such as the exponential integral and the complement of the error function. The definition of the exponential integral is

$$E_1(x^2) = \int_{x^2}^{\infty} t^{-1}\exp(-t)\,{\rm d}t = \Gamma(0,x^2).$$

The definition of the complement of the error function is

$$\mathrm{erfc}(x) = \int_x^{\infty}\exp(-t^2)\,{\rm d}t = \pi^{-1/2}\Gamma(1/2,x^2).$$

Numerical approximations to these functions are given, for example, by Hastings (1955). The recursion formula for the incomplete gamma function (Davis, 1972)

$$\Gamma(n+1, x^2) = n\Gamma(n, x^2) + x^{2n}\exp(-x^2)$$

may be used to obtain working formulae starting from the special values of $\Gamma(0, x^2)$ and $\Gamma(1/2, x^2)$ which are defined above. Also we note that $\Gamma(1, x^2) = \exp(-x^2)$.

3.4.10. Summation over the asymmetric unit and elimination of intramolecular energy terms

Let us consider the case where the unit cell contains Z molecules which are related by Z symmetry operations, and it is desired to include only intermolecular distances in the summation. In the direct sum (1) the indices j and k will then run only over the asymmetric unit, and all terms with $\mathbf{d} = 0$ are eliminated. The calculated energy refers then to one molecule (or mole) rather than to one unit cell. The correction term (2) also refers to one molecule according to the range of j and k. Since the reciprocal-lattice sum refers to the entire unit cell, terms (3) and (4) need to be divided by Z to refer the energy to one molecule.

Both the direct and reciprocal sums must be corrected for the elimination of intramolecular terms. Using the convergence function $W(R)$, we have

$$\begin{aligned} V(n, \mathbf{R}_j) = {} & \sum_{\text{inter}} |\mathbf{R}|^{-n} W(R) + \sum_{\text{intra}} |\mathbf{R}|^{-n} W(R) \\ & + \sum_{\text{inter}} |\mathbf{R}|^{-n}[1 - W(R)] + \sum_{\text{intra}} |\mathbf{R}|^{-n}[1 - W(R)]. \end{aligned}$$

As mentioned above, the second summation term, which is the intramolecular term in direct space, is simply left out of the calculation. When using the accelerated-convergence method the third and fourth summation terms are always obtained, evaluated in reciprocal space. The undesired inclusion of the intramolecular term (fourth term above) in the reciprocal-space sum may be compensated for by explicit subtraction of this term from the sum.

3.4.11. Reference formulae for particular values of *n*

In this section let $a^2 = \pi w^2 |\mathbf{R}_k + \mathbf{X}(\mathbf{d}) - \mathbf{R}_j|^2$ and $b^2 = \pi w^{-2} |\mathbf{H}(\mathbf{h})|^2$. Let $T_0 = \sum Q_{jj} = \sum q_j^2$; $T_1 = \sum\sum Q_{jk} = T_0 + 2\sum\sum_{j>k} Q_{jk}$. If the geometric mean combining law holds, $T_1 = (\sum_j q_j)^2$; let

$$\begin{aligned} T_2(h) &= \sum_j \sum_k Q_{jk} \exp[2\pi i \mathbf{H}(\mathbf{h}) \cdot (\mathbf{R}_k - \mathbf{R}_j)] \\ &= T_0 + 2\sum_{j>k}\sum Q_{jk} \cos[2\pi \mathbf{H}(\mathbf{h}) \cdot (\mathbf{R}_k - \mathbf{R}_j)]. \end{aligned}$$

Then

$$T_2(\mathbf{h}) = |F(\mathbf{h})|^2 = \left| \sum_j q_j \exp[2\pi i \mathbf{H}(\mathbf{h}) \cdot \mathbf{R}_j] \right|^2 = A(\mathbf{h})^2 + B(\mathbf{h})^2,$$

where

$$A(\mathbf{h}) = \sum_j q_j \cos[2\pi \mathbf{H}(\mathbf{h}) \cdot \mathbf{R}_j]$$

and

$$B(\mathbf{h}) = \sum_j q_j \sin[2\pi \mathbf{H}(\mathbf{h}) \cdot \mathbf{R}_j].$$

The formulae below describe $V(n, \mathbf{R}_j)$ in terms of T_0, T_1 and T_2; the distance $|\mathbf{R}_k + \mathbf{X}(\mathbf{d}) - \mathbf{R}_j|$ is simply represented by R_{jkd}.

$$\begin{aligned} V(1, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k q_j\, q_k \sum_{\mathbf{d}} R_{jkd}^{-1} \operatorname{erfc}(a) \\ & + (1/2\pi V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) |\mathbf{H}(\mathbf{h})|^{-2} \exp(-b^2) - wT_0 \\ V(2, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k Q_{jk} \sum_{\mathbf{d}} R_{jkd}^{-2} \exp(-a^2) \\ & + (\pi/2V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) |\mathbf{H}(\mathbf{h})|^{-1} \operatorname{erfc}(b) - (\pi/2) w^2 T_0 \\ V(3, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k Q_{jk} \sum_{\mathbf{d}} R_{jkd}^{-3} [\operatorname{erfc}(a) + 2a\pi^{-1/2} \exp(-a^2)] \\ & + (\pi/V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) E_1(b^2) - (2\pi/3) w^3 T_0 \\ V(4, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k Q_{jk} \sum_{\mathbf{d}} R_{jkd}^{-4} (1 + a^2) \exp(-a^2) \\ & + (\pi^{5/2}/V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) |\mathbf{H}(\mathbf{h})| \\ & \times [-\pi^{1/2} \operatorname{erfc}(b) + b^{-1} \exp(-b^2)] \\ & + (\pi^2/V_{\mathrm{d}}) w T_1 - (\pi^2/4) w^4 T_0 \\ V(5, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k Q_{jk} \sum_{\mathbf{d}} R_{jkd}^{-5} \\ & \times [\operatorname{erfc}(a) + 2\pi^{-1/2} a (1 + 2a^2/3) \exp(-a^2)] \\ & + (2\pi^3/3V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) |\mathbf{H}(\mathbf{h})|^2 \\ & \times [b^{-2} \exp(-b^2) - E_1(b^2)] \\ & + (2\pi^2/3V_{\mathrm{d}}) w^2 T_1 - (4\pi^2/15) w^5 T_0 \\ V(6, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k Q_{jk} \sum_{\mathbf{d}} R_{jkd}^{-6} [1 + a^2 + (a^4/2)] \exp(-a^2) \\ & + (\pi^{9/2}/3V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) |\mathbf{H}(\mathbf{h})|^3 \\ & \times [\pi^{1/2} \operatorname{erfc}(b) + [(1/2b^3) - (1/b)] \exp(-b^2)] \\ & + (\pi^3/6V_{\mathrm{d}}) w^3 T_1 - (\pi^3/12) w^6 T_0 \\ V(7, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k Q_{jk} \sum_{\mathbf{d}} R_{jkd}^{-7} \\ & \times [\operatorname{erfc}(a) + 2\pi^{-1/2} a [1 + (2/3)a^2 + (4/15)a^4] \\ & \times \exp(-a^2)] \\ & + (2\pi^5/15V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) |\mathbf{H}(\mathbf{h})|^4 \\ & \times [(-b^{-2} + b^{-4}) \exp(-b^2) + E_1(b^2)] \\ & + (2\pi^3/15V_{\mathrm{d}}) w^4 T_1 - (8\pi^3/105) w^7 T_0 \\ V(8, \mathbf{R}_j) = {} & (1/2)\sum_j{}' \sum_k Q_{jk} \sum_{\mathbf{d}} R_{jkd}^{-8} \\ & \times [1 + a^2 + (a^4/2) + (a^6/6)] \exp(-a^2) \\ & + (2\pi^{13/2}/45V_{\mathrm{d}}) \sum_{\mathbf{h}\neq 0} T_2(\mathbf{h}) |\mathbf{H}(\mathbf{h})|^5 \\ & \times [-\pi^{1/2} \operatorname{erfc}(b) + [(1/b) - (1/2b^3) + (3/4b^5)] \\ & \times \exp(-b^2)] \\ & + (\pi^4/30V_{\mathrm{d}}) w^5 T_1 - (\pi^4/48) w^8 T_0 \end{aligned}$$

3.4.12. Numerical illustrations

Consider the case of the sodium chloride crystal structure (a face-centred cubic structure) as a simple example for evaluation of the Coulombic sum. The sodium ion can be taken at the origin, and the chloride ion halfway along an edge of the unit cell. The results can easily be generalized for this structure type by using the unit-cell edge length, a, as a scaling constant.

First, consider the nearest neighbours. Each sodium and each chloride ion is surrounded by six ions of opposite sign at a distance of $a/2$. The Coulombic energy for the first coordination sphere is $-(1/2)(12)(2/a)(1389.3654) = -16672.385/a$ kJ mol^{-1}. Table 3.4.2.1 shows that the converged value of the lattice energy is $-4855.979/a$. Thus the nearest-neighbour energy is over three times more negative than the total lattice energy. In the second coordination sphere each ion is surrounded by 12 similar ions at a distance of $a/2^{1/2}$. The energy contribution of the second sphere is $+(1/2)(24)(2^{1/2}/a)(1389.3654) = +23578.313/a$. Thus, major cancellation occurs and the net energy for the first two coordination spheres is $+6905.928/a$ which actually has the wrong sign for a stable crystal. The third coordination sphere again makes a negative contribution. Each ion is surrounded by eight ions of opposite sign at a distance of $a/3^{1/2}$. The energy contribution is $-(1/2)(16)(3^{1/2}/a)(1389.3654) = -19251.612/a$, now giving a total so far of $-12345.684/a$. In the fourth coordination sphere each ion is surrounded by six others of the same sign at a distance of a. The energy contribution is $+(1/2)(12)(1/a)(1389.3654) = +8336.19/a$ to yield a total of $-4009.491/a$.

It is seen immediately by examining the numbers that the Coulombic sum is converging very slowly in direct space. Madelung (1918) devised a method for accurate evaluation of the sodium chloride lattice sum. However, his method is not generally applicable for more complex lattice structures. Evjen (1932) emphasized the importance of summing over a neutral domain, and replaced the sum with an integral outside of the first few shells of nearest neighbours. But the method of Ewald remained as the only completely general and accurate method of evaluating the Coulombic sum for a general lattice. Although it was derived in a somewhat different way, Ewald's method is equivalent to accelerated convergence for the special case of $n = 1$.

In the reciprocal lattice of sodium chloride only points with indices (hkl) all even or all odd are permitted by the face-centred symmetry. The reciprocal cell has edge length $1/a$ and the reciprocal-axis directions coincide with the direct-lattice axis directions. The closest points to the origin are the eight (111) forms at a distance of $(1/a)/3^{1/2}$. For sodium chloride this distance is 0.3078 Å^{-1}.

Table 3.4.12.1 shows the effect of convergence acceleration on the direct-space portion of the $(n = 1)$ sum for the sodium chloride structure. The constant term $-w\sum q_j^2$ is included in the values given. This constant term is always large if w is not zero; for instance, when $w = 0.1$ this term is −277.872 (Table 3.4.12.2). For $w = 0.1$ the reciprocal-lattice sum is zero to six figures. Thus, only the direct sum (plus the constant term) is needed, evaluated out to 20 Å in direct space, to obtain six-figure accuracy. As shown in Table 3.4.2.1 above, the same summation effort without the use of accelerated convergence gave 8% error, or only

Table 3.4.12.3. *Accelerated-convergence results for the dispersion sum (n = 6) of crystalline benzene (kJ mol^{-1}, Å); the figures shown are the direct-lattice sum plus the two constant terms*

18.0	−80.589				
20.0	−80.589				

Table 3.4.12.4. *The reciprocal-lattice results (kJ mol^{-1}, Å) for the dispersion sum (n = 6) of crystalline benzene*

Limit	$w = 0.1$	$w = 0.15$	$w = 0.2$	$w = 0.3$	$w = 0.4$
0.0	−5.547	−16.706	−32.326	−43.681	80.947
0.3	0.000	−0.004	−0.321	−16.792	−117.106
0.4	0.000	−0.004	−0.324	−18.656	−152.651
0.5			−0.324	−18.716	−155.940
0.6				−18.719	−157.102
0.7				−18.719	−157.227
0.8					−157.233
0.9					−157.234
1.0					−157.234

Table 3.4.12.5. *Approximate time (s) required to evaluate the dispersion sum (n = 6) for crystalline benzene within 0.001 kJ mol^{-1} truncation error*

w	Direct terms	Reciprocal terms	Time, direct	Time, reciprocal	Total time
0.0	(not yet converged at 20 Å summation limit)				>107
0.1	15904	0	77	0	77
0.15	4718	34	23	6	29
0.2	2631	78	13	14	27
0.3	1313	246	7	46	53
0.4	524	804	3	149	152

slightly better than one-figure accuracy. The accelerated-convergence technique therefore yielded nearly five orders of magnitude improvement in accuracy, even without evaluation of the reciprocal-lattice sum.

The column showing $w = 0.15$ shows an example of how the reciprocal-lattice sum can also be neglected if lower accuracy is required. Table 3.4.12.2 shows that the reciprocal-lattice sum is still only 0.003. But now the direct-lattice sum only needs to be evaluated out to 14 Å, with further savings in calculation effort. For w values larger than 0.15 the reciprocal sum is needed. For $w = 0.4$ this sum must be evaluated out to 0.8 Å^{-1} to obtain six-figure accuracy.

Table 3.4.12.3 illustrates an application for the $(n = 6)$ dispersion sum. When $w = 0.1$ Å^{-1} five figures of accuracy can be obtained without consideration of the reciprocal sum. The direct sum is required out to 18 Å. If $w = 0.15$, better than four-figure accuracy can still be obtained without evaluating the reciprocal-lattice sum. In this case, the direct lattice needs to be summed only to 12 Å, and there is a saving of an order of magnitude in the length of the calculation. As with the Coulombic sum, if w is greater than 0.15 the reciprocal-lattice summation is needed; Table 3.4.12.4 shows the values.

The time required to obtain a lattice sum of given accuracy will vary depending on the particular structure considered and of course on the computer and program which are used. An example of timing for the benzene dispersion sum is given in Table 3.4.12.5 for the *PCK83* program (Williams, 1984) running on a VAX-11/750 computer. In this particular case direct terms were evaluated at a rate of about 200 terms s^{-1} and reciprocal terms, being a sum themselves, were evaluated at a slower rate of about 5 terms s^{-1}.

Table 3.4.12.5 shows the time required for evaluation of the dispersion sum using various values of the convergence constant, w. The timing figures show that there is an optimum choice for w; for the *PCK83* program the optimum value indicated is 0.15–0.2 Å^{-1}. In the program of Pietila & Rasmussen (1984) values in the range 0.15–0.2 Å^{-1} are also suggested. For the *WMIN* program (Busing, 1981) a slightly higher value of 0.25 Å^{-1} is suggested. Trial calculations can be used to determine the optimum value of w for the situation of a particular crystal structure, program and computer.

3.5. Extensions of the Ewald method for Coulomb interactions in crystals

By T. A. Darden

3.5.1. Introduction

High-precision single-crystal X-ray structural analysis of small organic molecules, yielding the space group, the unit-cell parameters and the fractional coordinates of the atoms making up the molecule(s) in the asymmetric unit, has become a routine matter as long as crystals of sufficient quality can be obtained. The thermodynamic stability of the crystal, as described by the enthalpy of sublimation ΔH_{sub}, can also be determined experimentally (although not always to high precision). Theoretical models for calculating intermolecular interaction energies can be used to connect the crystal structure to the molar enthalpy of sublimation using the relationship

$$\Delta H_{sub}(0\ \mathrm{K}) = -E_{lattice},$$

where the lattice or packing energy $E_{lattice}$ is the total (molar) intermolecular interaction energy between all the molecules in the crystal, which are treated as rigid entities with zero-point energies of intra- and intermolecular vibrations neglected. Connection to experimentally accessible heats of sublimation at higher temperatures involves thermodynamic corrections. Methods for calculating thermodynamic quantities of solids are discussed in Gavezzotti (2002*a*) and (in more detail) in Frenkel & Smit (2002).

Thus, given a parameterized intermolecular potential-energy function, or if computationally affordable a first-principles approach such as density-functional theory (or preferably, when it becomes feasible for crystals, a good-quality post-Hartree–Fock potential-energy surface that describes dispersion interactions), one can sum the intermolecular energies to obtain the lattice energy as a function of the above parameters defining the crystal structure. If such an energy function is used together with a method for systematic search of the crystal-structure parameters, one could in principle predict the minimum-lattice-energy crystal structure for a rigid organic molecule. To extend this approach to flexible molecules one would need to minimize the sum of the intramolecular energy plus the lattice energy. If the experimental crystal structure corresponds to the thermodynamic minimum-energy structure (*i.e.* it is not a metastable state determined by crystal-growth kinetics), one could in principle predict the experimental crystal structure of an organic compound through this minimization protocol. Moreover, one could ideally predict the additional metastable forms of the crystal.

Prediction of the structure of crystals of an organic molecule from its molecular structure is a difficult problem that has been compared to the protein folding problem (Dunitz, 2003; Dunitz & Scheraga, 2004). Like the protein folding problem, a solution of the crystal prediction problem has significant practical ramifications. A compound is often polymorphic, that is it has more than one crystal structure, and it may be difficult to characterize the conditions under which a particular crystal structure is formed (Dunitz & Bernstein, 1995). Polymorphs may have very different physical properties. An obvious example is diamond *versus* graphite, but other commercially important examples include food additives, various solid forms of explosives and the bioavailability of various forms of a drug such as ritonavir (Chemburkar *et al.*, 2000). A method for predicting the possible crystal structures of the compound, and ideally for predicting the dominant crystal structure given the experimental conditions, would thus be very valuable. Note that due to the subtleties of crystallization, the lowest-free-energy polymorph at given temperature and pressure may not be the likeliest to form. The kinetics of growth of microcrystals may largely determine which low-energy polymorph appears (Dunitz, 2003). However, it is generally agreed that accurate calculation of the relative free energy of polymorphs is a prerequisite for predicting crystal structures.

To assess progress towards solving this latter problem, a series of blind tests of crystal-structure prediction has been undertaken (Day, Motherwell, Ammon *et al.*, 2005). The results of these tests have highlighted the need for continued improvements in sampling methods and intermolecular energy potentials. Since extensive sampling of the crystal-structure parameters is necessary [between 10^4 and 10^5 starting structures, each followed by parameter minimizations (Price & Price, 2005)], there is a trade-off in the computational cost *versus* accuracy of the intermolecular energy functions used. Calculating the work of transforming between polymorphs is yet more ambitious in terms of sampling. Consequently empirical force fields are likely to be needed for the near term at least.

In the remainder of the introduction we outline some of the approaches to empirical potentials used in the calculation of the lattice energy, and then, motivated by these developments, discuss techniques for efficient summation of the electrostatic and other slow-decaying interaction terms that occur in these potential functions.

Methodological developments in the intermolecular force fields used in crystal-structure prediction from early times to the present state of the art have been reviewed (Price & Price, 2005). Until recently, these force fields were made up of atom–atom interactions. The earliest involved only repulsion and dispersion, usually in the 'exp-6' form

$$U^{MN} = U^{MN}_{rep} + U^{MN}_{disp} = \sum_{i\in M, j\in N} A_{ij}\exp(-B_{ij}r_{ij}) - C_{i,j}r_{ij}^{-6},$$

where U^{MN} denotes the intermolecular potential energy between molecules M and N and r_{ij} is the distance between atoms $i \in M$ and $j \in N$. Sometimes the exponential form in the above equation is replaced by a simpler power law, as in the Lennard–Jones potential. As was pointed out by Dunitz (2003), in comparison with more sophisticated force fields, this repulsion–dispersion form readily allows analysis of the significance of particular atom–atom interactions, since the interactions are short-ranged and thus can be localized. That is, the r^{-6} form of the attractive dispersion energy means that interaction energies are halved for every 12% increase in distance. In contrast, introduction of long-range Coulombic interactions not only entails subtleties in lattice summation (the subject of this contribution), but greatly complicates the assignment of 'key' atom–atom interactions. Gavezzotti and Fillipini systematically explored the use of the exp-6 potential in fitting organic crystal structures with and without hydrogen-bond interactions (Gavezzotti & Fillipini, 1994). They were surprisingly successful in accounting for weak hydrogen bonding in this way, but selective use of point charges improved the directionality of the potential. Earlier, Williams derived exp-6 parameters for the atoms C, H, N, O, Cl, F and polar H for use in organic crystal structures, but found it necessary (Williams & Cox, 1984) to supplement these with selected point charges, both atomic and at off-atom sites. Price and

Copyright © 2010 International Union of Crystallography

co-workers have used a more sophisticated electrostatic model based on distributed multipole analysis (DMA) with multipoles up to hexadecapole order positioned at atom centres (Stone, 1996). A similar approach has been adopted by Mooji *et al.*, with the addition of dipole polarizabilities to account for intermolecular induction energy (Mooji *et al.*, 1999). The AMOEBA force field has similar capabilities (Ren & Ponder, 2003).

Recently, a systematic study (Day *et al.*, 2004; Day, Motherwell & Jones, 2005) of the effect of the electrostatic model on crystal-structure prediction for rigid organic molecules was carried out. The exp-6 parameters from the W99 force field (Williams, 2001) were used in conjunction with point charges derived either from a bond-increment model or electrostatic potential (ESP) fit, or with a DMA model as used by Price and co-workers. Importantly, they found a systematic and significant improvement in prediction success going from the simple bond-increment model to the ESP charges to point multipoles. Similar results were found by Broderson *et al.* (2003). This is a positive indicator for the use of theory in attacking this difficult prediction problem. On the other hand, Broderson *et al.* found that more sophisticated electrostatic models did not help in predicting the packing of flexible molecules. As discussed by Price & Price (2005), crystal-packing energies of flexible molecules are more problematic for at least two reasons. First the intramolecular energy must be fully compatible with the intermolecular energy in order that energy deformation from the gas-phase minimum be on the same scale as the concomitant gain in packing energy. Secondly, the conformational dependence of the electrostatic model must be accurately accounted for, or any gains from a more sophisticated model are immediately negated. Existing force fields are unable to meet these challenges, which may explain the lower success rate for predicting crystal structures of flexible molecules. Price has developed a methodology for flexible molecules wherein intramolecular conformations are systematically explored. For each conformer studied, the gas-phase intramolecular energy and DMA electrostatic model are calculated using quantum-chemical methods. The optimal packing of that conformer is then obtained by treating it as a rigid molecule, and the resulting minimum lattice energy is added to its intramolecular energy to give its total energy. The total energy for that conformer is then compared with that of the other conformers to predict the optimal conformation and packing of the flexible molecule. This approach has proved successful in a number of cases, for example with the successful prediction of a novel second polymorph of 1-hydroxy-7-azabenzotriazole (Nowell *et al.*, 2006).

The above electrostatic models are all derived from gas-phase quantum-chemical calculations. A different line of development has been the parameterization of electrostatic models from condensed-phase experimental or theoretical electron densities, which should better represent the polarization due to the crystal environment. This is accomplished using aspherical multipole refinement of experimental X-ray charge densities (Destro *et al.*, 2000) or of theoretical charge densities from quantum-chemical calculations carried out under the space-group symmetry (Dovesi *et al.*, 2005). Crystal structure analysis is usually carried out assuming the independent-atom model (IAM), where the individual atomic densities are modelled as those of the spherically symmetric isolated atoms, with deviations in the experimental density being fitted to anisotropic temperature factors modelling the thermal motion of the nuclei. However, the IAM breaks down for data of sufficiently high quality, and the residual or deformation density is then fitted by a linear combination of atom-centred density basis elements resembling the well known Slater atomic basis sets from quantum chemistry (*i.e.* solid harmonics times a decaying exponential in the distance r from the atom). Technical details are provided in Coppens (1997) and Chapter 1.2 of this volume. The theoretical density can be similarly approached as a sum of pro-molecule density (superposition of isolated atomic densities in the molecular geometry) plus deformation density modelled by a sum of atomic Slater-like density elements. Until recently, the theoretical densities were thought to be of lower quality than the experimental densities, but continued improvements in the level of theory that can be applied have resulted in much closer agreement (Coppens & Volkov, 2004). Coppens and co-workers as well as others (Spackman *et al.*, 1988) have applied these modelled densities in studies of intermolecular electrostatic energies. The Slater-like functions are typically difficult to work with in this context, so multipole approximations are used except at close range, where numerical integration is used instead (Volkov *et al.*, 2004).

A similar density-based approach using gas-phase theoretical density was developed previously (Gavezzotti, 2002*b*). Gavezzotti splits the density into numerical 'pixels' (small cubes of volume) within which the density is considered constant, allowing in principle exact numerical calculation of intermolecular electrostatic interactions. He sums the pixel–pixel interactions discretely, using a hierarchical approach to increase efficiency. The electrostatic interactions are supplemented by induction and repulsion terms, also modelled by pixel-based interactions. These developments, in particular the large size of the positive and negative components of the electrostatic interactions treated in terms of actual electron density, have caused a reassessment of the idea that intermolecular interactions can be accurately decomposed even in principle into localized atom–atom interactions (Dunitz & Gavezzotti, 2005).

Cisneros *et al.* have also begun implementing an intermolecular potential based on the explicit modelling of gas-phase theoretical electron density, using the methodology of auxiliary basis set fitting (Cisneros *et al.*, 2005). The density is expanded into atom and off-atom sites using Gaussian density functions similar to those used as atomic basis sets in quantum chemical codes. More recently, other components of the potential such as induction, charge transfer and non-isotropic site–site repulsion based on density overlap have been implemented (Piquemal *et al.*, 2006) and efficient calculation of terms in periodic boundary conditions has also been implemented (Cisneros *et al.*, 2006), generalizing previous developments for point multipoles (Sagui *et al.*, 2004).

Summarizing the above developments, it appears that accurate evaluation of crystal lattice energies necessitates the use of complex electrostatic interactions beyond the spherical-atom approximation, and ultimately including an account of penetration effects through explicit modelling of electron density. The electrostatic lattice energies are differences between large positive and negative contributions that are long-ranged, necessitating an accurate treatment of their lattice summation. Dispersion interactions, modelled by higher-order inverse powers of distance, are short-ranged but their calculation can be greatly accelerated through lattice-summation techniques.

Ewald summation in ideal infinite crystals, for interactions that depend on inverse powers of site–site distance, is covered in Chapter 3.4 of this volume, where there is also a numerical demonstration of the advantages of the Ewald approach over direct numerical summation. In this contribution we focus on the lattice-summation problem for large but finite crystals, highlighting the role of summation order and leading to a derivation of the surface term and polarization response. We also consider extensions to Coulombic interactions between Gaussian density elements, both spherical and Hermite (multipolar), and methods to further accelerate the lattice summation to (almost) linear scaling.

These developments are organized into three sections. The first section treats lattice summation of point charges. We begin with definitions and an explanation of the origin of the conditional convergence problem for these sums, anticipating the nature of the results to follow. Following that we provide for the benefit of less mathematically oriented readers the standard physics-based derivation of the Ewald sum for point charges, minus any

accounting for the order of convergence or resulting surface term. This is followed by a more careful derivation focused on the order of summation, including results for higher-order inverse powers as well as the Coulomb interactions, finishing with a discussion of the surface term, the polarization response to an external dielectric and the pressure calculation. Although pitched at a higher mathematical level, we have tried to provide many details in the derivations unavailable elsewhere for the benefit of the reader. The alert reader will note that the key identity, equation (3.5.2.19), that separates $1/r^n$ into short-ranged and long-ranged components, is the same as that used Chapter 3.4 of this volume, highlighting the essential similarity of our approach. In the second section we generalize these point-charge results to lattice sums of interacting spherical Gaussian and Hermite Gaussian-based densities. The third and final section provides a discussion of two methods that greatly increase the numerical efficiency of these lattice sums in the case of large unit cells by utilizing the fast Fourier transform. Again we have tried to provide mathematical details not available elsewhere.

3.5.2. Lattice sums of point charges

We begin by discussing an idealized infinite crystal C, made up of point charges.

3.5.2.1. Basic quantities

The periodicity of an idealized crystal C is specified by lattice basis vectors $\mathbf{a}_1$, $\mathbf{a}_2$ and $\mathbf{a}_3$, which are linearly independent as vectors and thus form a basis for the usual vector space of points in three dimensions. The conjugate reciprocal vectors $\mathbf{a}_\alpha^*$ are defined by the relations $\mathbf{a}_\alpha^* \cdot \mathbf{a}_\beta = \delta_{\alpha\beta}$ (the Kronecker delta) for $\alpha, \beta = 1, 2, 3$. Thus for example $\mathbf{a}_1^*$ is given by $\mathbf{a}_1^* = (\mathbf{a}_2 \times \mathbf{a}_3)/[\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)]$. General lattice vectors $\mathbf{n}$ are given by integral combinations of the lattice basis vectors:

$$\mathbf{n} = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 + n_3\mathbf{a}_3, \tag{3.5.2.1}$$

where n_1, n_2, n_3 are integers. General reciprocal-lattice vectors $\mathbf{m}$ are given by integral combinations of the reciprocal-lattice basis vectors:

$$\mathbf{m} = m_1\mathbf{a}_1^* + m_2\mathbf{a}_2^* + m_3\mathbf{a}_3^*. \tag{3.5.2.2}$$

An arbitrary point $\mathbf{r}$ in the crystal ($\mathbf{r}$ also denotes the vector from the origin of coordinates to the point) is given by

$$\mathbf{r} = s_1\mathbf{a}_1 + s_2\mathbf{a}_2 + s_3\mathbf{a}_3,$$

where s_1, s_2, s_3 are the fractional coordinates of the point. From the above equation and the defining relations for the reciprocal basis we see that $s_\alpha = \mathbf{r} \cdot \mathbf{a}_\alpha^*$ for $\alpha = 1, 2, 3$. The unit cell U is the set of points $\mathbf{r}$ with associated fractional coordinates s_1, s_2, s_3 satisfying $-\frac{1}{2} \leq s_\alpha \leq \frac{1}{2}, \alpha = 1, 2, 3$. The idealized infinite crystal C is generated by the union of all periodic translations of the unit cell U, using the set of general lattice vectors $\mathbf{n}$. A point charge q at position $\mathbf{r}$ in U has periodic 'image' charges $q_\mathbf{n}$ at positions $\mathbf{r}_\mathbf{n} = \mathbf{r} + \mathbf{n}$ for all lattice vector $\mathbf{n}$. The periodic image of U, denoted $U_\mathbf{n}$, is given by the periodic images $q_\mathbf{n}$ of all point charges q in U. Thus, the crystal is made up of the union of images $U_\mathbf{n}$, including $U = U_\mathbf{0}$, or

$$C = \bigcup_\mathbf{n} U_\mathbf{n}.$$

A point charge q_i in U at position $\mathbf{r}_i$ interacts with other unit-cell charges $q_j, j \neq i$ at positions $\mathbf{r}_j$ as well as with all of their periodic images $q_{j\mathbf{n}}$ at positions $\mathbf{r}_{j\mathbf{n}} = \mathbf{r}_j + \mathbf{n}$ for all lattice vectors $\mathbf{n}$. It also interacts with its own periodic images $q_{i\mathbf{n}}$ at $\mathbf{r}_{i\mathbf{n}}$ for all nonzero lattice vectors $\mathbf{n}$, that is all $\mathbf{n} = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 + n_3\mathbf{a}_3$ with $(n_1, n_2, n_3) \neq (0, 0, 0)$. Suppose the unit cell U is made up of N point charges $q_1, \ldots, q_N$ at positions $\mathbf{r}_1, \ldots, \mathbf{r}_N$. Then the electrostatic energy of U, given by the sum of the Coulombic interactions of charges in U with each other and with the rest of C, is written as

$$\begin{aligned} E(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= E(\mathbf{r}_1, \ldots, \mathbf{r}_N) \\ &= \tfrac{1}{2}{\sum_\mathbf{n}}' \sum_{i=1}^N \sum_{j=1}^N \frac{q_i q_j}{|\mathbf{r}_i - \mathbf{r}_j - \mathbf{n}|}, \end{aligned} \tag{3.5.2.3}$$

where here and below $\underline{\mathbf{r}}^{\{\mathbf{N}\}}$ denotes the set of points $\{\mathbf{r}_1, \ldots, \mathbf{r}_N\}$ and where the outer sum on the right is over the general lattice vectors $\mathbf{n}$, the prime indicating that terms with $i = j$ and $\mathbf{n} = \mathbf{0}$ are omitted. The treatment of this infinite sum requires some care. The energy diverges unless the unit cell is neutral (*i.e.* unless $\sum_{i=1}^N q_i = 0$). When U is neutral, the sum, if carried out in a naive fashion, can still converge quite slowly (see Chapter 3.4). In addition, the convergence is *conditional*, that is the resulting energy can vary depending on the order in which the sum is carried out! To better understand these phenomena, it is helpful to re-express the above energy. Let $E(U, U)$ denote the Coulomb interaction energy of U with itself and $E(U, U_\mathbf{n}), \mathbf{n} \neq \mathbf{0}$ the Coulomb interaction energy of U with $U_\mathbf{n}$, that is

$$E(U, U) = \sum_{i<j} \frac{q_i q_j}{|\mathbf{r}_i - \mathbf{r}_j|}$$

and

$$E(U, U_\mathbf{n}) = \sum_{i=1}^N \sum_{j=1}^N \frac{q_i q_j}{|\mathbf{r}_i - \mathbf{r}_j - \mathbf{n}|} = \sum_{q_i \in U} \sum_{q_{j\mathbf{n}} \in U_\mathbf{n}} \frac{q_i q_{j\mathbf{n}}}{|\mathbf{r}_i - \mathbf{r}_{j\mathbf{n}}|}.$$

Then we can abbreviate equation (3.5.2.3) by

$$E(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) = E(U, U) + \tfrac{1}{2}\sum_{\mathbf{n}\neq\mathbf{0}} E(U, U_\mathbf{n}). \tag{3.5.2.4}$$

Note that for large $\mathbf{n}$ (that is, $\mathbf{n}$ with large norm $|\mathbf{n}|$) $E(U, U_\mathbf{n})$ can be approximated by a Taylor expansion. Let $\bar{\mathbf{r}}$ denote the centroid of points in U, given by $\bar{\mathbf{r}} = (1/N)\sum_{i=1}^N \mathbf{r}_i$, and let $\bar{\mathbf{r}}_\mathbf{n}$ denote the centroid of $U_\mathbf{n}$. Then, expanding in terms of $\mathbf{r}_i - \bar{\mathbf{r}} = \Delta\mathbf{r}_i$ and $\mathbf{r}_{j\mathbf{n}} - \bar{\mathbf{r}}_\mathbf{n} = \mathbf{r}_j - \bar{\mathbf{r}} = \Delta\mathbf{r}_j$ (which are small compared to $\bar{\mathbf{r}} - \bar{\mathbf{r}}_\mathbf{n} = -\mathbf{n}$) we have

$$\begin{aligned}\frac{1}{|\mathbf{r}_i-\mathbf{r}_{j\mathbf{n}}|} &= \frac{1}{|(\bar{\mathbf{r}}-\bar{\mathbf{r}}_{\mathbf{n}})+(\mathbf{r}_i-\bar{\mathbf{r}})-(\mathbf{r}_{j\mathbf{n}}-\bar{\mathbf{r}}_{\mathbf{n}})|}\\ &= \frac{1}{|\mathbf{n}-(\Delta\mathbf{r}_i-\Delta\mathbf{r}_j)|}\\ &\simeq \frac{1}{|\mathbf{n}|}+\sum_{\alpha=1}^{3}\frac{\mathbf{n}_\alpha}{|\mathbf{n}|^3}(\Delta\mathbf{r}_i-\Delta\mathbf{r}_j)_\alpha\\ &\quad+\tfrac{1}{2}\sum_{\alpha,\beta=1}^{3}\frac{(3\mathbf{n}_\alpha\mathbf{n}_\beta-\delta_{\alpha\beta}\mathbf{n}^2)}{|\mathbf{n}|^5}\\ &\quad\times(\Delta\mathbf{r}_i-\Delta\mathbf{r}_j)_\alpha(\Delta\mathbf{r}_i-\Delta\mathbf{r}_j)_\beta\\ &\quad+\ldots.\end{aligned}$$

Let $Q=\sum_{i=1}^{N}q_i$ and $\mathbf{D}=\sum_{i=1}^{N}q_i\Delta\mathbf{r}_i$ denote the net charge and dipole moment of the unit cell U, and let $\mathbf{G}_{\alpha\beta}=\sum_{i=1}^{N}q_i\Delta\mathbf{r}_{i\alpha}\Delta\mathbf{r}_{i\beta}$ denote the quadrupole moment of the unit cell. Using the expansion in the above equation, we can Taylor expand the interaction energy $E(U,U_{\mathbf{n}})$ as

$$\begin{aligned}E(U,U_{\mathbf{n}}) &= \sum_{i=1}^{N}\sum_{j=1}^{N}q_iq_j\frac{1}{|\mathbf{n}-(\Delta\mathbf{r}_i-\Delta\mathbf{r}_j)|}\\ &\simeq \frac{1}{|\mathbf{n}|}Q^2\\ &\quad+\sum_{\alpha,\beta=1}^{3}\frac{(3\mathbf{n}_\alpha\mathbf{n}_\beta-\delta_{\alpha\beta}\mathbf{n}^2)}{|\mathbf{n}|^5}(Q\mathbf{G}_{\alpha\beta}-\mathbf{D}_\alpha\mathbf{D}_\beta)\\ &\quad+\ldots.\end{aligned}\tag{3.5.2.5}$$

Note that the first-order term in the expansion has dropped out, since the dipole moments $\mathbf{D}$ of U and $U_{\mathbf{n}}$ are the same. If $Q\neq 0$ then for large $|\mathbf{n}|$ the leading term in the Taylor expansion of $E(U,U_{\mathbf{n}})$ is $Q^2/|\mathbf{n}|$. Since $\int\int\int(1/|\mathbf{r}|)\,\mathrm{d}^3\mathbf{r}=4\pi\int_0^\infty r\,\mathrm{d}r=\infty$, then using a standard integral comparison $\sum_{\mathbf{n}\neq\mathbf{0}}1/|\mathbf{n}|$ is infinite, and so the resulting electrostatic energy of U diverges. If $Q=0$ we see that the leading term in the expansion of $E(U,U_{\mathbf{n}})$ is given by $-\sum_{\alpha,\beta}[(3\mathbf{n}_\alpha\mathbf{n}_\beta-\delta_{\alpha\beta}\mathbf{n}^2)/|\mathbf{n}|^5]\mathbf{D}_\alpha\mathbf{D}_\beta$, that is a quadratic expression in the dipole moment $\mathbf{D}$ times a prefactor that decays like $1/|\mathbf{n}|^3$. Since $\int\int\int 1/|\mathbf{r}|^3\,\mathrm{d}^3\mathbf{r}=4\pi\int_0^\infty 1/r\,\mathrm{d}r=\infty$, $\sum_{\mathbf{n}\neq\mathbf{0}}1/|\mathbf{n}|^3$ also diverges (logarithmically), and so the electrostatic energy of U cannot converge absolutely in this case either. Hence, if it converges at all, it does so *conditionally*, that is the energy of U depends on the order in which we sum the contributions from image cells $U_{\mathbf{n}}$. If $Q=0$ and $\mathbf{D}=\mathbf{0}$, the leading term in the Taylor expansion of $E(U,U_{\mathbf{n}})$ depends on the quadrupole moment of the unit cell and decays like $1/|\mathbf{n}|^5$ for large $|\mathbf{n}|$, and thus since $\sum_{\mathbf{n}\neq\mathbf{0}}1/|\mathbf{n}|^5$ does converge, the electrostatic energy of U converges absolutely. From these considerations we might hope to express the energy of a neutral unit cell U in terms of an absolutely convergent sum plus a term quadratic in the unit-cell dipole moment $\mathbf{D}$ which also depends on the method of summation. As we will see below this is precisely what the Ewald summation method gives us.

3.5.2.2. Ewald sum: first derivation

In this section we give the standard Ewald-sum derivation found in textbooks such as Kittel (1986). To do this we need two preliminary results, namely the electrostatic potential due to an isolated Gaussian charge distribution having total charge of one, and then that due to a periodic array of such distributions.

First we derive the electrostatic potential $\Psi(\mathbf{r})$ due to an isolated Gaussian density $\rho(\mathbf{r})$ given by

$$\rho(\mathbf{r})=(\alpha/\pi)^{3/2}\exp(-\alpha\mathbf{r}^2).\tag{3.5.2.6}$$

Owing to the spherical symmetry of $\rho(\mathbf{r})$ we can define the one-dimensional function $\psi(r)$ by $\psi(r)=\Psi(\mathbf{r})$ for any $\mathbf{r}$ with $|\mathbf{r}|=r$. We next invoke Gauss' law (Eyges, 1980) under spherical symmetry to evaluate the electric field $\mathbf{E}(\mathbf{r})$ due to ρ at any distance $r=|\mathbf{r}|$. In the case of spherical symmetry Gauss' law states that the electric field at a point $\mathbf{r}$, due to a spherically symmetric charge distribution centred at the origin, is the same as if all the charge of the distribution from the origin out to $|\mathbf{r}|$ were collected into a point charge at the origin. More specifically, if $\mathbf{S}$ is the sphere of radius $r=|\mathbf{r}|$ with surface $\partial\mathbf{S}$, Gauss' law states

$$(1/4\pi)\int_{\partial\mathbf{S}}\mathbf{E}\,\mathrm{d}\mathbf{s}=\int_{\mathbf{S}}\rho(\mathbf{u})\,\mathrm{d}^3\mathbf{u},$$

and thus, defining the scalar quantity $E(r)=|\mathbf{E}(\mathbf{r})|$, we get

$$\begin{aligned}E(r) &= \frac{1}{r^2}\int_{\mathbf{S}}\rho(\mathbf{u})\,\mathrm{d}^3\mathbf{u}\\ &= \frac{1}{r^2}\left(\frac{\alpha}{\pi}\right)^{3/2}\int_{u=0}^{r}4\pi u^2\exp(-\alpha u^2)\,\mathrm{d}u\\ &= \frac{\mathrm{erf}(\alpha^{1/2}r)}{r^2}-\frac{2(\alpha/\pi)^{1/2}\exp(-\alpha r^2)}{r}\end{aligned}$$

and thus, since (again by symmetry) $E(r)=-(\mathrm{d}/\mathrm{d}r)\psi(r)$, we can verify that

$$\psi(r)=\frac{\mathrm{erf}(\alpha^{1/2}r)}{r}+C,\tag{3.5.2.7}$$

where C is an arbitrary constant of integration. We obtain a potential with the desired asymptotic behaviour, *i.e.* $\psi(r)\to 0$ as $r\to\infty$, by setting $C=0$. Note then that $\psi(r)\simeq 1/r$ for large r as expected.

Next we derive the electrostatic potential $\Phi^{\mathrm{P}}(\mathbf{r})$ due to a periodic array of Gaussian charge distributions, each of the form just studied. That is, for points $\mathbf{r}$ in the unit cell U, define the periodic density $\rho^{\mathrm{P}}(\mathbf{r})$ by

$$\rho^{\mathrm{P}}(\mathbf{r})=\sum_{\mathbf{n}}\rho(\mathbf{r}+\mathbf{n}),$$

where the density ρ is defined in equation (3.5.2.6) and the sum is over all general lattice vectors $\mathbf{n}$, defined in equation (3.5.2.1). Since ρ^{P} is periodic, *i.e.* $\rho^{\mathrm{P}}(\mathbf{r}+\mathbf{n}_0)=\rho(\mathbf{r})$ for any general lattice vector $\mathbf{n}_0$, we can expand it in a Fourier series over the unit cell:

$$\rho^{\mathrm{P}}(\mathbf{r})=\sum_{\mathbf{m}}C_{\mathbf{m}}\exp(2\pi i\mathbf{m}\cdot\mathbf{r}),\tag{3.5.2.8}$$

where the sum is over all reciprocal-lattice vectors $\mathbf{m}$, defined in equation (3.5.2.2), and the Fourier coefficient $C_{\mathbf{m}}$ is given by

$$
\begin{aligned}
C_{\mathbf{m}} &= \frac{1}{V}\int_U \rho^{\mathrm{P}}(\mathbf{r})\exp(-2\pi i\mathbf{m}\cdot\mathbf{r})\,\mathrm{d}^3\mathbf{r} \\
&= \frac{1}{V}\sum_{\mathbf{n}}\int_U \rho(\mathbf{r}+\mathbf{n})\exp[-2\pi i\mathbf{m}\cdot(\mathbf{r}+\mathbf{n})]\,\mathrm{d}^3\mathbf{r} \\
&= \frac{1}{V}\int_{\Re^3} \rho(\mathbf{r})\exp(-2\pi i\mathbf{m}\cdot\mathbf{r})\,\mathrm{d}^3\mathbf{r} \\
&= \frac{1}{V}\left(\frac{\alpha}{\pi}\right)^{3/2}\int_{\Re^3} \exp[-\alpha(\mathbf{r}+\pi i\mathbf{m})]^2\exp(-\pi^2\mathbf{m}^2/\alpha)\,\mathrm{d}^3\mathbf{r} \\
&= \frac{1}{V}\exp(-\pi^2\mathbf{m}^2/\alpha), \qquad (3.5.2.9)
\end{aligned}
$$

where V is the volume of the unit cell U. The periodicity of ρ^{P} implies that of Φ^{P}, so we can also expand the latter in a Fourier series:

$$\Phi^{\mathrm{P}}(\mathbf{r}) = \sum_{\mathbf{m}} B_{\mathbf{m}}\exp(2\pi i\mathbf{m}\cdot\mathbf{r}). \qquad (3.5.2.10)$$

Next we recall Poisson's equation (Eyges, 1980) for Φ^{P} in terms of ρ^{P}:

$$\nabla\cdot\nabla\Phi^{\mathrm{P}}(\mathbf{r}) = -4\pi\rho^{\mathrm{P}}(\mathbf{r}). \qquad (3.5.2.11)$$

Using equations (3.5.2.10) and (3.5.2.8) we can rewrite equation (3.5.2.11) as

$$\sum_{\mathbf{m}}(-4\pi^2\mathbf{m}^2)B_{\mathbf{m}}\exp(2\pi i\mathbf{m}\cdot\mathbf{r}) = -4\pi\sum_{\mathbf{m}} C_{\mathbf{m}}\exp(2\pi i\mathbf{m}\cdot\mathbf{r}),$$

thus using the uniqueness of Fourier-series coefficients $\pi\mathbf{m}^2B_{\mathbf{m}} = C_{\mathbf{m}}$. If $\mathbf{m}\neq\mathbf{0}$ this latter equation can be solved for $B_{\mathbf{m}}$. However, for $\mathbf{m} = \mathbf{0}$ it requires that $C_{\mathbf{m}} = 0$, whereas from equation (3.5.2.9) $C_{\mathbf{m}} = 1/V$. To avoid this contradiction we modify ρ^{P} by subtracting $1/V$ (uniform neutralizing plasma). That is, ρ^{P} is now defined by

$$\rho^{\mathrm{P}}(\mathbf{r}) = \sum_{\mathbf{n}}\rho(\mathbf{r}+\mathbf{n}) - (1/V). \qquad (3.5.2.12)$$

Note that ρ^{P} is still periodic. Also note that for $\mathbf{m}\neq\mathbf{0}$ $C_{\mathbf{m}}$ is still given by equation (3.5.2.9), whereas now $C_{\mathbf{0}} = 0$. Although we have avoided the contradiction, the value of $B_{\mathbf{0}}$ is still not determined. Some authors define it by considering $\mathbf{m}$ as a real variable and taking the limit as $\mathbf{m}\to\mathbf{0}$ (this depends on which direction the origin is approached from), but most treatments take it to be 0 (however, see Section 3.5.2.3). In the latter case the electrostatic potential Φ^{P} due to ρ^{P} is given by

$$\Phi^{\mathrm{P}}(\mathbf{r}) = \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}\exp(2\pi i\mathbf{m}\cdot\mathbf{r}). \qquad (3.5.2.13)$$

Now as before let $q_1, q_2, \ldots, q_N$ be point charges located at positions $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N$ within the unit cell U. From the discussion in Section 3.5.2.1 we assume the unit cell is *neutral*, *i.e.* $q_1 + \ldots + q_N = 0$. Let $\mathbf{r}$ be a point in U with $\mathbf{r}\neq\mathbf{r}_i$, $i = 1, \ldots, N$. We want to obtain the electrostatic potential Φ due to the point charges in U together with their periodic images in the remainder of the crystal C. That is,

$$\Phi_{\mathrm{lattice}}(\mathbf{r}) = \sum_{i=1}^{N}\sum_{\mathbf{n}}\frac{q_i}{|\mathbf{r}_i+\mathbf{n}-\mathbf{r}|}.$$

We next supplement the potential due to the point charge q_i at $\mathbf{r}_i+\mathbf{n}$ by the potential due to an equally charged Gaussian counterion, that is $(-q_i)$ times a density of the form ρ in equation (3.5.2.6), centred at $\mathbf{r}_i+\mathbf{n}$. Using equation (3.5.2.7) the resulting *direct sum* potential is given by

$$\Phi_{\mathrm{dir}}(\mathbf{r}) = \sum_{i=1}^{N}\sum_{\mathbf{n}}\frac{q_i\,\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}_i+\mathbf{n}-\mathbf{r}|)}{|\mathbf{r}_i+\mathbf{n}-\mathbf{r}|},$$

where $\mathrm{erfc}(x) = 1-\mathrm{erf}(x)$. Note that since $\mathrm{erfc}(x)$ decays exponentially fast to zero as $x\to\infty$, the sum in the above equation converges rapidly and absolutely.

However, having added the potential due to counterions we now need to cancel it. That is, we must consider the *reciprocal* electrostatic potential due to $(+q_i)$ times a density of the form ρ, centred at $\mathbf{r}_i+\mathbf{n}$, for all direct-lattice vectors $\mathbf{n}$. Since the unit cell is neutral, the sum of these *reciprocal* potentials over $i = 1, \ldots, N$ and all $\mathbf{n}$ is the same as the sum over $i = 1, \ldots, N$ of q_i times the potential due to ρ^{P} centred at $\mathbf{r}_i$ where ρ^{P} is given by equation (3.5.2.12). Note that the extra term involving $1/V$ drops out by neutrality. [In the case of non-neutrality, such as discussion of the free energy of charging an ion (Hummer *et al.*, 1996), the potential due to the uniform compensating plasma must be included (see below). Hummer has derived the potential due to a uniformly charged unit cell in the special case of a cubic unit cell (Hummer, 1996).] Thus, using equation (3.5.2.13) we arrive at the *reciprocal sum* potential:

$$
\begin{aligned}
\Phi_{\mathrm{rec}}(\mathbf{r}) &= \sum_{i=1}^{N} q_i\Phi^{\mathrm{P}}(\mathbf{r}-\mathbf{r}_i) \\
&= \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2} \\
&\quad\times\sum_{i=1}^{N} q_i\exp[2\pi i\mathbf{m}\cdot(\mathbf{r}-\mathbf{r}_i)] \\
&= \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}\exp(2\pi i\mathbf{m}\cdot\mathbf{r})S(-\mathbf{m}),
\end{aligned}
$$

where the structure factor $S(\mathbf{m})$ is given by

$$S(\mathbf{m}) = \sum_{i}^{N} q_i\exp(2\pi i\mathbf{m}\cdot\mathbf{r}_i). \qquad (3.5.2.14)$$

We have now expressed $\Phi_{\mathrm{lattice}}(\mathbf{r})$ as the sum of $\Phi_{\mathrm{dir}}(\mathbf{r})$ plus $\Phi_{\mathrm{rec}}(\mathbf{r})$ (with the caveat that in the process some infinite series have been casually rearranged and that the contribution of the reciprocal vector $\mathbf{m} = \mathbf{0}$ has been ignored). To get a valid electrostatic potential $\Phi_{\mathrm{lattice}}(\mathbf{r})$ at the position of a charge q_i in U we must remove the Coulomb potential due to q_i and then take the limit as $\mathbf{r}\to\mathbf{r}_i$. Noting that $1 = \mathrm{erf}(x) + \mathrm{erfc}(x)$ and that $\lim_{x\to 0}\mathrm{erf}(x)/x = 2/\sqrt{\pi}$, we have

$$\begin{aligned}\Phi_{\rm lattice}(\mathbf{r}_i) &= \lim_{\mathbf{r}\to\mathbf{r}_i}\left[\Phi_{\rm lattice}(\mathbf{r}) - \frac{q_i}{|\mathbf{r}-\mathbf{r}_i|}\right] \\ &= \sum_{j\neq i}\frac{q_j\ \mathrm{erfc}(\alpha^{1/2}|\mathbf{r}_j-\mathbf{r}_i|)}{|\mathbf{r}_j-\mathbf{r}_i|} \\ &\quad + \sum_{j=1}^{N}\sum_{\mathbf{n}\neq\mathbf{0}}\frac{q_j\ \mathrm{erfc}(\alpha^{1/2}|\mathbf{r}_j+\mathbf{n}-\mathbf{r}_i|)}{|\mathbf{r}_j+\mathbf{n}-\mathbf{r}_i|} \\ &\quad + \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}\exp(2\pi i\mathbf{m}\cdot\mathbf{r}_i)S(-\mathbf{m}) \\ &\quad - 2q_i\Big(\frac{\alpha}{\pi}\Big)^{1/2}.\end{aligned}$$

Thus we can write the electrostatic energy of U from equation (3.5.2.3) as

$$\begin{aligned}E_{\rm Ewald}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= \tfrac{1}{2}\sum_{i=1}^{N} q_i\,\Phi_{\rm lattice}(\mathbf{r}_i) \\ &= \tfrac{1}{2}{\sum_{\mathbf{n}}}'\sum_{i=1}^{N}\sum_{j=1}^{N}\frac{q_iq_j\ \mathrm{erfc}(\alpha^{1/2}|\mathbf{r}_j+\mathbf{n}-\mathbf{r}_i|)}{|\mathbf{r}_j+\mathbf{n}-\mathbf{r}_i|} \\ &\quad + \frac{1}{2\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}S(\mathbf{m})S(-\mathbf{m}) \\ &\quad - \Big(\frac{\alpha}{\pi}\Big)^{1/2}\sum_{i=1}^{N}q_i^2, \qquad (3.5.2.15)\end{aligned}$$

where as above the prime indicates that terms with $i=j$ and $\mathbf{n}=\mathbf{0}$ are omitted.

3.5.2.3. Ewald sum: more complete derivation

The derivation in Section 3.5.2.2 is incomplete. In addition to the caveats concerning the expression for $\Phi_{\rm lattice}(\mathbf{r})$ in terms of $\Phi_{\rm dir}(\mathbf{r})$ plus $\Phi_{\rm rec}(\mathbf{r})$, there is no mention of a quadratic term involving the unit-cell dipole moment $\mathbf{M}$. In this section we provide a more complete derivation of the Ewald sum, which will in addition explain the conditional convergence discussed previously. We follow the developments in Smith (1981, 1994).

The derivation depends on the following identity:

$$\begin{aligned}\frac{1}{|\mathbf{r}|} &= \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}|)}{|\mathbf{r}|} + \frac{1}{\pi}\int_{\Re^3}\frac{\exp(-\pi^2\mathbf{u}^2/\alpha)}{\mathbf{u}^2}\exp(-2\pi i\mathbf{u}\cdot\mathbf{r})\,\mathrm{d}^3\mathbf{u} \\ &= \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}|)}{|\mathbf{r}|} + \frac{1}{\pi}\sum_{\mathbf{m}}\int_{U^*}\frac{\exp(-\pi^2|\mathbf{v}+\mathbf{m}|^2/\alpha)}{|\mathbf{v}+\mathbf{m}|^2} \\ &\quad\times\exp[-2\pi i(\mathbf{v}+\mathbf{m})\cdot\mathbf{r}]\,\mathrm{d}^3\mathbf{v}, \qquad (3.5.2.16)\end{aligned}$$

where U^* is the reciprocal unit cell, *i.e.* the set of points $\mathbf{v}=t_1a_1^*+t_2a_2^*+t_3a_3^*$ with $-\frac{1}{2}\le t_\alpha\le\frac{1}{2}$, $\alpha=1,2,3$. Actually we derive (following Essmann *et al.*, 1995) a generalization of identity (3.5.2.16), valid for general inverse powers $1/|\mathbf{r}|^p$, $p>0$. For this first note that for $u>0$

$$\begin{aligned}\Gamma(u) &= \int_0^\infty t^{u-1}\exp(-t)\,\mathrm{d}t \\ &= \lambda^u\int_0^\infty t^{u-1}\exp(-\lambda t)\,\mathrm{d}t, \qquad (3.5.2.17)\end{aligned}$$

where $\Gamma(u)$ is the Euler gamma function. Next note that for $a>0$

$$\begin{aligned}\exp(-a\mathbf{r}^2) &= (\pi/a)^{3/2}\int_{\Re^3}\exp(-\pi^2\mathbf{u}^2/a) \\ &\quad\times\exp(-2\pi i\mathbf{u}\cdot\mathbf{r})\,\mathrm{d}^3\mathbf{u}, \qquad (3.5.2.18)\end{aligned}$$

which is the Fourier transform of the Gaussian, as derived above within equation (3.5.2.9). In equation (3.5.2.17) substitute $\lambda=|\mathbf{r}|^2$ and $u=p/2$ to get, for $\alpha>0$,

$$\begin{aligned}\frac{\Gamma(p/2)}{|\mathbf{r}|^p} &= \int_0^\alpha t^{p/2-1}\exp(-\mathbf{r}^2t)\,\mathrm{d}t + \int_\alpha^\infty t^{p/2-1}\exp(-\mathbf{r}^2t)\,\mathrm{d}t \\ &= \mathrm{I}_p + \mathrm{II}_p.\end{aligned}$$

In II_p we substitute $\mathbf{r}^2t=s^2$, whereas in I_p we use equation (3.5.2.18), change the order of integration, and substitute $\pi^2\mathbf{u}^2/t=s^2$ to obtain

$$\begin{aligned}\frac{1}{|\mathbf{r}|^p} &= \frac{1}{\Gamma(p/2)}\frac{1}{|\mathbf{r}|^p}\int_{\alpha^{1/2}|\mathbf{r}|}^\infty 2s^{p-1}\exp(-s^2)\,\mathrm{d}s \\ &\quad + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)}\int_{\Re^3}\mathrm{d}^3\mathbf{u}\exp(-2\pi i\mathbf{u}\cdot\mathbf{r})\Big(\frac{\pi|\mathbf{u}|}{\alpha^{1/2}}\Big)^{p-3} \\ &\quad\times\int_{\pi|\mathbf{u}|/\alpha^{1/2}}^\infty 2s^{2-p}\exp(-s^2)\,\mathrm{d}s \\ &= \frac{f_p(\alpha^{1/2}|\mathbf{r}|)}{|\mathbf{r}|^p} \\ &\quad + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)}\int_{\Re^3}\exp(-2\pi i\mathbf{u}\cdot\mathbf{r})g_p(\pi|\mathbf{u}|/\alpha^{1/2})\,\mathrm{d}^3\mathbf{u} \\ &= \frac{f_p(\alpha^{1/2}|\mathbf{r}|)}{|\mathbf{r}|^p} \\ &\quad + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)}\sum_{\mathbf{m}}\int_{U^*}g_p\Big(\frac{\pi|\mathbf{v}+\mathbf{m}|}{\alpha^{1/2}}\Big) \\ &\quad\times\exp[-2\pi i(\mathbf{v}+\mathbf{m})\cdot\mathbf{r}]\,\mathrm{d}^3\mathbf{v}, \qquad (3.5.2.19)\end{aligned}$$

where

$$f_p(x) = \frac{1}{\Gamma(p/2)}\int_x^\infty 2s^{p-1}\exp(-s^2)\,\mathrm{d}s \qquad (3.5.2.20)$$

and

$$g_p(x) = x^{p-3}\int_x^\infty 2s^{2-p}\exp(-s^2)\,\mathrm{d}s. \qquad (3.5.2.21)$$

Specializing to the case $p=1$ we see that $f_p(x)=\mathrm{erfc}(x)$ and that $g_p(x)=\exp(-x^2)/x^2$, which proves identity (3.5.2.16). Another important case is $p=6$, for which $f_p(x)=(1+x^2+x^4/2)\exp(-x^2)$ and $g_p(x)=(1-2x^2)\exp(-x^2)/3+2x^3\pi^{1/2}\mathrm{erfc}(x)$.

Note that from equation (3.5.2.17), substituting $t=s^2$, $\lambda=\mathbf{r}^2$ and $u=p/2$ we have

$$\frac{1}{|\mathbf{r}|^p} = \frac{2}{\Gamma(p/2)} \int_0^\infty s^{p-1} \exp(-r^2 s^2)\, \mathrm{d}s.$$

Also, substituting $s = |\mathbf{r}|t$ into equation (3.5.2.20) we have

$$\frac{f_p(\alpha^{1/2}|\mathbf{r}|)}{|\mathbf{r}|^p} = \frac{2}{\Gamma(p/2)} \int_{\alpha^{1/2}}^\infty t^{p-1} \exp(-r^2 t^2)\, \mathrm{d}t$$

and so

$$\begin{aligned}\lim_{\mathbf{r}\to\mathbf{0}} &\frac{1}{|\mathbf{r}|^p}[1 - f_p(\alpha^{1/2}|\mathbf{r}|)] \\ &= \lim_{\mathbf{r}\to\mathbf{0}} \frac{2}{\Gamma(p/2)} \int_0^{\alpha^{1/2}} t^{p-1} \exp(-r^2 t^2)\, \mathrm{d}t \\ &= \frac{2\alpha^{p/2}}{p\Gamma(p/2)}. \end{aligned} \tag{3.5.2.22}$$

Note that $g_p(x)$ is a smooth function of x for $x \neq 0$, and that its derivatives are uniformly bounded for x bounded away from 0. To show this, substitute $s = xt$ in equation (3.5.2.21) to write

$$g_p(x) = 2 \int_1^\infty t^{2-p} \exp(-x^2 t^2)\, \mathrm{d}t.$$

In the case that $p = 6$, $g_p(x)$ is smooth with uniformly bounded derivatives for all x, but this is unfortunately not true for all p. However, from the above expression we can show that for $p > 3$, $g_p(x)$ is bounded and continuous as $x \to 0$, whereas for $1 \leq p \leq 3$ $g_p(x) \to \infty$ as $x \to 0$. Thus for $p > 3$ we see that for any $x > 0$, $g_p(x) < g_p(0) = 2/(p-3)$. However for $1 \leq p \leq 3$, for any $R > 1$ if $x > 0$ sufficiently small $\exp(-x^2R^2) > \frac{1}{2}$; thus $g_p(x) > 2\int_1^R t^{2-p} \exp(-x^2t^2)\, \mathrm{d}t > \int_1^R t^{2-p}\, \mathrm{d}t \geq \ln(R)$ and thus $g_p(x)$ is unbounded as $x \to 0$.

Despite this latter result, the integral of $g_p(\mathbf{r})$ over $\Re^3$ is bounded for $p \geq 1$. This result is important below for the validity of rearranging the order of summation or taking limits inside infinite sums involving g_p. To prove boundedness, use the above expression for g_p and integrate by parts to write

$$\begin{aligned}\int_{\Re^3} g_p(\mathbf{r})\, \mathrm{d}^3\mathbf{r} &= 4\pi \int_0^\infty x^2 g_p(x)\, \mathrm{d}x \\ &= 4\pi \int_0^\infty \mathrm{d}x \int_1^\infty t^{1-p}(2x^2 t) \exp(-x^2t^2)\, \mathrm{d}t \\ &= 4\pi \Bigg[\int_0^\infty \exp(-x^2)\, \mathrm{d}x \\ &\quad + (1-p) \int_1^\infty t^{-p}\, \mathrm{d}t \int_0^\infty \exp(-x^2t^2)\, \mathrm{d}x \Bigg] \\ &= 4\pi \Bigg[\int_0^\infty \exp(-x^2)\, \mathrm{d}x \\ &\quad + (1-p) \int_1^\infty t^{-(p+1)}\, \mathrm{d}t \int_0^\infty \exp(-s^2)\, \mathrm{d}s \Bigg] \\ &= \frac{2\pi^{3/2}}{p}. \end{aligned}$$

3.5.2.3.1. The case of $p > 3$

We first discuss the lattice sum for the case $p > 3$. In this case the lattice sum converges absolutely, since the tail of this sum can be bounded from above by a constant times the integral

$$\int_{|\mathbf{r}|>K} \frac{1}{|\mathbf{r}|^p}\, \mathrm{d}^3\mathbf{r} = 4\pi \int_K^\infty r^{(2-p)}\, \mathrm{d}r = \frac{K^{(3-p)}}{p-3} \tag{3.5.2.23}$$

for some $K > 0$. Although the sum can thus be evaluated directly, it can be significantly accelerated using the same Ewald direct- and reciprocal-space decomposition. For $\mathbf{r} \neq \mathbf{0}$, using equation (3.5.2.19) we have

$$\begin{aligned}\sum_{\mathbf{n}} \frac{1}{|\mathbf{r}+\mathbf{n}|^p} = \sum_{\mathbf{n}} \frac{f_p(\alpha^{1/2}|\mathbf{r}+\mathbf{n}|)}{|\mathbf{r}+\mathbf{n}|^p} + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)} \\ \times \sum_{\mathbf{n}} \sum_{\mathbf{m}} \int_{U^*} h_{p,\mathbf{m},\mathbf{r}}(\mathbf{v}) \exp(-2\pi i \mathbf{v}\cdot\mathbf{n})\, \mathrm{d}^3\mathbf{v}, \end{aligned}$$

where $h_{p,\mathbf{m},\mathbf{r}}(\mathbf{v}) = g_p(\pi|\mathbf{v}+\mathbf{m}|/\alpha^{1/2}) \exp[-2\pi i(\mathbf{v}+\mathbf{m})\cdot\mathbf{r}]$. Since $f_p(\alpha^{1/2}|\mathbf{r}+\mathbf{n}|)$ is bounded, the first of the above sums converges absolutely and we turn to the second. We recognize the integral $\int_{U^*} h_{p,\mathbf{m},\mathbf{r}}(\mathbf{v}) \exp(-2\pi i \mathbf{v}\cdot\mathbf{n})\, \mathrm{d}^3\mathbf{v}$ as $(1/V)$ times $\hat{h}_{p,\mathbf{m},\mathbf{r}}(\mathbf{n})$, the $\mathbf{n}$th Fourier coefficient of $h_{p,\mathbf{m},\mathbf{r}}$, where V is the volume of the unit cell U ($1/V$ is the volume of U^*). From the above results for g_p it is clear that for $\mathbf{m} \neq \mathbf{0}$, $h_{p,\mathbf{m},\mathbf{r}}$ are smooth and have uniformly (in $\mathbf{v}$, $\mathbf{r}$ and $\mathbf{m} \neq \mathbf{0}$) bounded derivatives. Thus the sum of the Fourier coefficients can be shown to converge absolutely and uniformly in $\mathbf{m}$, which guarantees uniform (over $\mathbf{m} \neq \mathbf{0}$) convergence of the sum of these integrals to $(1/V)h_{p,\mathbf{m},\mathbf{r}}(\mathbf{0})$, which in turn equals $(1/V)g_p(\pi|\mathbf{m}|/\alpha^{1/2}) \exp(-2\pi i \mathbf{m}\cdot\mathbf{r})$.

The case of $\mathbf{m} = \mathbf{0}$ is not as straightforward, since the uniform boundedness of derivatives of $h_{p,\mathbf{m},\mathbf{r}}$ does not generally hold in this case. One way of handling it is as follows. Since everything else in the above equation converges as $|\mathbf{n}| \to \infty$, the sum of the Fourier coefficients for $h_{p,\mathbf{m}=\mathbf{0},\mathbf{r}}$ converges to something. That is, if

$$S(n_1, n_2, n_3) = \sum_{k_1=-n_1}^{n_1} \sum_{k_2=-n_2}^{n_2} \sum_{k_3=-n_3}^{n_3} \hat{h}_{p,\mathbf{0},\mathbf{r}}(k_1, k_2, k_3)$$

for $n_\alpha > 0$, $\alpha = 1, 2, 3$, then for some s, $S(n_1, n_2, n_3) \to s$ as $\max(n_1, n_2, n_3) \to \infty$. If

$$\sigma(n) = [1/(n+1)]^3 \sum_{n_1=0}^{n} \sum_{n_2=0}^{n} \sum_{n_3=0}^{n} S(n_1, n_2, n_3),$$

then it is straightforward to show that $\sigma(n)$ also converges to s as $n \to \infty$ [see, for example, Chapter 1 of Körner (1988) for the one-dimensional proof]. On the other hand, due to the boundedness and continuity of h_p, $\sigma(n) \to h_{p,\mathbf{m},\mathbf{r}}(\mathbf{0})$ as $n \to \infty$. [This involves the three-dimensional version of the Fejér kernel, which converges to the three-dimensional Dirac delta function. See, for example, Chapter 2 of Körner (1988) for the one-dimensional proof.] Thus $S(n_1, n_2, n_3) \to h_{p,\mathbf{m},\mathbf{r}}(\mathbf{0})$ as $\max(n_1, n_2, n_3) \to \infty$. Hence the above sum of integrals with $\mathbf{m} = \mathbf{0}$ converges to $(1/V)h_{p,\mathbf{0},\mathbf{r}}(\mathbf{0})$.

Thus from the above arguments we have

$$\sum_{\mathbf{n}} \frac{1}{|\mathbf{r}+\mathbf{n}|^p} = \sum_{\mathbf{n}} \frac{f_p(\alpha^{1/2}|\mathbf{r}+\mathbf{n}|)}{|\mathbf{r}+\mathbf{n}|^p} + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)} \frac{1}{V} \sum_{\mathbf{m}} g_p(\pi|\mathbf{m}|/\alpha^{1/2}) \times \exp(-2\pi i \mathbf{m}\cdot\mathbf{r}). \quad (3.5.2.24)$$

Using the limiting behaviour given in (3.5.2.22) we can extend this result to the case $\mathbf{r} = \mathbf{0}$. By removing the singularity when $\mathbf{n} = \mathbf{0}$ we get

$$\begin{aligned}\sum_{\mathbf{n}\neq\mathbf{0}} \frac{1}{|\mathbf{n}|^p} &= \lim_{\mathbf{r}\to\mathbf{0}} \sum_{\mathbf{n}\neq\mathbf{0}} \frac{1}{|\mathbf{r}+\mathbf{n}|^p} \\ &= \lim_{\mathbf{r}\to\mathbf{0}} \left(\sum_{\mathbf{n}} \frac{1}{|\mathbf{r}+\mathbf{n}|^p} - \frac{1}{|\mathbf{r}|^p} \right) \\ &= \sum_{\mathbf{n}\neq\mathbf{0}} \frac{f_p(\alpha^{1/2}|\mathbf{n}|)}{|\mathbf{n}|^p} - \frac{2\alpha^{p/2}}{p\Gamma(p/2)} + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)} \\ &\quad \times \frac{1}{V} \sum_{\mathbf{m}} g_p(\pi|\mathbf{m}|/\alpha^{1/2}). \end{aligned} \quad (3.5.2.25)$$

Now assume particles i and j in the unit cell U interact by the potential $\phi_{ij} = C(i,j)/|\mathbf{r}_j - \mathbf{r}_i|^p$. Using equations (3.5.2.24) and (3.5.2.25) (the latter for particles interacting with their own images) the total energy for the unit cell U consisting of N particles interacting *via* the potential φ with each other and all of the image cells is given by

$$\begin{aligned} E(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= \tfrac{1}{2}{\sum_{\mathbf{n}}}' \sum_{i=1}^{N}\sum_{j=1}^{N} \frac{C(i,j)}{|\mathbf{r}_i - \mathbf{r}_j - \mathbf{n}|^p} \\ &= \tfrac{1}{2}{\sum_{\mathbf{n}}}' \sum_{i=1}^{N}\sum_{j=1}^{N} \frac{C(i,j) f_p(\alpha^{1/2}|\mathbf{r}_j - \mathbf{r}_i + \mathbf{n}|)}{|\mathbf{r}_j - \mathbf{r}_i + \mathbf{n}|^p} \\ &\quad + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)} \frac{1}{2V} \sum_{\mathbf{m}} g_p(\pi|\mathbf{m}|/\alpha^{1/2}) \\ &\quad \times \sum_{i=1}^{N}\sum_{j=1}^{N} C(i,j) \exp[-2\pi i \mathbf{m}\cdot(\mathbf{r}_j - \mathbf{r}_i)] \\ &\quad - \frac{\alpha^{p/2}}{p\Gamma(p/2)} \sum_{i=1}^{N} C(i,i), \end{aligned}$$

where as before the prime on the first summation means that terms where $i = j$ and $\mathbf{n} = \mathbf{0}$ are omitted.

In the case when $C(i,j)$ factorizes, *i.e.* $C(i,j) = C(i)C(j)$, the above lattice sum can be further simplified and accelerated using the structure factor $S(\mathbf{m})$ given by

$$S(\mathbf{m}) = \sum_{j=1}^{N} C(j) \exp(2\pi i \mathbf{m}\cdot\mathbf{r}_i). \quad (3.5.2.26)$$

In this case,

$$\begin{aligned} E(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= \tfrac{1}{2}{\sum_{\mathbf{n}}}' \sum_{i=1}^{N}\sum_{j=1}^{N} \frac{C(i)C(j) f_p(\alpha^{1/2}|\mathbf{r}_j - \mathbf{r}_i + \mathbf{n}|)}{|\mathbf{r}_j - \mathbf{r}_i + \mathbf{n}|^p} \\ &\quad + \frac{\pi^{3/2}\alpha^{(p-3)/2}}{\Gamma(p/2)} \frac{1}{2V} \sum_{\mathbf{m}} g_p(\pi|\mathbf{m}|/\alpha^{1/2}) S(\mathbf{m}) S(-\mathbf{m}) \\ &\quad - \frac{\alpha^{p/2}}{p\Gamma(p/2)} \sum_{i=1}^{N} C(i)^2. \end{aligned}$$

Note that as expected, due to the absolute convergence of the lattice sums, there is no shape-dependent correction term to the Ewald sum. This is connected with the fact that $g_p(x)$ is bounded and continuous as $x \to 0$. Next we see what additional assumptions are necessary when this is no longer true, and what form the correction term takes. We cover the most interesting case, namely the Coulombic case $p = 1$.

3.5.2.3.2. The case p = 1

In the case $1 \le p \le 3$, the lattice sum does not converge absolutely, since the integral in equation (3.5.2.23) diverges. Thus extra conditions are needed and the order of summation must be specified. We restrict discussion to the case $p = 1$, that is to a crystal of point charges interacting *via* Coulomb's law. We consider a large but finite crystal, taking the limit as it grows larger while maintaining a specific shape. To that end, let P be a closed, bounded region in $\Re^3$ centred on the origin, such as a cube, sphere or ellipsoid. For a positive integer K, let $\Omega(P,K)$ denote the set of lattice vectors such that $|\mathbf{n}|/K$ is in P, that is $\Omega(P,K) = \{\mathbf{n} : |\mathbf{n}|/K \in P\}$. Charges in the central unit cell $\mathbf{U}_0$ interact with each other and with image charges in $\mathbf{U}_\mathbf{n}$ for $\mathbf{n} \in \Omega(P,K)$. The electrostatic energy of the central cell in this finite crystal is given by

$$E_{P,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) = \tfrac{1}{2} {\sum_{\mathbf{n}\in\Omega(P,K)}}' \sum_{i=1}^{N}\sum_{j=1}^{N} \frac{q_i q_j}{|\mathbf{r}_i - \mathbf{r}_j - \mathbf{n}|} \quad (3.5.2.27)$$

and we want the limit of $E_{P,K}$ as $K \to \infty$.

Recalling that $g_p(x) = \exp(-x^2)/x^2$ for $p = 1$, if we define $h_{\mathbf{m},\mathbf{r}}(\mathbf{v})$ by

$$h_{\mathbf{m},\mathbf{r}}(\mathbf{v}) = \frac{\exp[-\pi^2(\mathbf{m}+\mathbf{v})^2/\alpha]}{|\mathbf{m}+\mathbf{v}|^2} \exp[-2\pi i(\mathbf{v}+\mathbf{m})\cdot\mathbf{r})],$$

then for $\mathbf{m} \neq \mathbf{0}$, $h_{\mathbf{m},\mathbf{r}}(\mathbf{v})$ is bounded and smooth with uniformly (in $\mathbf{m} \neq \mathbf{0}$) bounded derivatives. For $\mathbf{m} = \mathbf{0}$ we have $h_{\mathbf{m},\mathbf{r}}(\mathbf{v}) = [1 - 2\pi i(\mathbf{v}\cdot\mathbf{r}) - 2\pi^2(\mathbf{v}\cdot\mathbf{r})^2]/\mathbf{v}^2 - \pi^2/\alpha + \theta(\mathbf{v})$, where $\theta(\mathbf{v})$ is smooth with bounded derivatives, and with $\theta(\mathbf{0}) = 0$. Then, using the same arguments that lead to equation (3.5.2.24), we can write for $\mathbf{r} \neq \mathbf{0}$

$$\begin{aligned} \sum_{\mathbf{n}\in\Omega(P,K)} \frac{1}{|\mathbf{r}+\mathbf{n}|} &= \sum_{\mathbf{n}} \frac{\operatorname{erfc}(\alpha^{1/2}|\mathbf{r}+\mathbf{n}|)}{|\mathbf{r}+\mathbf{n}|} \\ &\quad + \frac{1}{\pi V} \sum_{\mathbf{m}\neq\mathbf{0}} \frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2} \exp(-2\pi i \mathbf{m}\cdot\mathbf{r}) \\ &\quad - \frac{\pi}{\alpha V} + \frac{1}{\pi} H_{P,K}(\mathbf{r}) + \varepsilon(K) \\ &= \varphi_{\text{Ewald}}(\mathbf{r}) + \frac{1}{\pi} H_{P,K}(\mathbf{r}) + \varepsilon(K) \end{aligned} \quad (3.5.2.28)$$

where here and below $\varepsilon(K)$ denotes a quantity (the remainder in the equation) that converges to zero as $K \to \infty$ and

$$H_{P,K}(\mathbf{r}) = \sum_{\mathbf{n}\in\Omega(P,K)} \int_{U^*} \frac{1 - 2\pi i(\mathbf{v}\cdot\mathbf{r}) - 2\pi^2(\mathbf{v}\cdot\mathbf{r})^2}{\mathbf{v}^2} \times \exp(-2\pi i\mathbf{v}\cdot\mathbf{n})\,\mathrm{d}^3\mathbf{v}.$$

The Ewald potential $\varphi_{\mathrm{Ewald}}(\mathbf{r})$, given for $\mathbf{r}\neq\mathbf{0}$ by

$$\varphi_{\mathrm{Ewald}}(\mathbf{r}) = \sum_{\mathbf{n}} \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}+\mathbf{n}|)}{|\mathbf{r}+\mathbf{n}|} - \frac{\pi}{\alpha V} + \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}} \frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}\exp(-2\pi i\mathbf{m}\cdot\mathbf{r}),$$

has a couple of noteworthy properties. First, note that since the left-hand side of equation (3.5.2.28) is independent of α, as is $H_{P,K}(\mathbf{r})$, $\varphi_{\mathrm{Ewald}}(\mathbf{r})$ is itself independent of α. Secondly, the average of $\varphi_{\mathrm{Ewald}}(\mathbf{r})$ over the unit cell U is zero. To establish this latter property, first note that for $\mathbf{m}\neq\mathbf{0}$, $\int_U \exp(2\pi\mathbf{m}\cdot\mathbf{r})\,\mathrm{d}^3\mathbf{r} = 0$. Thus the reciprocal sum in the above equation integrates to zero over U. Next, the integral of $-\pi/(\alpha V)$ over U is clearly $-\pi/\alpha$. Finally, note that

$$\begin{aligned}
&\sum_{\mathbf{n}}\int_U \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}+\mathbf{n}|)}{|\mathbf{r}+\mathbf{n}|}\,\mathrm{d}^3\mathbf{r}\\
&\quad= \int_{\Re^3} \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}|)}{|\mathbf{r}|}\,\mathrm{d}^3\mathbf{r}\\
&\quad= 8\pi^{1/2}\int_{r=0}^{\infty} r\,\mathrm{d}r \int_{\alpha^{1/2}r}^{\infty} \exp(-t^2)\,\mathrm{d}t\\
&\quad= 4\pi^{1/2}\int_0^{\infty} \exp(-t^2)\,\mathrm{d}t \int_0^{t/\alpha^{1/2}} 2r\,\mathrm{d}r\\
&\quad= \frac{4\pi^{1/2}}{\alpha}\int_0^{\infty} t^2\exp(-t^2)\,\mathrm{d}t\\
&\quad= \frac{\pi}{\alpha},
\end{aligned}$$

completing the proof. The self or Wigner potential $q\zeta$ with ζ given by

$$\begin{aligned}
\zeta &= \lim_{|\mathbf{r}|\to 0}\left[\varphi_{\mathrm{Ewald}}(\mathbf{r}) - \frac{1}{|\mathbf{r}|}\right]\\
&= -2\left(\frac{\alpha}{\pi}\right)^{1/2} + \sum_{\mathbf{n}\neq\mathbf{0}} \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{n}|)}{|\mathbf{n}|}\\
&\quad - \frac{\pi}{\alpha V} + \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}} \frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}
\end{aligned}$$

is the potential of a charge q in a periodic array of images of itself together with a uniform neutralizing plasma throughout the crystal. For cubic unit cells with side L, $\zeta \simeq -2.837297/L$ (Nijboer & Ruijgrok, 1988). Owing to the above properties, the Ewald potential provides a consistent approach to the treatment of non-neutral unit cells, such as when calculating ionic charging free energies (Hummer *et al.*, 1996; Darden *et al.*, 1999).

If we define the structure factor $S(\mathbf{m})$ by

$$S(\mathbf{m}) = \sum_{j=1}^{N} q_j \exp(2\pi i\mathbf{m}\cdot\mathbf{r}_j)$$

and the unit-cell dipole moment $\mathbf{D}$ by

$$\mathbf{D} = \sum_{j=1}^{N} q_j\mathbf{r}_j,$$

then assuming the unit cell is neutral we can write the energy $E_{P,K}$ as

$$\begin{aligned}
E_{P,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= \tfrac{1}{2}{\sum_{\mathbf{n}}}' \sum_{i=1}^{N}\sum_{j=1}^{N} q_iq_j \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}_j-\mathbf{r}_i+\mathbf{n}|)}{|\mathbf{r}_j-\mathbf{r}_i+\mathbf{n}|}\\
&\quad + \frac{1}{2\pi V}\sum_{\mathbf{m}\neq\mathbf{0}} \frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2} S(\mathbf{m})S(-\mathbf{m})\\
&\quad + 2\pi\sum_{\mathbf{n}\in\Omega(P,K)}\int_{U^*} \frac{(\mathbf{v}\cdot\mathbf{D})^2}{\mathbf{v}^2}\exp(-2\pi i\mathbf{v}\cdot\mathbf{n})\,\mathrm{d}^3\mathbf{v}\\
&\quad - \left(\frac{\alpha}{\pi}\right)^{1/2}\sum_{j=1}^{N} q_j^2 + \varepsilon(K). \qquad (3.5.2.29)
\end{aligned}$$

Thus, recalling equation (3.5.2.15), we can write

$$E_{P,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) = E_{\mathrm{Ewald}}(\underline{\mathbf{r}}^{\mathbf{N}}) + J(\mathbf{D},P,K) + \varepsilon(K), \qquad (3.5.2.30)$$

where

$$J(\mathbf{D},P,K) = 2\pi\sum_{\mathbf{n}\in\Omega(P,K)}\int_{U^*}\frac{(\mathbf{v}\cdot\mathbf{D})^2}{\mathbf{v}^2}\exp(-2\pi i\mathbf{v}\cdot\mathbf{n})\,\mathrm{d}^3\mathbf{v}.$$

Note that if $\mathbf{D}=\mathbf{0}$, $J(\mathbf{D},P,K)=0$ and the Coulomb lattice sum converges absolutely, *i.e.* the result is the same as the Ewald sum regardless of the shape P, *i.e.* order of convergence. Expressions for $J(\mathbf{D},P) = \lim_{K\to\infty} J(\mathbf{D},P,K)$ have been derived in some cases by Smith (1981). In particular, if P is the unit sphere $J(\mathbf{D},P) = 2\pi\mathbf{D}^2/(3V)$. Following Smith's approach we show this by first deriving an integral representation for $J(\mathbf{D},P)$ and then evaluating it for the case P is the unit sphere.

First note that for any continuous function f, $\sum_{\mathbf{n}\in\Omega(P,K)} f(\mathbf{n}/K)V/K^3$ converges to $\int_P f(\rho)\,\mathrm{d}^3\rho$ as $K\to\infty$. Then, in the above integral for $J(\mathbf{D},P,K)$ we can substitute $\mathbf{w} = K\mathbf{v}$ to get

$$\begin{aligned}
J(\mathbf{D},P,K) &= \frac{2\pi}{V}\int_{K\cdot U^*}\frac{(\mathbf{w}\cdot\mathbf{D})^2}{\mathbf{w}^2}\,\mathrm{d}^3\mathbf{w}\\
&\quad\times\sum_{\mathbf{n}\in\Omega(P,K)}\exp\left(-2\pi i\mathbf{w}\cdot\frac{\mathbf{n}}{K}\right)\frac{V}{K^3}\\
&= \frac{2\pi}{V}\int_{K\cdot U^*}\frac{(\mathbf{w}\cdot\mathbf{D})^2}{\mathbf{w}^2}\,\mathrm{d}^3\mathbf{w}\\
&\quad\times\int_P\exp(-2\pi i\mathbf{w}\cdot\rho)\,\mathrm{d}^3\rho + \varepsilon(K)
\end{aligned}$$

and thus

$$J(\mathbf{D}, P) = \frac{2\pi}{V} \int_{\Re^3} \frac{(\mathbf{w}\cdot\mathbf{D})^2}{\mathbf{w}^2}\, \mathrm{d}^3\mathbf{w} \int_P \exp(-2\pi i \mathbf{w}\cdot\rho)\, \mathrm{d}^3\rho.$$

Specializing to the case $P = S$, the unit sphere, we see by using spherical coordinates for ρ with the pole parallel to $\mathbf{w}$ that $\int_S \exp(-2\pi i\mathbf{w}\cdot\rho)\,\mathrm{d}^3\rho$ is a function only of the norm of $\mathbf{w}$, that is $\int_S \exp(-2\pi i\mathbf{w}\cdot\rho)\,\mathrm{d}^3\rho = g(|\mathbf{w}|)$. Then, again using spherical coordinates, this time for $\mathbf{w}$ with the pole parallel to $\mathbf{D}$, and noting that $\int_{\theta=0}^{\pi} \cos^2(\theta)\sin(\theta)\,\mathrm{d}\theta = \frac{1}{3}\int_{\theta=0}^{\pi}\sin(\theta)\,\mathrm{d}\theta$, we have

$$\begin{aligned}
J(\mathbf{D}, S) &= \frac{2\pi}{V} \int_{\Re^3} \frac{(\mathbf{w}\cdot\mathbf{D})^2}{\mathbf{w}^2} g(|\mathbf{w}|)\, \mathrm{d}^3\mathbf{w} \\
&= \frac{2\pi\mathbf{D}^2}{V} \int_{w=0}^{\infty} w^2 g(w)\, \mathrm{d}w \\
&\quad \times \int_{\theta=0}^{\pi} \cos^2(\theta)\sin(\theta)\,\mathrm{d}\theta \int_{\varphi=0}^{2\pi} \mathrm{d}\varphi \\
&= \frac{2\pi\mathbf{D}^2}{3V} \int_{\Re^3} g(|\mathbf{w}|)\, \mathrm{d}^3\mathbf{w} \\
&= \frac{2\pi\mathbf{D}^2}{3V} \int_S \mathrm{d}^3\rho \\
&\quad \times \int_{\Re^3} \exp(-2\pi i\mathbf{w}\cdot\rho)\, \mathrm{d}^3\mathbf{w}, \qquad (3.5.2.31)
\end{aligned}$$

where we have switched the order of integration in the last step. Finally, since $\int_{\Re^3} \exp(-2\pi i\mathbf{w}\cdot\rho)\,\mathrm{d}^3\mathbf{w} = \delta_3(\rho)$, the three-dimensional Dirac delta function, this last double integral equals one, completing the derivation of the Ewald correction term in the case of a large but finite crystal having a macroscopically spherical shape.

3.5.2.4. The surface term

Above we have derived the form of the electrostatic energy in the case of a macroscopically spherical crystal in terms of the Ewald sum plus a correction term. In this section, following the approach of van Eijck & Kroon (1997), we develop a surface-integral-based expression for the shape-dependent correction term for more general macroscopic shapes.

Given a closed bounded region P that contains the unit sphere S in its interior and a $K > 0$, and recalling equations (3.5.2.4) and (3.5.2.27), we can write the electrostatic energy of the central unit cell in the finite crystal as

$$\begin{aligned}
E_{P,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= E(U,U) + \tfrac{1}{2} \sum_{\mathbf{n}\in\Omega(P,K),\mathbf{n}\neq\mathbf{0}} E(U, U_{\mathbf{n}}) \\
&= E(U,U) + \tfrac{1}{2} \sum_{\mathbf{n}\in\Omega(S,K),\mathbf{n}\neq\mathbf{0}} E(U, U_{\mathbf{n}}) \\
&\quad + \tfrac{1}{2} \sum_{\mathbf{n}\in\Omega(P,K)\setminus\Omega(S,K)} E(U, U_{\mathbf{n}}) \\
&= E_{S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) + [E_{P,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) - E_{S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}})].
\end{aligned}$$

The asymptotic form of $E_{S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}})$ has been developed above. Recalling equation (3.5.2.5), for large K and neutral unit cells, we can approximate $\delta E_{P\setminus S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) = [E_{P,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) - E_{S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}})]$ by

$$\begin{aligned}
\delta E_{P\setminus S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= \tfrac{1}{2} \sum_{(\mathbf{n}/K)\in P\setminus S} E(U, U_{\mathbf{n}}) \\
&\simeq \tfrac{1}{2} \sum_{(\mathbf{n}/K)\in P\setminus S} \frac{\mathbf{D}^2}{|\mathbf{n}|^3} - 3\frac{(\mathbf{D}\cdot\mathbf{n})^2}{|\mathbf{n}|^5} \\
&\simeq \frac{1}{2V} \int_{\mathbf{r}\in P\setminus S} \frac{\mathbf{D}^2}{|\mathbf{r}|^3} - 3\frac{(\mathbf{D}\cdot\mathbf{r})^2}{|\mathbf{r}|^5}\, \mathrm{d}^3\mathbf{r} \\
&\simeq \frac{1}{2V} \oint_{\mathbf{r}\in\partial P\setminus\partial S} \frac{\mathbf{D}\cdot\mathbf{r}}{|\mathbf{r}|^3}\mathbf{D}\cdot\,\mathrm{d}\sigma,
\end{aligned}$$

where we have used Gauss' divergence theorem (Arfken & Weber, 2000) together with

$$\nabla\cdot\left(\frac{\mathbf{D}\cdot\mathbf{r}}{|\mathbf{r}|^3}\mathbf{D}\right) = \frac{\mathbf{D}\cdot\mathbf{D}}{|\mathbf{r}|^3} - 3\frac{(\mathbf{D}\cdot\mathbf{r})^2}{|\mathbf{r}|^5}.$$

Since, considering the outward unit normal on S,

$$\begin{aligned}
\frac{1}{2V} \oint_{\mathbf{r}\in\partial S} \frac{\mathbf{D}\cdot\mathbf{r}}{|\mathbf{r}|^3}\mathbf{D}\cdot\,\mathrm{d}\sigma &= \frac{\mathbf{D}^2}{2V} \int\int \cos^2(\theta)\sin(\theta)\,\mathrm{d}\theta\,\mathrm{d}\varphi \\
&= \frac{2\pi\mathbf{D}^2}{3V}
\end{aligned}$$

and since from the previous results

$$\lim_{K\to\infty} E_{S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) = E_{\mathrm{Ewald}}(\underline{\mathbf{r}}^{\mathbf{N}}) + \frac{2\pi\mathbf{D}^2}{3V},$$

we can now generalize the lattice summation to asymptotic shapes P:

$$\lim_{K\to\infty} E_{S,K}(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) = E_{\mathrm{Ewald}}(\underline{\mathbf{r}}^{\mathbf{N}}) + \frac{1}{2V} \oint_{\mathbf{r}\in\partial P} \frac{\mathbf{D}\cdot\mathbf{r}}{|\mathbf{r}|^3}\mathbf{D}\cdot\mathrm{d}\sigma.$$

The latter surface integral is referred to as the 'surface term' and clearly must equal the quantity $J(\mathbf{D}, P)$ discussed above. It was derived previously by Deem *et al.* (1990) by different arguments. Van Eijck and Kroon calculate it explicitly for some specific crystal shapes. They consider, however, that in actual crystal growth, surface charge distributions should develop to cancel the surface-integral contribution (see also Smith, 1981). In contrast, Scheraga and co-workers argue for the importance of considering this term, which they refer to as the 'Lorentz–Ewald correction', in crystal-structure prediction (Pillardy *et al.*, 2000), although in this they are disputed by van Eijck & Kroon (2000) (see also the response by Wedemeyer *et al.*, 2000).

The results in this section are all derived assuming the crystal is surrounded by vacuum, or at least by a medium with no dielectric screening capability. In the following section we study the effect of a surrounding continuum dielectric medium, assuming a spherical crystal (to make the calculations tractable).

3.5.2.5. The polarization response

In this section, following the approach in Smith (1981, 1994), we derive the polarization correction to the electrostatic energy of U due to immersing the large but finite crystal in a uniform dielectric with dielectric constant $\epsilon > 1$, assuming the macroscopic shape of the crystal is spherical. We first derive the dielectric reaction potential at a point $\mathbf{r} \in U$ due to the charges

$q_1, \ldots, q_N \in U$ and their periodic images in $U_{\mathbf{n}}$, $\mathbf{n} \in \Omega(P, K)$, assuming the unit cell is neutral, *i.e.* $q_1 + \ldots + q_N = 0$, that $P = S$, the unit sphere, and that the sphere KS is immersed in the dielectric.

To begin with, given a point $\mathbf{r} \in \Re^3$ and a point $\mathbf{r}_0 \in KS$, with spherical polar coordinates (r, θ, φ) and $(r_0, \theta_0, \varphi_0)$, respectively, the electrostatic potential at $\mathbf{r}$ due to a unit charge at $\mathbf{r}_0$ is given by the solution to Laplace's equation. Let β be the angle between $\mathbf{r}$ and $\mathbf{r}_0$, that is $\beta = \cos^{-1}(\mathbf{r} \cdot \mathbf{r}_0/|\mathbf{r}||\mathbf{r}_0|)$. Owing to the axial symmetry, the general solution $\psi(\mathbf{r}; \mathbf{r}_0)$ to Laplace's equation in this case can be written

$$\psi(\mathbf{r}; \mathbf{r}_0) = \sum_{l=0}^{\infty} [a_l r^l + b_l r^{-(l+1)}] P_l[\cos(\beta)],$$

where $P_l[\cos(\beta)]$ are the Legendre polynomials (Böttcher, 1973). The contributions a_l can be thought of as due to charges further from the origin than $\mathbf{r}$, while b_l are due to charges closer to the origin. A particular solution to Laplace's equation is given by $1/|\mathbf{r} - \mathbf{r}_0|$. Thus, we can write the potential due to the unit charge at $\mathbf{r}_0$ in the presence of the dielectric continuum surrounding KS as

$$V_1(\mathbf{r}) = \frac{1}{|\mathbf{r} - \mathbf{r}_0|} + \sum_{l=0}^{\infty} \left[A_l r^l + \frac{B_l}{r^{(l+1)}} \right] P_l[\cos(\beta)] \quad \text{for } r \le K,$$

$$V_2(\mathbf{r}) = \sum_{l=0}^{\infty} \left[C_l r^l + \frac{D_l}{r^{(l+1)}} \right] P_l[\cos(\beta)] \quad \text{for } r \ge K.$$

We now apply boundary conditions, noting that P_l are an orthogonal basis of functions, so that boundary conditions can be applied term by term. Then we have

(1) V_1 must be finite as $r \to 0$, implying $B_l = 0$ for all l;

(2) V_2 must go to zero as $r \to \infty$, implying $C_l = 0$ for all $l > 0$.

We expand $1/|\mathbf{r} - \mathbf{r}_0|$ (for $r > r_0$) in Legendre polynomials to allow comparison of V_1 with V_2 as $r \to K$ from below:

$$\frac{1}{|\mathbf{r} - \mathbf{r}_0|} = \sum_{l=0}^{\infty} \frac{r_0^l}{r^{(l+1)}} P_l[\cos(\beta)].$$

Using this we get:

(1) $V_2 = V_1$ for $r = K$, implying $D_l = r_0^l + A_l K^{(2l+1)}$;

(2) $\epsilon(\partial V_2/\partial r) = (\partial V_1/\partial r)$ for $r = K$, implying $A_l = -\{(\epsilon - 1)(l + 1)/[l + \epsilon(l + 1)]\}[r_0^l/K^{(2l+1)}]$.

Finally, since we need the solution for the potential due to each of the charges in $U_{\mathbf{n}}$, we invoke the spherical harmonic addition theorem (Arfken & Weber, 2000) applying it to the points $\mathbf{r}$, $\mathbf{r}_0$:

$$\frac{2l+1}{4\pi} P_l[\cos(\beta)] = \sum_{m=-l}^{+l} (-1)^m Y_l^m(\theta, \varphi) Y_l^{-m}(\theta_0, \varphi_0),$$

where (Arfken & Weber, 2000)

$$Y_l^m(\theta, \varphi) = (-1)^m \left[\frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!} \right]^{1/2} P_l^m[\cos(\theta)] \exp(im\varphi)$$

and the associated Legendre polynomials $P_l^m(x)$, $-l \le m \le l$ are defined by Rodrigues' formula,

$$P_l^m[\cos(\theta)] = (-1)^l \frac{1}{2^l l!} \sin(\theta)^m \frac{d^{l+m}}{d[\cos(\theta)]^{l+m}} [1 - \cos^2(\theta)]^l, \tag{3.5.2.32}$$

and

$$P_l^m[\cos(\theta)] = (-1)^m \frac{(l+m)!}{(l-m)!} P_l^{-m}[\cos(\theta)]. \tag{3.5.2.33}$$

In particular, the first-order spherical harmonics are given by

$$Y_1^1(\theta, \varphi) = -\left(\frac{3}{8\pi} \right)^{1/2} \sin(\theta) \exp(i\varphi),$$

$$Y_1^0(\theta, \varphi) = \left(\frac{3}{4\pi} \right)^{1/2} \cos(\theta),$$

$$Y_1^{-1}(\theta, \varphi) = \left(\frac{3}{8\pi} \right)^{1/2} \sin(\theta) \exp(-i\varphi). \tag{3.5.2.34}$$

The spherical harmonics satisfy an orthogonality relation:

$$\int_{\theta=0}^{\pi} \int_{\varphi=0}^{2\pi} [Y_l^m(\theta, \varphi)]^* Y_{l'}^{m'} \sin(\theta) \, \mathrm{d}\theta \, \mathrm{d}\varphi = \delta_{l,l'} \delta_{m,m'}.$$

Then, for $\mathbf{r} \in U$ we express the polarization potential due to the dielectric response to a unit charge at $\mathbf{r}_0 \in KS$ as

$$\psi_{\mathrm{Pol}}(\mathbf{r}; \mathbf{r}_0) = -\sum_{l=0}^{\infty} \sum_{m=-l}^{+l} C(l, m, \epsilon) \frac{1}{K^{2l+1}} g_{l,m}(\mathbf{r}) g_{l,-m}(\mathbf{r}_0),$$

where

$$C(l, m, \epsilon) = (-1)^m \frac{4\pi}{2l+1} \frac{(\epsilon - 1)(l+1)}{l + \epsilon(l+1)}$$

and

$$g_{l,m}(\mathbf{r}) = r^l Y_l^m(\theta, \varphi).$$

We now examine the total polarization potential

$$\begin{aligned}
\psi_{\mathrm{Pol},K,S}(\mathbf{r}) &= \sum_{\mathbf{n} \in \Omega(S,K)} \sum_{j=1}^{N} q_j \psi_{\mathrm{Pol}}(\mathbf{r}; \mathbf{r}_j + \mathbf{n}) \\
&= -\frac{1}{V} \sum_{l=0}^{\infty} \sum_{m=-l}^{+l} C(l, m, \epsilon) \frac{1}{K^{l-1}} g_{l,m}(\mathbf{r}) \cdot K \frac{V}{K^3} \\
&\quad \times \sum_{\mathbf{n} \in \Omega(S,K)} \sum_{j=1}^{N} q_j \left[g_{l,-m}\left(\frac{\mathbf{r}_j + \mathbf{n}}{K} \right) - g_{l,-m}\left(\frac{\mathbf{n}}{K} \right) \right] \\
&= -\frac{1}{V} \sum_{l=0}^{\infty} \sum_{m=-l}^{+l} C(l, m, \epsilon) \frac{1}{K^{l-1}} g_{l,m}(\mathbf{r}) \\
&\quad \times \left[\mathbf{D} \cdot \int_S \nabla g_{l,-m}(\rho) \, \mathrm{d}^3\rho \right] + \varepsilon(K),
\end{aligned} \tag{3.5.2.35}$$

where $\mathbf{D}$ is the unit-cell dipole and we have used unit-cell neutrality in the next to last equation.

The gradient ∇ with respect to the usual Cartesian directions, expressed in spherical polar coordinates (Arfken & Weber, 2000) can be re-expressed as

$$\frac{\partial}{\partial x}+i\frac{\partial}{\partial y}=\sin(\theta)\exp(i\varphi)\frac{\partial}{\partial r}+\frac{1}{r}\cos(\theta)\exp(i\varphi)\frac{\partial}{\partial\theta}+\frac{i\exp(i\varphi)}{r\sin(\theta)}\frac{\partial}{\partial\varphi}$$
$$\frac{\partial}{\partial x}-i\frac{\partial}{\partial y}=\sin(\theta)\exp(-i\varphi)\frac{\partial}{\partial r}+\frac{1}{r}\cos(\theta)\exp(-i\varphi)\frac{\partial}{\partial\theta}-\frac{i\exp(-i\varphi)}{r\sin(\theta)}\frac{\partial}{\partial\varphi}$$
$$\frac{\partial}{\partial z}=\cos(\theta)\frac{\partial}{\partial r}-\frac{1}{r}\sin(\theta)\frac{\partial}{\partial\theta}.$$

Using spherical polar coordinates to carry out the integrations over the unit sphere in equation (3.5.2.35), we see after the first partial integration over φ that

$$\int_S\left(\frac{\partial}{\partial x}+i\frac{\partial}{\partial y}\right)g_{l,-m}(\rho)\,\mathrm{d}^3\rho=0\quad\text{if } m\neq 1,$$
$$\int_S\left(\frac{\partial}{\partial x}-i\frac{\partial}{\partial y}\right)g_{l,-m}(\rho)\,\mathrm{d}^3\rho=0\quad\text{if } m\neq -1\ \text{ and}$$
$$\int_S\frac{\partial}{\partial z}g_{l,-m}(\rho)\,\mathrm{d}^3\rho=0\quad\text{if } m\neq 0.$$

We recognize the factors multiplying $(\partial/\partial r)$ above as being proportional to Y_1^1, Y_1^0 and Y_1^{-1}, respectively, so that, using the above orthogonality of spherical harmonics, these contribute nothing to the integrals unless $l=1$.

Next, examining I given by

$$I=\int_{\theta=0}^{\pi}\int_{\varphi=0}^{2\pi}\left[\cos(\theta)\exp(i\varphi)\frac{\partial}{\partial\theta}+\frac{i\exp(i\varphi)}{\sin(\theta)}\frac{\partial}{\partial\varphi}\right]\times g_{l,-1}(r,\theta,\varphi)\sin(\theta)\,\mathrm{d}\theta\,\mathrm{d}\varphi,$$

integrating over φ and then applying integration by parts over θ to the first term, expressing $g_{l,-1}(r,\theta,\varphi)$ using the Rodrigues' formulas (3.5.2.32) and (3.5.2.33), and finally substituting $w=\cos(\theta)$ we see that I is proportional to the integral J given by

$$J=\int_{w=-1}^{1}(1-w^2)\frac{d^{l+1}}{dw^{l+1}}(1-w^2)^l\,\mathrm{d}w,$$

which in turn is zero unless $l=1$. Putting the above results together we see that

$$\int_S\left(\frac{\partial}{\partial x}+i\frac{\partial}{\partial y}\right)g_{l,-m}(\rho)\,\mathrm{d}^3\rho=0\quad\text{unless}\quad l=1,\quad m=1.$$

Similarly

$$\int_S\left(\frac{\partial}{\partial x}-i\frac{\partial}{\partial y}\right)g_{l,-m}(\rho)\,\mathrm{d}^3\rho=0\quad\text{unless}\quad l=1,\quad m=-1.$$

Finally,

$$I=\int_{\theta=0}^{\pi}\int_{\varphi=0}^{2\pi}\sin(\theta)\frac{\partial}{\partial\theta}g_{l,0}(r,\theta,\varphi)\sin(\theta)\,\mathrm{d}\theta\,\mathrm{d}\varphi$$

is proportional to

$$J=\int_{w=-1}^{1}w\frac{\mathrm{d}^l}{\mathrm{d}w^l}(1-w^2)^l\,\mathrm{d}w$$

and J is zero unless $l=1$. Thus

$$\int_S\frac{\partial}{\partial z}g_{l,-m}(\rho)\,\mathrm{d}^3\rho=0\quad\text{unless}\quad l=1,\quad m=0.$$

Expressing $g_{1,m}$ in terms of the explicit forms for Y_1^m given in equations (3.5.2.34), we get

$$\int_S\left(\frac{\partial}{\partial x}-i\frac{\partial}{\partial y}\right)g_{1,1}(\rho)\,\mathrm{d}^3\rho=-(8\pi/3)^{1/2}$$

and thus

$$\int_S\nabla g_{1,1}(\rho)\,\mathrm{d}^3\rho=-(8\pi/3)^{1/2}(1/2,i/2,0).$$

Similarly

$$\int_S\nabla g_{1,0}(\rho)\,\mathrm{d}^3\rho=(4\pi/3)^{1/2}(0,0,1)$$

and finally

$$\int_S\nabla g_{1,-1}(\rho)\,\mathrm{d}^3\rho=(8\pi/3)^{1/2}(1/2,-i/2,0).$$

Substituting these into equation (3.5.2.35) we get

$$\lim_{K\to\infty}\psi_{\mathrm{Pol},K,S}(\mathbf{r})=\frac{-4\pi}{3V}\frac{2\epsilon-2}{2\epsilon+1}(\mathbf{r}\cdot\mathbf{D}).$$

Recalling the shape-dependent term $J(\mathbf{D},S)=2\pi\mathbf{D}^2/3V$ from equation (3.5.2.31) and adding the reaction energy $\sum_{j=1}^{N}q_j\psi_{\mathrm{Pol},K,S}(\mathbf{r}_j)$, we see that the electrostatic energy of the unit cell U inside a large spherical crystal which in turn is immersed in a dielectric continuum with dielectric constant ϵ is given by

$$E_{S,K,\epsilon}(\underline{\mathbf{r}}^{\{\mathbf{N}\}})=E_{\mathrm{Ewald}}(\underline{\mathbf{r}}^{\{\mathbf{N}\}})+\frac{2\pi\mathbf{D}^2}{3V}-\frac{2\pi}{3V}\frac{2\epsilon-2}{2\epsilon+1}\mathbf{D}^2+\varepsilon(K)$$
$$=E_{\mathrm{Ewald}}(\underline{\mathbf{r}}^{\{\mathbf{N}\}})+\frac{1}{2\epsilon+1}\cdot\frac{2\pi}{V}\mathbf{D}^2+\varepsilon(K),$$

where E_{Ewald} is given in equation (3.5.2.15). Note that we recover the usual Ewald sum in the limit as $\epsilon\to\infty$ ('tin-foil' boundary conditions).

The force on a charge q_j in the central cell is obtained by taking the gradient of the energy with respect to $\mathbf{r}_j$ for the finite spherical crystal, and then taking the limit as $K\to\infty$, or by taking the

gradient of the limiting energy above (*i.e.* the limit of the gradient is the gradient of the limit):

$$\mathbf{F}_j = -\nabla_j E_{\rm Ewald}(\underline{\mathbf{r}}^{\mathbf{N}}) - \frac{1}{2\epsilon+1}\cdot\frac{4\pi}{V}q_j\mathbf{D}. \qquad (3.5.2.36)$$

Thus we can find tractable analytic expressions for the energy and force on particles within the central unit cell as long as the asymptotic shape of the crystal immersed in the dielectric medium is spherical. In Section 3.5.2.6 below we show that we can also arrive at a tractable result for the thermodynamic pressure under these circumstances, although surprisingly it does not seem to agree with the mechanical pressure as given by Smith (1994), which may reflect some not yet fully understood subtleties in the implementation of periodic boundary conditions.

3.5.2.6. Calculating the pressure

We first discuss the scalar pressure, following the developments in Smith (1987, 1993). According to the thermodynamic definition, the scalar pressure P is defined by

$$P = -\left(\frac{\partial A}{\partial V}\right)_T,$$

where A is the Helmholtz free energy, V is the volume and T is the temperature. In turn, A is given by $A = -(1/\beta)\ln Z_N(V,T)$ where $\beta = 1/kT$ (k is Boltzmann's constant) and Z_N is the canonical ensemble partition function,

$$Z_N(V,T) = \frac{1}{N!h^{3N}}\int\int \exp[-\beta H_N(\underline{\mathbf{r}}^{\{\mathbf{N}\}},\underline{\mathbf{p}}^{\{\mathbf{N}\}})]\,{\rm d}\underline{\mathbf{r}}^{\{\mathbf{N}\}}\,{\rm d}\underline{\mathbf{p}}^{\{\mathbf{N}\}},$$

where H_N is the system Hamiltonian, h is Planck's constant and $\underline{\mathbf{p}}^{\{\mathbf{N}\}}$ denotes the set of momenta $\{\mathbf{p}_1,\ldots,\mathbf{p}_N\}$ with $\mathbf{p}_i$ conjugate to $\mathbf{r}_i$. Introducing the scaling relations $\mathbf{r}_i = V^{1/3}\mathbf{s}_i$, $\boldsymbol{\pi}_i = V^{2/3}m_i\dot{\mathbf{s}}_i$ and $\mathbf{p}_i = V^{-1/3}\boldsymbol{\pi}_i$, we get

$$\begin{aligned}P &= -\frac{1}{[N!h^{3N}Z_N(V,T)]}\\ &\quad\times\int\int\left[\frac{\partial}{\partial V}H_N(V^{1/3}\underline{\mathbf{s}}^{\{\mathbf{N}\}},V^{-1/3}\underline{\boldsymbol{\pi}}^{\{\mathbf{N}\}})\right]_T\\ &\quad\times\exp[-\beta H_N(V^{1/3}\underline{\mathbf{s}}^{\{\mathbf{N}\}},V^{-1/3}\underline{\boldsymbol{\pi}}^{\{\mathbf{N}\}})]\,{\rm d}\underline{\mathbf{s}}^{\{\mathbf{N}\}}\,{\rm d}\underline{\boldsymbol{\pi}}^{\{\mathbf{N}\}}\\ &= -\left\langle\left[\frac{\partial}{\partial V}H_N(V^{1/3}\underline{\mathbf{s}}^{\{\mathbf{N}\}},V^{-1/3}\underline{\boldsymbol{\pi}}^{\{\mathbf{N}\}})\right]\right\rangle,\end{aligned}$$

where $\langle\ \rangle$ denotes the expectation or ensemble average. For the above system of N point charges $q_1,\ldots,q_N$ having mass $m_1,\ldots,m_N$ at positions $\mathbf{r}_1,\ldots,\mathbf{r}_N$ in the central unit cell U_0 of a large spherical crystal (of radius K) immersed in a dielectric continuum, the Hamiltonian can be written

$$\begin{aligned}H_N(\underline{\mathbf{r}}^{\{\mathbf{N}\}},\underline{\mathbf{p}}^{\{\mathbf{N}\}}) &= \tfrac{1}{2}\sum_{j=1}^{N}\frac{\mathbf{p}_j^2}{m_j} + E_{\rm Ewald}(\underline{\mathbf{r}}^{\{\mathbf{N}\}})\\ &\quad+\frac{1}{2\epsilon+1}\cdot\frac{2\pi}{V}\mathbf{D}^2+\varepsilon(K)\end{aligned}$$

and so

$$\begin{aligned}&H_N(V^{1/3}\underline{\mathbf{s}}^{\{\mathbf{N}\}},V^{-1/3}\underline{\boldsymbol{\pi}}^{\{\mathbf{N}\}})\\ &\quad=\tfrac{1}{2}V^{-2/3}\sum_{j=1}^{N}\frac{\boldsymbol{\pi}_j^2}{m_j}+E_{\rm Ewald}(V^{1/3}\underline{\mathbf{r}}^{\{\mathbf{N}\}})\\ &\qquad+V^{-1/3}\frac{2\pi}{2\epsilon+1}\left(\sum_{j=1}^{N}q_j\mathbf{s}_j\right)^2+\varepsilon(K).\end{aligned}$$

The direct- and reciprocal-lattice vectors are scaled as $\mathbf{n} = V^{1/3}\boldsymbol{\eta}$ and $\mathbf{m} = V^{-1/3}\boldsymbol{\mu}$. The derivative with respect to volume of the Ewald direct sum is straightforward using the chain rule, since if $x = |\mathbf{r}_j+\mathbf{n}| = V^{1/3}|\mathbf{s}_j+\boldsymbol{\eta}|$ then $\partial x/\partial V = x/3V$ and $({\rm d}/{\rm d}x)[{\rm erfc}(\alpha^{1/2}x)/x] = -[(2/\pi^{1/2})\exp(-\alpha x^2)/x + {\rm erfc}(\alpha^{1/2}x)/x^2]$. Since $\mathbf{m}$ and $\mathbf{r}_j$ scale oppositely with V, $\partial S(\mathbf{m})/\partial V = 0$. Continuing with the other terms in the Ewald reciprocal sum, and taking the limit as $K\to\infty$, we get

$$\begin{aligned}P &= \frac{1}{3V}\left\langle\sum_{j=1}^{N}\frac{\mathbf{p}_j^2}{m_j}+\tfrac{1}{2}{\sum_{\mathbf{n}}}'\sum_{i=1}^{N}\sum_{j=1}^{N}q_iq_j\right.\\ &\quad\times\left\{\frac{2}{\pi^{1/2}}\exp\left[-\alpha(\mathbf{r}_j-\mathbf{r}_i+\mathbf{n})^2\right]+\frac{{\rm erfc}(\alpha^{1/2}|\mathbf{r}_j-\mathbf{r}_i+\mathbf{n}|)}{|\mathbf{r}_j-\mathbf{r}_i+\mathbf{n}|}\right\}\\ &\quad+\frac{1}{2\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}\left(1-\frac{2\pi\mathbf{m}^2}{\alpha}\right)S(\mathbf{m})S(-\mathbf{m})\\ &\quad\left.+\frac{1}{2\epsilon+1}\cdot\frac{2\pi}{V}\mathbf{D}^2\right\rangle.\end{aligned}$$

The scalar pressure has been generalized to the pressure tensor (Brown & Neyertz, 1995) using a more general scaling technique based on the expression for $\mathbf{r}$ in terms of unit-cell basis vectors and fractional coordinates, treating the standard Ewald sum without the surface correction or dielectric response term. To accommodate the latter, the energy of the central unit cell within a large ellipsoidal crystal immersed in a dielectric continuum must be studied. In Redlack & Grindley (1972, 1975) expressions are provided for the surface correction in ellipsoidal crystals in a vacuum. If this result were combined with the polarization response term (we are not aware of any papers giving this term for an ellipsoidal crystal immersed in a dielectric continuum) it is reasonable to assume that the standard Ewald sum would apply in this case as well, in the limits $K\to\infty$ and $\epsilon\to\infty$. The trace of the pressure tensor defined by Nosé & Klein (1983) agrees with the above scalar pressure in the limit $\epsilon\to\infty$.

Interestingly, Smith (1994) derives a scalar pressure that differs from the above. In particular he finds a surface term that remains even in the limit of 'tin-foil' boundary conditions, *i.e.* when $\epsilon\to\infty$. He gives a mechanical definition of the pressure tensor in terms of momentum flux across surfaces within and surrounding the crystal. Periodic boundary conditions are enforced using velocity constraints *via* the techniques of DeLeeuw *et al.* (1990). He derives forces on particles within the central unit cell (and on their images in other cells interior to the crystal) that agree in the large K limit with our result above in equation (3.5.2.36). However, combining the forces with particle positions in the scalar virial expression, after summing over particles and their images, and proceeding to the limit as $K\to\infty$ leads to a vacuum surface correction involving the reciprocal sum term at $\mathbf{m} = \mathbf{0}$ that, unlike our thermodynamic pressure expression above, is not cancelled by the dielectric response potential in the limit $\epsilon\to\infty$. To reiterate, his mechanical virial tensor, restricted to the standard Ewald sum part of the final expression, agrees completely with the results of Nosé & Klein (1983). Furthermore, his scalar virial, given by the trace of his virial tensor, has an ϵ-dependent part due to the dielectric response

that agrees completely with our results above. However, the trace of the vacuum surface correction tensor within his mechanical pressure tensor does not agree with the equivalent term in our thermodynamic pressure derived above, and thus is not cancelled in the infinite dielectric limit.

3.5.3. Generalization to Gaussian- and Hermite-based continuous charge distributions

In this section we develop the generalization of Ewald sums to interacting molecular densities modelled by linear combinations of spherical or Hermite Gaussians. In Coppens (1997) the electrostatic potential and energy for crystal densities modelled by linear combinations of Slater-like density elements is discussed. As with quantum-chemical programs, there are trade-offs in the choice of density elements. The use of Slater-like densities provides accuracy with the use of fewer elements, but the Gaussian and Hermite Gaussian elements are far more convenient analytically. In particular the Ewald summation, as well as the fast-Fourier-transform-based methods discussed in Section 3.5.4, generalize straightforwardly to these elements. We note ahead of time that the case of lattice sums of point multipoles are obtained by specializing the results for Hermite Gaussians, just as the results for spherical Gaussians specialize to the above lattice summation results for point charges.

A somewhat different approach to Ewald summation over Hermite Gaussian elements, focused on application to periodic density-functional calculations, is given in Trickey *et al.* (2004). The continuous fast multipole method (Challacombe *et al.*, 1997) provides yet a different but highly efficient approach to lattice summation of continuous charge densities.

3.5.3.1. Lattice sums of interacting spherical Gaussians

We begin by discussing the electrostatic interaction energy between a normalized spherical Gaussian charge distribution ρ_1, centred at a point $\mathbf{R}_1 \in U$ and having exponent θ_1, and a second normalized spherical Gaussian charge distribution ρ_2, centred at $\mathbf{R}_2 \in U$ and having exponent θ_2, together with the latter's periodic images, centred at $\mathbf{R}+\mathbf{n}$, $\mathbf{n} \in \Omega(S,K)$. Their interaction energy can be written

$$E_{12} = \sum_{\mathbf{n}\in\Omega(S,K)} \int_{\Re^3}\int_{\Re^3} \rho_1(\mathbf{r}_1-\mathbf{R}_1)\rho_2(\mathbf{r}_2-\mathbf{R}_2-\mathbf{n}) \times 1/|\mathbf{r}_2-\mathbf{r}_1|\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2, \tag{3.5.3.1}$$

where $\rho_j(\mathbf{r}) = (\theta_j/\pi)^{3/2}\exp(-\theta_j\mathbf{r}^2)$, $j = 1, 2$. We now recall equation (3.5.2.16), applying its two right-hand components separately, to get $E_{12} = E_{12}^{\mathrm{d}} + E_{12}^{\mathrm{r}}$, where

$$E_{12}^{\mathrm{d}} = \sum_{\mathbf{n}\in\Omega(S,K)} \int_{\Re^3}\int_{\Re^3} \rho_1(\mathbf{r}_1-\mathbf{R}_1)\rho_2(\mathbf{r}_2-\mathbf{R}_2-\mathbf{n}) \times \frac{\mathrm{erfc}(\alpha^{1/2}|\mathbf{r}_2-\mathbf{r}_1|)}{|\mathbf{r}_2-\mathbf{r}_1|}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2$$

and

$$E_{12}^{\mathrm{r}} = \frac{1}{\pi}\sum_{\mathbf{n}\in\Omega(S,K)} \int_{\Re^3}\int_{\Re^3} \rho_1(\mathbf{r}_1-\mathbf{R}_1)\rho_2(\mathbf{r}_2-\mathbf{R}_2-\mathbf{n}) \times \int_{\Re^3} \frac{\exp(-\pi^2\mathbf{u}^2/\alpha)}{\mathbf{u}^2}\exp[-2\pi i\mathbf{u}\cdot(\mathbf{r}_2-\mathbf{r}_1)]\,\mathrm{d}^3\mathbf{u}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2.$$

The direct pair energy E_{12}^{d} involves the damped Coulomb interaction, which has been discussed by Gill & Adamson (1996). We can calculate E_{12}^{d} using the following standard results from quantum chemistry, which are derived in Helgaker *et al.* (2000): Let $\rho_p(\mathbf{r})$, $\rho_q(\mathbf{r})$ be two normalized spherical Gaussian charge distributions having exponents p and q and centred at points $\mathbf{P}$ and $\mathbf{Q}$, *i.e.* $\rho_p(\mathbf{r}) = (p/\pi)^{3/2}\exp[-p(\mathbf{r}-\mathbf{P})^2]$ and $\rho_q(\mathbf{r}) = (q/\pi)^{3/2}\exp[-q(\mathbf{r}-\mathbf{Q})^2]$. Then the electrostatic potential $V_p(\mathbf{R})$ at a point $\mathbf{R}$ due to the charge distribution $\rho_p(\mathbf{r})$ is given by

$$V_p(\mathbf{R}) = \left(\frac{4p}{\pi}\right)^{1/2} F_0[p(\mathbf{P}-\mathbf{R})^2], \tag{3.5.3.2}$$

where F_0 is the zeroth-order Boy's function, with $F_0(x) = \int_0^1 \exp(-xt^2)\,\mathrm{d}t$ for $x > 0$. The Coulomb interaction energy E_{pq} between ρ_p and ρ_q is given by

$$\begin{aligned} E_{pq} &= \int_{\Re^3}\int_{\Re^3} \frac{\rho_p(\mathbf{r}_1-\mathbf{P})\rho_q(\mathbf{r}_2-\mathbf{Q})}{|\mathbf{r}_1-\mathbf{r}_2|}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2 \\ &= \int_{\Re^3} V_p(\mathbf{r}_2)\rho_q(\mathbf{r}_2-\mathbf{Q})\,\mathrm{d}^3\mathbf{r}_2 \\ &= \left(\frac{4\mu_{pq}}{\pi}\right)^{1/2} F_0[\mu_{pq}(\mathbf{P}-\mathbf{Q})^2], \end{aligned} \tag{3.5.3.3}$$

where $1/\mu_{pq} = 1/p + 1/q$. The Boy's function can be related to the error function:

$$\frac{2}{\pi^{1/2}}F_0(x^2) = \frac{\mathrm{erf}(|x|)}{|x|}. \tag{3.5.3.4}$$

Substituting equation (3.5.3.4) into (3.5.3.2), we see that

$$V_p(\mathbf{R}) = \frac{\mathrm{erf}(p^{1/2}|\mathbf{R}-\mathbf{P}|)}{|\mathbf{R}-\mathbf{P}|}, \tag{3.5.3.5}$$

a result which we had derived above by another method [see equation (3.5.2.7)]. From equations (3.5.3.3) and (3.5.3.5), substituting α for p and ρ_p for ρ_q, we have for any point $\mathbf{r} \in \Re^3$

$$\int_{\Re^3} \frac{\mathrm{erf}(\alpha^{1/2}|\mathbf{r}-\mathbf{r}_1|)}{|\mathbf{r}-\mathbf{r}_1|}\rho_p(\mathbf{r}_1-\mathbf{P})\,\mathrm{d}^3\mathbf{r}_1 = \frac{\mathrm{erf}(\mu_{p\alpha}^{1/2}\,|\mathbf{r}-\mathbf{P}|)}{|\mathbf{r}-\mathbf{P}|},$$

where $1/\mu_{p\alpha} = 1/p + 1/\alpha$. Iterating this result with $\mu_{p\alpha}$ replacing α and ρ_q replacing ρ_p we get the damped interaction energy between ρ_p and ρ_q,

$$
\begin{aligned}
E_{pq}^{\mathrm{d}} &= \int_{\Re^3}\int_{\Re^3} \rho_p(\mathbf{r}_1-\mathbf{P})\rho_q(\mathbf{r}_2-\mathbf{Q}) \\
&\quad\times \frac{\operatorname{erfc}(\alpha^{1/2}|\mathbf{r}_2-\mathbf{r}_1|)}{|\mathbf{r}_2-\mathbf{r}_1|}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2 \\
&= \int_{\Re^3}\int_{\Re^3} \frac{\rho_p(\mathbf{r}_1-\mathbf{P})\rho_q(\mathbf{r}_2-\mathbf{Q})}{|\mathbf{r}_1-\mathbf{r}_2|}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2 \\
&\quad - \int_{\Re^3}\int_{\Re^3} \rho_p(\mathbf{r}_1-\mathbf{P})\rho_q(\mathbf{r}_2-\mathbf{Q}) \\
&\quad\times \frac{\operatorname{erf}(\alpha^{1/2}|\mathbf{r}_2-\mathbf{r}_1|)}{|\mathbf{r}_2-\mathbf{r}_1|}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2 \\
&= \frac{\operatorname{erf}(\mu_{pq}^{1/2}|\mathbf{P}-\mathbf{Q}|)}{|\mathbf{P}-\mathbf{Q}|} - \frac{\operatorname{erf}(\mu_{pq\alpha}^{1/2}|\mathbf{P}-\mathbf{Q}|)}{|\mathbf{P}-\mathbf{Q}|} \\
&= \frac{\operatorname{erfc}(\mu_{pq\alpha}^{1/2}|\mathbf{P}-\mathbf{Q}|)}{|\mathbf{P}-\mathbf{Q}|} - \frac{\operatorname{erfc}(\mu_{pq}^{1/2}|\mathbf{P}-\mathbf{Q}|)}{|\mathbf{P}-\mathbf{Q}|},
\end{aligned}
\tag{3.5.3.6}
$$

where $1/\mu_{pq} = 1/p + 1/q$ and $1/\mu_{pq\alpha} = 1/p + 1/q + 1/\alpha$. Notice that in the limit $\alpha \to \infty$, $E_{pq,\alpha} \to 0$ as expected, since $\operatorname{erfc}(x) \to 0$ as $x \to \infty$, and that in the limit $p \to \infty$, $q \to \infty$, $E_{pq,\alpha} \to \operatorname{erfc}(\alpha^{1/2}|\mathbf{P}-\mathbf{Q}|)/|\mathbf{P}-\mathbf{Q}|$, the damped interaction between two unit point charges at $\mathbf{P}$ and $\mathbf{Q}$, as in the standard Ewald direct sum.

To calculate the reciprocal pair energy E_{12}^{r} we first apply the first right-hand component of equation (3.5.2.16) together with the Fourier transforms of the normalized Gaussians ρ_p and ρ_q from equation (3.5.2.18) to obtain

$$
\begin{aligned}
E_{pq}^{\mathrm{r}} &= \frac{1}{\pi}\int_{\Re^3}\int_{\Re^3}\int_{\Re^3} \rho_p(\mathbf{r}_1-\mathbf{P})\rho_q(\mathbf{r}_2-\mathbf{Q})\frac{\exp(-\pi^2\mathbf{u}^2/\alpha)}{\mathbf{u}^2} \\
&\quad\times \exp[-2\pi i\mathbf{u}\cdot(\mathbf{r}_1-\mathbf{r}_2)]\,\mathrm{d}^3\mathbf{u}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2 \\
&= \frac{1}{\pi}\int_{\Re^3}\int_{\Re^3}\int_{\Re^3} \frac{1}{\mathbf{u}^2}\exp[-\pi^2(\mathbf{u}^2/\alpha + \mathbf{v}^2/p + \mathbf{w}^2/q)] \\
&\quad\times \exp(2\pi i\mathbf{v}\cdot\mathbf{P})\exp(2\pi i\mathbf{w}\cdot\mathbf{Q})\,\mathrm{d}^3\mathbf{u}\,\mathrm{d}^3\mathbf{v}\,\mathrm{d}^3\mathbf{w} \\
&\quad\times \int_{\Re^3}\exp[-2\pi i(\mathbf{u}+\mathbf{v})\cdot\mathbf{r}_1]\,\mathrm{d}^3\mathbf{r}_1 \\
&\quad\times \int_{\Re^3}\exp[2\pi i(\mathbf{u}-\mathbf{w})\cdot\mathbf{r}_2]\,\mathrm{d}^3\mathbf{r}_2 \\
&= \frac{1}{\pi}\int_{\Re^3}\frac{\exp(-\pi^2\mathbf{u}^2/\mu_{pq\alpha})}{\mathbf{u}^2}\exp[-2\pi i\mathbf{u}\cdot(\mathbf{P}-\mathbf{Q})]\,\mathrm{d}^3\mathbf{u},
\end{aligned}
\tag{3.5.3.7}
$$

where we have used the fact that $\int \exp[-2\pi i(\mathbf{u}+\mathbf{v})\cdot\mathbf{r}_1]\,\mathrm{d}^3\mathbf{r}_1 = \delta^3(\mathbf{u}+\mathbf{v})$, with δ^3 the three-dimensional delta function, and similarly for the integral over $\mathbf{r}_2$. Note that in the limit $p \to \infty$, $q \to \infty$, E_{pq}^{r} reduces to the equivalent expression for unit point charges at $\mathbf{P}$ and $\mathbf{Q}$, and in the limit $\alpha \to \infty$, E_{pq}^{r} reduces to the Fourier-space expression for the direct Coulomb interaction between the Gaussians ρ_p and ρ_q.

Recalling the developments leading to equation (3.5.2.28), and using equations (3.5.3.6) and (3.5.3.7), we can write the interaction energy E_{12} from equation (3.5.3.1) as

$$
\begin{aligned}
E_{12} &= \sum_{\mathbf{n}} \frac{\operatorname{erfc}(\mu_{12\alpha}^{1/2}|\mathbf{R}_{12}-\mathbf{n}|) - \operatorname{erfc}(\mu_{12}^{1/2}|\mathbf{R}_{12}-\mathbf{n}|)}{|\mathbf{R}_{12}-\mathbf{n}|} \\
&\quad + \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}} \frac{\exp(-\pi^2\mathbf{m}^2/\mu_{12\alpha})}{\mathbf{m}^2}\exp[-2\pi i\mathbf{m}\cdot(\mathbf{R}_{12})] \\
&\quad - \frac{\pi}{\mu_{12\alpha}V} + \frac{1}{\pi}H_{S,K}(\mathbf{R}_{12}) + \varepsilon(K),
\end{aligned}
\tag{3.5.3.8}
$$

where $\mathbf{R}_{12} = \mathbf{R}_1 - \mathbf{R}_2$, $1/\mu_{12} = 1/\theta_1 + 1/\theta_2$ and $1/\mu_{12\alpha} = 1/\theta_1 + 1/\theta_2 + 1/\alpha$.

Note that although the energy of a finite-exponent Gaussian charge distribution interacting with itself is finite, when considering a generalization of lattice sums involving point charges it is necessary to remove the direct Coulomb interaction of the Gaussian with itself. From equations (3.5.3.3) and (3.5.3.6), if $p = q$, then as $\mathbf{Q} \to \mathbf{P}$, $E_{pq}^{\mathrm{d}} - E_{pq} \to -2(\mu_{pq\alpha}/\pi)^{1/2}$. We can now generalize equation (3.5.2.29). Let $\rho_1, \ldots, \rho_N$ be normalized spherical Gaussian charge distributions with Gaussian exponents $\theta_1, \ldots, \theta_N$, centred at $\{\mathbf{R}_1, \ldots, \mathbf{R}_N\} = \underline{\mathbf{R}}^{\{\mathbf{N}\}} \in U$ (point charges are included by taking $\theta \to \infty$), and let $q_1, \ldots, q_N$ satisfy $q_1 + \ldots + q_N = 0$ (neutral unit cell). Then the energy of the central unit cell U within a large spherical crystal, due to interactions of the Gaussian charge distributions $q_i\rho_i$ with each other and with their periodic images within the crystal, is given by

$$
\begin{aligned}
E_{S,K}(\underline{\mathbf{R}}^{\{\mathbf{N}\}}) &= \tfrac{1}{2}{\sum_{\mathbf{n}}}' \sum_{i,j=1}^{N} q_iq_j\left\{\frac{\operatorname{erfc}(\mu_{ij\alpha}^{1/2}|\mathbf{R}_{ij}-\mathbf{n}|)}{|\mathbf{R}_{ij}-\mathbf{n}|} - \frac{\operatorname{erfc}(\mu_{ij}^{1/2}|\mathbf{R}_{ij}-\mathbf{n}|)}{|\mathbf{R}_{ij}-\mathbf{n}|}\right\} \\
&\quad + \frac{1}{2\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\sum_{i,j=1}^{N} q_iq_j\frac{\exp(-\pi^2\mathbf{m}^2/\mu_{ij\alpha})}{\mathbf{m}^2} \\
&\quad\times \exp(-2\pi i\mathbf{m}\cdot\mathbf{R}_{ij}) \\
&\quad - \frac{\pi}{2V}\sum_{i,j=1}^{N}\frac{q_iq_j}{\mu_{ij\alpha}} - \sum_{i=1}^{N} q_i^2\left(\frac{\mu_{ii\alpha}}{\pi}\right)^{1/2} \\
&\quad + \frac{2\pi\mathbf{D}^2}{3V} + \varepsilon(K),
\end{aligned}
$$

where $\mathbf{R}_{ij} = \mathbf{R}_i - \mathbf{R}_j$, $1/\mu_{ij} = 1/\theta_i + 1/\theta_j$, $1/\mu_{ij\alpha} = 1/\theta_i + 1/\theta_j + 1/\alpha$ and as before $\mathbf{D} = q_1\mathbf{R}_1 + \ldots + q_N\mathbf{R}_N$ is the unit-cell dipole.

Note that from the above derivation, the α in $\mu_{ij\alpha}$ is allowed to be different for each pair ij. One choice that leads to an efficient algorithm (particularly when combined with the fast-Fourier-transform-based methods discussed below) is to separate the Gaussian charge distributions $q_j\rho_j$ into compact and diffuse sets, based on their exponents θ_j, and choose α to be infinite for ij pairs where at least one of the two Gaussians is diffuse. These pair interactions are then evaluated entirely in reciprocal space. Next choose α so that $\mu_{ij\alpha}$ is constant for all compact pairs ij. More specifically, given $\beta > 0$, a Gaussian $q_j\rho_j$ is classified as compact if $\theta_j \geq 2\beta$ and diffuse otherwise. We denote these cases as $j \in C$ and $j \in D$, respectively. Then for $i, j \in C$, choose α so that $1/\mu_{ij\alpha} = 1/\theta_i + 1/\theta_j + 1/\alpha = 1/\beta$. Otherwise, choose α to be infinite. Then the Coulomb energy of the central unit cell $E_{S,K}(\underline{\mathbf{R}}^{\{\mathbf{N}\}})$ can be re-expressed as

$$E_{S,K}(\underline{\mathbf{R}}^{\{\mathbf{N}\}}) = \tfrac{1}{2}{\sum_{\mathbf{n}}}' \sum_{(i,j)\in C\times C} q_i q_j \left\{ \frac{\operatorname{erfc}(\beta^{1/2}|\mathbf{R}_{ij}-\mathbf{n}|)}{|\mathbf{R}_{ij}-\mathbf{n}|} - \frac{\operatorname{erfc}(\mu_{ij}^{1/2}|\mathbf{R}_{ij}-\mathbf{n}|)}{|\mathbf{R}_{ij}-\mathbf{n}|} \right\}$$
$$+ \frac{1}{2\pi V} \sum_{\mathbf{m}\neq\mathbf{0}} \sum_{(i,j)\in C\times C} q_i q_j \, \frac{\exp(-\pi^2\mathbf{m}^2/\beta)}{\mathbf{m}^2} \times \exp(-2\pi i \mathbf{m}\cdot\mathbf{R}_{ij})$$
$$+ \frac{1}{2\pi V} \sum_{\mathbf{m}\neq\mathbf{0}} \sum_{(i,j)\notin C\times C} q_i q_j \, \frac{\exp(-\pi^2\mathbf{m}^2/\mu_{ij})}{\mathbf{m}^2} \times \exp(-2\pi i \mathbf{m}\cdot\mathbf{R}_{ij})$$
$$- \frac{\pi}{2V} \sum_{(i,j)\in C\times C} q_i q_j \left(\frac{1}{\beta} - \frac{1}{\theta_i} - \frac{1}{\theta_j}\right) - \sum_{i\in C} q_i^2 \left(\frac{\beta}{\pi}\right)^{1/2} - \sum_{i\notin C} q_i^2 \left(\frac{\theta_i}{2\pi}\right)^{1/2} + \frac{2\pi\mathbf{D}^2}{3V} + \varepsilon(K). \tag{3.5.3.9}$$

Note that in the limit that $\theta_i \to \infty$ for all i, all of the Gaussians become compact and this formula reduces to equation (3.5.2.30) for a large spherical crystal of point charges. The volume-dependent term $(\pi/2V)\sum_{(i,j)\in C\times C} q_i q_j (1/\beta - 1/\theta_i - 1/\theta_j)$ is somewhat surprising, and would not appear in a more straightforward Ewald derivation such as our first Ewald derivation. It vanishes by unit-cell neutrality for the case of point charges or multipoles, and would also vanish if we chose a single α for all Gaussian pairs.

3.5.3.2. Higher angular momentum: Hermite Gaussians

More complex crystal charge distributions can be realized by considering normalized Hermite Gaussian distributions in place of the normalized spherical Gaussian distributions discussed above. Let ρ be a normalized spherical Gaussian charge distribution with exponent θ, centred at $\mathbf{R} = (\mathbf{R}_x, \mathbf{R}_y, \mathbf{R}_z)$, *i.e.* $\rho(\mathbf{r}) = (\theta/\pi)^{3/2}\exp[-\theta(\mathbf{r}-\mathbf{R})^2]$. The associated normalized Hermite Gaussians Λ_{tuv}, where t, u, v are non-negative integers, are defined by

$$\Lambda_{tuv}(\mathbf{r},\theta,\mathbf{R}) = \left(\frac{\theta}{\pi}\right)^{3/2} (\partial/\partial\mathbf{R}_x)^t \left(\partial/\partial\mathbf{R}_y\right)^u \left(\partial/\partial\mathbf{R}_z\right)^v \times \exp[-\theta(\mathbf{r}-\mathbf{R})^2].$$

Note that this definition of Hermite Gaussians differs from that found in some textbooks, *e.g.* Helgaker *et al.* (2000), in that we have normalized the Gaussian ρ it is derived from in order to allow exponents to tend to infinity to arrive at ideal point charges or point multipoles. We will refer to these Hermite Gaussians as normalized Hermite Gaussians to emphasize this distinction. The Hermite definition reduces to the spherical Gaussian when t, u and v are all zero, *i.e.* $\Lambda_{000}(\mathbf{r},\theta,\mathbf{R}) = \rho(\mathbf{r})$.

Above we discussed the interaction between spherical Gaussian charge distributions ρ. Here we generalize these to higher angular momentum charge distributions ϱ given by

$$\varrho(\mathbf{r},\theta,\mathbf{R},\mathbf{c}) = \sum_{tuv} \mathbf{c}_{tuv}\Lambda_{tuv}(\mathbf{r},\theta,\mathbf{R}),$$

where $\mathbf{c}$ is a vector of coefficients, a finite number of which are nonzero. For example, if $\mathbf{c}_{000}$ is the only nonzero coefficient, we are reduced to the spherical charge distributions discussed above.

The fact that the partial derivatives within Λ_{tuv} are with respect to the position of the centre of the distribution allows us to easily calculate the Coulomb interaction energy between two normalized Hermite Gaussian distributions. The partial derivatives can be pulled out of the double integral, so that the interaction energy is given by the corresponding partial derivatives of the interaction energy of the two spherical Gaussian charge distributions:

$$E_{12} = \int_{\Re^3}\int_{\Re^3} \frac{\Lambda_{t_1u_1v_1}(\mathbf{r}_1,\theta_1,\mathbf{R}_1)\Lambda_{t_2u_2v_2}(\mathbf{r}_2,\theta_2,\mathbf{R}_2)}{|\mathbf{r}_1-\mathbf{r}_2|}\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2$$
$$= \left(\frac{\partial}{\partial\mathbf{R}_{1x}}\right)^{t_1}\left(\frac{\partial}{\partial\mathbf{R}_{1y}}\right)^{u_1}\left(\frac{\partial}{\partial\mathbf{R}_{1z}}\right)^{v_1}\left(\frac{\partial}{\partial\mathbf{R}_{2x}}\right)^{t_2} \times \left(\frac{\partial}{\partial\mathbf{R}_{2y}}\right)^{u_2}\left(\frac{\partial}{\partial\mathbf{R}_{2z}}\right)^{v_2}\left(\frac{\theta_1\theta_2}{\pi^2}\right)^{3/2}\int_{\Re^3}\int_{\Re^3}\frac{1}{|\mathbf{r}_1-\mathbf{r}_2|} \times \exp[-\theta_1(\mathbf{r}_1-\mathbf{R}_1)^2]\exp[-\theta_2(\mathbf{r}_2-\mathbf{R}_2)^2]\,\mathrm{d}^3\mathbf{r}_1\,\mathrm{d}^3\mathbf{r}_2.$$

Next we consider the interaction energy between a generalized charge distribution ϱ_1 centred at $\mathbf{R}_1 \in U$ and another generalized charge distribution ϱ_2 centred at $\mathbf{R}_2 \in U$, together with all the latter's periodic images, centred at $\mathbf{R}_2 + \mathbf{n}$, $\mathbf{n} \in \Omega(S,K)$. Examining equation (3.5.3.8), we note that the terms to be differentiated all depend on $\mathbf{R}_{12} = \mathbf{R}_1 - \mathbf{R}_2$. Thus

$$E_{12} = \sum_{\mathbf{n}}\sum_{t_1u_1v_1}\sum_{t_2u_2v_2}(-1)^{(t_2+u_2+v_2)}\mathbf{c}_{1,t_1u_1v_1}\mathbf{c}_{2,t_2u_2v_2} \times \left(\frac{\partial}{\partial\mathbf{R}_{12x}}\right)^{t_1+t_2}\left(\frac{\partial}{\partial\mathbf{R}_{12y}}\right)^{u_1+u_2}\left(\frac{\partial}{\partial\mathbf{R}_{12z}}\right)^{v_1+v_2} \times \left\{\frac{\operatorname{erfc}(\mu_{12\alpha}^{1/2}|\mathbf{R}_{12}-\mathbf{n}|)}{|\mathbf{R}_{12}-\mathbf{n}|} - \frac{\operatorname{erfc}(\mu_{12}^{1/2}|\mathbf{R}_{12}-\mathbf{n}|)}{|\mathbf{R}_{12}-\mathbf{n}|}\right\}$$
$$+ \frac{1}{\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\mu_{12\alpha})}{\mathbf{m}^2}C_1(\mathbf{m})C_2(-\mathbf{m}) - \mathbf{c}_{1,000}\mathbf{c}_{2,000}\frac{\pi}{\mu_{p12\alpha}V} + \frac{1}{\pi}H_{S,K}^{12}(\mathbf{R}_{12}) + \varepsilon(K), \tag{3.5.3.10}$$

where $C_i(\mathbf{m})$, i =1, 2 are given by

$$C_i(\mathbf{m}) = \sum_{t_iu_iv_i}\mathbf{c}_{i,t_iu_iv_i} \times \left(\frac{\partial}{\partial\mathbf{R}_{ix}}\right)^{t_i}\left(\frac{\partial}{\partial\mathbf{R}_{iy}}\right)^{u_i}\left(\frac{\partial}{\partial\mathbf{R}_{iz}}\right)^{v_i}\exp(-2\pi i\mathbf{m}\cdot\mathbf{R}_i)$$

and

$$H_{S,K}^{12}(\mathbf{R}_{12}) = \sum_{t_1u_1v_1}\sum_{t_2u_2v_2}(-1)^{(t_2+u_2+v_2)}\mathbf{c}_{1,t_1u_1v_1}\mathbf{c}_{2,t_2u_2v_2} \times \left(\frac{\partial}{\partial\mathbf{R}_{12x}}\right)^{t_1+t_2}\left(\frac{\partial}{\partial\mathbf{R}_{12y}}\right)^{u_1+u_2}\left(\frac{\partial}{\partial\mathbf{R}_{12z}}\right)^{v_1+v_2} \times H_{S,K}(\mathbf{R}_{12}).$$

Note that by the arguments leading to equation (3.5.2.28), $H_{S,K}(\mathbf{r})$ is quadratic in $\mathbf{r}$, *i.e.* derivatives of higher than second order vanish.

We now can discuss the Coulomb energy of the central unit cell U within a large spherical crystal when the charge density in the

unit cell is described by a basis Θ of normalized Hermite Gaussians and a set of expansion points $\mathbf{R}_1, \ldots, \mathbf{R}_N$ within U that are repeated periodically in the crystal (for example, some of the expansion points could be atomic nuclei). Let $\theta_1, \ldots, \theta_L$ be positive Gaussian exponents (or infinite, in the case of nuclear charge or point charges or ideal multipoles) and let the charge density about the expansion point $\mathbf{R}_i$ be given by

$$\varrho_i(\mathbf{r}, \mathbf{R}_i, \Theta) = \sum_{l=1}^{L} \sum_{tuv} \mathbf{c}_{i,l,tuv} \Lambda_{tuv}(\mathbf{r}, \theta_l, \mathbf{R}_i),$$

where, as above, for each i, l the coefficients $\mathbf{c}_{i,l,tuv}$ are nonzero for a finite number of tuv. As above we can separate the exponents θ_l into compact and diffuse, *i.e.* $l \in C$ or $l \in D$, according to whether $\theta_l \geq 2\beta$ or $\theta < 2\beta$, respectively. Let $q_i = \sum_{l=1}^{L} \mathbf{c}_{i,l,000}$ denote the net charge at the expansion point $\mathbf{R}_i$.

We are interested in the Coulomb energy of charge densities $\varrho_i(\mathbf{r}, \mathbf{R}_i, \Theta)$, $i = 1, \ldots, N$, interacting with each other and their periodic images at expansion points $\mathbf{R}_i + \mathbf{n}, \mathbf{n} \in \Omega(S, K)$ for large K. As above, the direct Coulomb interaction of $\varrho_i(\mathbf{r}, \mathbf{R}_i, \Theta)$ with itself is not permitted. This can be modified for more sophisticated treatments *e.g.* in the context of the Coulomb integrals in a periodic density-functional-theory approach, but clearly a nuclear charge cannot interact with itself. The unit cell is assumed to be neutral, *i.e.* $\sum_{i=1}^{N} q_i = 0$. Then, using equations (3.5.3.9) and (3.5.3.10) we can write the Coulomb energy of $\underline{\varrho}^{\{\mathbf{N}\}} = \{\varrho_1, \ldots, \varrho_N\}$ within the spherical crystal as

$$\begin{aligned}
E_{S,K}(\underline{\varrho}^{\{\mathbf{N}\}}) = {} & \tfrac{1}{2}{\sum_{\mathbf{n}}}' \sum_{i=1}^{N} \sum_{l_i \in C} \sum_{t_i u_i v_i} \mathbf{c}_{i,l_i,t_i u_i v_i} \\
& \times \sum_{j=1}^{N} \sum_{l_j \in C} \sum_{t_j u_j v_j} (-1)^{(t_j+u_j+v_j)} \mathbf{c}_{j,l_j,t_j u_j v_j} \\
& \times \left(\frac{\partial}{\partial \mathbf{R}_{ijx}}\right)^{t_i+t_j} \left(\frac{\partial}{\partial \mathbf{R}_{ijy}}\right)^{u_i+u_j} \left(\frac{\partial}{\partial \mathbf{R}_{ijz}}\right)^{v_i+v_j} \\
& \times \left\{ \frac{\operatorname{erfc}(\beta^{1/2}|\mathbf{R}_{ij} - \mathbf{n}|)}{|\mathbf{R}_{ij} - \mathbf{n}|} - \frac{\operatorname{erfc}(\mu_{l_i l_j}^{1/2}|\mathbf{R}_{ij} - \mathbf{n}|)}{|\mathbf{R}_{ij} - \mathbf{n}|} \right\} \\
& + \frac{1}{2\pi V} \sum_{\mathbf{m} \neq \mathbf{0}} \frac{1}{\mathbf{m}^2} \exp(-\pi^2 \mathbf{m}^2/2\beta) \sum_{l_1 \in C} S_{l_1}(\mathbf{m}) \\
& \times \exp(-\pi^2 \mathbf{m}^2/2\beta) \sum_{l_2 \in C} S_{l_2}(-\mathbf{m}) \\
& + \frac{1}{2\pi V} \sum_{\mathbf{m} \neq \mathbf{0}} \frac{1}{\mathbf{m}^2} \sum_{(l_1,l_2) \notin C \times C} \exp(-\pi^2 \mathbf{m}^2/\theta_{l_1}) \\
& \times \exp(-\pi^2 \mathbf{m}^2/\theta_{l_2}) S_{l_1}(\mathbf{m}) S_{l_2}(-\mathbf{m}) \\
& - \frac{\pi}{2V} \sum_{l_1 \in C} \sum_{l_2 \in C} \sum_{i=1}^{N} \sum_{j=1}^{N} \mathbf{c}_{i,l_1,000} \mathbf{c}_{j,l_2,000} \\
& \times \left(\frac{1}{\beta} - \frac{1}{\theta_{l_1}} - \frac{1}{\theta_{l_2}}\right) \\
& - \sum_{i=1}^{N} E_{\text{self}}(\varrho_i) + \frac{2\pi \mathbf{D}^2}{3V} + \varepsilon(K), \qquad (3.5.3.11)
\end{aligned}$$

where the structure factors $S_l(\mathbf{m})$ are given by

$$\begin{aligned}
S_l(\mathbf{m}) = {} & \sum_{i=1}^{N} \sum_{tuv} \mathbf{c}_{i,l,tuv} \left(\frac{\partial}{\partial \mathbf{R}_{ix}}\right)^{t} \left(\frac{\partial}{\partial \mathbf{R}_{iy}}\right)^{u} \left(\frac{\partial}{\partial \mathbf{R}_{iz}}\right)^{v} \\
& \times \exp(2\pi i \mathbf{m} \cdot \mathbf{R}_i). \qquad (3.5.3.12)
\end{aligned}$$

$E_{\text{self}}(\varrho_i)$ is given by

$$\begin{aligned}
E_{\text{self}}(\varrho_i) = {} & \lim_{\mathbf{R} \to \mathbf{0}} \sum_{t_1 u_1 v_1} \sum_{t_2 u_2 v_2} (-1)^{(t_2+u_2+v_2)} \\
& \times \left(\frac{\partial}{\partial \mathbf{R}_\mathbf{x}}\right)^{t_1+t_2} \left(\frac{\partial}{\partial \mathbf{R}_\mathbf{y}}\right)^{u_1+u_2} \left(\frac{\partial}{\partial \mathbf{R}_\mathbf{z}}\right)^{v_1+v_2} \\
& \times \left\{ \sum_{(l_1,l_2) \in C \times C} \mathbf{c}_{i,l_1,t_1 u_1 v_1} \mathbf{c}_{i,l_2,t_2 u_2 v_2} \frac{\operatorname{erf}(\beta^{1/2}|\mathbf{R}|)}{|\mathbf{R}|} \right. \\
& \left. + \sum_{(l_1,l_2) \notin C \times C} \mathbf{c}_{i,l_1,t_1 u_1 v_1} \mathbf{c}_{i,l_2,t_2 u_2 v_2} \frac{\operatorname{erf}(\mu_{12}^{1/2}|\mathbf{R}|)}{|\mathbf{R}|} \right\},
\end{aligned}$$

where $1/\mu_{12} = 1/\theta_{l_1} + 1/\theta_{l_2}$, and the unit-cell dipole components are given by

$$\begin{aligned}
\mathbf{D}_x &= \sum_{i=1}^{N} q_i \mathbf{R}_x + \sum_{i=1}^{N} \sum_{l=1}^{L} \mathbf{c}_{i,l,100}, \\
\mathbf{D}_y &= \sum_{i=1}^{N} q_i \mathbf{R}_y + \sum_{i=1}^{N} \sum_{l=1}^{L} \mathbf{c}_{i,l,010}, \\
\mathbf{D}_z &= \sum_{i=1}^{N} q_i \mathbf{R}_z + \sum_{i=1}^{N} \sum_{l=1}^{L} \mathbf{c}_{i,l,001}.
\end{aligned}$$

In the limit that all Gaussians are compact with $\theta_l \to \infty$, $E_{S,K}(\underline{\varrho}^{\{\mathbf{N}\}})$ reduces to the Coulomb energy of ideal multipoles positioned at the expansion points.

3.5.4. Computational efficiency

The Ewald-sum methods discussed above lead to calculations that are much faster than straightforward summation, as well as clarifying the nature of the conditional convergence. However, there are opportunities for further significant speed-ups, which we cover in this section. The computational cost of the Ewald sum is dominated by the direct and reciprocal sum. We cover these in turn.

3.5.4.1. The direct sum

For all the cases discussed above – point charge, normalized spherical Gaussians and the more complex densities made up of sums over a basis of normalized Hermite Gaussians – the Ewald direct sum involves terms like $|\mathbf{R}_{12} - \mathbf{n}|$ and in the Hermite case partial derivatives with respect to the x, y and z components of these terms. Given the efficiency opportunities in the reciprocal sum to be discussed below, it is advantageous to choose an Ewald parameter (referred to above as α in the point-charge case or β for the compact–compact Gaussian or Hermite Gaussian interactions) so that direct-sum terms can be neglected past a fixed cutoff, *i.e.* when $|\mathbf{R}_{12} - \mathbf{n}| > R_C$. Given a fixed Ewald parameter α, the cutoff may be fixed independently of the unit-cell size. At constant or near constant material density (number of atoms per cubic ångstrom) this leads to 'linear scaling', *i.e.* the computational cost of the Ewald direct sum grows linearly with the unit-cell volume or number of atoms in the unit cell U.

For the point-charge or normalized spherical Gaussian case, the remaining issue is efficient evaluation of the erfc function. Various table lookup schemes have been advanced, as well as a polynomial expression (Allen & Tildesley, 1987). Ewald summation for ideal multipoles up to quadrupole have been discussed by Smith (1982, 1998) and Aguado & Madden (2003), using optimized combinations of terms to minimize the cost of the direct sum. A more general scheme, covering higher-order multipoles, was proposed by Sagui *et al.* (2004). In the latter

scheme the McMurchie–Davidson recursion (McMurchie & Davidson, 1978; Helgaker *et al.*, 2000) was used to calculate the higher-order derivatives of $\mathrm{erfc}(\alpha^{1/2}r)/r$ for the multipole–multipole interaction tensor. This same approach was used by Cisneros *et al.* (2006) to calculate the interaction tensor for normalized Hermite Gaussian interactions. Although originally formulated for Hermite Gaussian interactions, it applies to more general partial derivative calculations. Let $\mathbf{r} = (x, y, z)$ be a point in $\Re^3$ with $|\mathbf{r}| = r$, and let $g(r)$ be a smooth function of r. For example, $g(r) = \mathrm{erf}(\alpha^{1/2}r)/r$. We are interested in the partial derivatives with respect to x, y and z of $g(r)$. Let $R(0, 0, 0, 0) = g(r)$, and for $n > 0$ let $R(0, 0, 0, n) = (1/r)(\mathrm{d}/\mathrm{d}r)R(0, 0, 0, n-1)$. For non-negative integers t, u, v, let $R(t, u, v, n) = (\partial/\partial x)^t(\partial/\partial y)^u(\partial/\partial z)^v R(0, 0, 0, n)$. Then we have the following recursion:

$$
\begin{aligned}
R(t+1, u, v, n) &= xR(t, u, v, n+1) + tR(t-1, u, v, n+1),\\
R(t, u+1, v, n) &= yR(t, u, v, n+1) + uR(t, u-1, v, n+1),\\
R(t, u, v+1, n) &= zR(t, u, v, n+1) + vR(t, u, v-1, n+1).
\end{aligned}
$$

The proof of the last recursion depends on the fact that $\partial/\partial z = (z/r)\partial/\partial r$ and on Leibniz' generalization of the product rule for differentiation, namely $(fg)^{(k)} = \sum_{j=0}^{k} \binom{k}{j} f^{(j)} g^{(k-j)}$, and is as follows:

$$
\begin{aligned}
R(t, u, v+1, n) &= (\partial/\partial x)^t(\partial/\partial y)^u(\partial/\partial z)^v(\partial/\partial z)R(0, 0, 0, n)\\
&= (\partial/\partial x)^t(\partial/\partial y)^u(\partial/\partial z)^v z(1/r)\\
&\quad \times (\mathrm{d}/\mathrm{d}r)R(0, 0, 0, n)\\
&= (\partial/\partial x)^t(\partial/\partial y)^u(\partial/\partial z)^v zR(0, 0, 0, n+1)\\
&= (\partial/\partial x)^t(\partial/\partial y)^u[z(\partial/\partial z)^v R(0, 0, 0, n+1)\\
&\quad + v(\partial/\partial z)^{v-1}R(0, 0, 0, n+1)]\\
&= zR(t, u, v, n+1) + vR(t, u, v-1, n+1).
\end{aligned}
$$

The other two recursions are proved similarly. To apply this to the case $g(r) = \mathrm{erf}(\alpha^{1/2}r)/r$ we recall from equation (3.5.3.4) that $(2/\pi^{1/2})F_0(x^2) = \mathrm{erf}(|x|)/|x|$ and that for the higher-order Boy's functions $F_n(x)$, $(\mathrm{d}/\mathrm{d}x)F_n(x) = -F_{n+1}(x)$. Efficient evaluation of the Boy's functions is discussed by Helgaker *et al.* (2000).

Further economies for point multipoles can be achieved by using symmetry. For example, it is only necessary to keep track of six quadrupolar terms, with a similar reduction for Hermite Gaussians. A general discussion, including rotation of multipoles or Hermite Gaussians from local molecule frame to laboratory frame, is provided in Sagui *et al.* (2004) as well as in Cisneros *et al.* (2006).

3.5.4.2. Reciprocal-sum speed-ups: the smooth particle mesh Ewald and fast Fourier Poisson methods

The smooth particle mesh Ewald (PME) (Essmann *et al.*, 1995) and fast Fourier Poisson (FFP) (York & Yang, 1994) methods both rely on the three-dimensional fast Fourier transform (3DFFT) for computational efficiency. In combination with the above use of cutoffs in the direct sum, they lower the computational cost of the Ewald sum from $O(N^{3/2})$ (Perram *et al.*, 1988) to $O[N\log(N)]$, where N is the number of particles and *e.g.* $O(N^{3/2})$ denotes a quantity such that $O(N^{3/2})/N^{3/2}$ remains bounded as $N \to \infty$. For the point-charge case, the key insight is that if the point charges happen to be located on a regular grid, the structure factors [equation (3.5.2.14)] become discrete Fourier transforms and can be rapidly calculated using FFTs.

Like other variants of the original particle–particle particle–mesh (P^3M) method (Hockney & Eastwood, 1981), the smooth PME method interpolates charge onto grid positions. The smooth PME, like the original PME algorithm (Darden *et al.*, 1993), formulates this problem as one of interpolation of the complex exponentials appearing in the structure factor. This interpolation process is very accurate at low frequency, *i.e.* for small $|\mathbf{m}|$, and becomes progressively less accurate as $|\mathbf{m}|$ grows. However, the weight function $\exp(-\pi^2\mathbf{m}^2/\alpha)/\mathbf{m}^2$ multiplying the structure factor in the reciprocal sum severely damps the high-frequency (large $|\mathbf{m}|$) terms, thus preserving overall accuracy. In contrast, the FFP method relies on the fact that $\exp(-\pi^2\mathbf{m}^2/\alpha)/\mathbf{m}^2 S(\mathbf{m})$ is the Fourier transform of a superposition of normalized spherical Gaussian charge distributions $q_j\rho_j$, centred at $\mathbf{r}_j$, as discussed above. This Fourier transform is approximated by the FFT of the gridded charge density obtained by direct sampling of the Gaussians onto the grid (similar to the use of the FFT in macromolecular X-ray crystallography). Note that the smooth PME method has been easily extended to the treatment of London dispersion interactions, since these involve similar structure factors with a different weight function g_p, $p = 6, 8, 10$. The extension is not so straightforward with the FFP approach. However, as discussed below, the FFP approach has advantages in the case of continuous charge density when more than one Gaussian exponent is involved.

For the case of point charges, P^3M methods based on least-squares approximation of the exact Ewald reciprocal sum gradient (Pollock & Glosli, 1996; Darden *et al.*, 1997) can be made more efficient than the smooth PME method at the same accuracy, despite requiring more FFTs (Deserno & Holm, 1998). However, for the case of ideal multipoles or normalized Hermite Gaussians, the number of such FFTs becomes prohibitive, whereas the smooth PME, which relies on analytic differentiation of B-splines, does not need more FFTs as the order of differentiation ($t + u + v$) in equation (3.5.3.12) grows.

3.5.4.2.1. The smooth PME approach

We begin by re-expressing the complex exponentials appearing in the structure factors in equations (3.5.2.14), (3.5.2.26) and (3.5.3.12). Recall the form of $\mathbf{m}$ from equation (3.5.2.2), and let M_1, M_2, M_3 be positive integers of the scale of the unit-cell dimensions. Then for $\mathbf{r} \in U$ we can write

$$
\begin{aligned}
\mathbf{m}\cdot\mathbf{r} &= m_1\mathbf{a}_1^*\cdot\mathbf{r} + m_2\mathbf{a}_2^*\cdot\mathbf{r} + m_3\mathbf{a}_3^*\cdot\mathbf{r}\\
&= z_1w_1 + z_2w_2 + z_3w_3,
\end{aligned}
$$

where $w_\alpha = M_\alpha\mathbf{a}_\alpha^*\cdot\mathbf{r}$ and $z_\alpha = m_\alpha/M_\alpha$, $\alpha = 1, 2, 3$, and thus

$$
\exp(2\pi i\mathbf{m}\cdot\mathbf{r}) = \exp(2\pi i z_1w_1)\exp(2\pi i z_2w_2)\exp(2\pi i z_3w_3).
$$

To motivate the smooth PME approach, suppose we can approximate $\exp(2\pi i z w)$ by some function $g(w; z)$ of the form

$$
g(w; z) = \lambda(z)\sum_{k=-\infty}^{\infty} B(w-k)\exp(2\pi i z k), \tag{3.5.4.1}
$$

where $B(w)$ is a well behaved function with continuous derivatives as needed for the general structure factor in equation (3.5.3.12). We first examine the structure factor for point-charge Ewald sums, defined in equation (3.5.2.14). This can be approximated as

$$
\begin{aligned}
S(\mathbf{m}) &= \sum_{j=1}^{N} q_j \exp(2\pi i z_1 w_{1j}) \exp(2\pi i z_2 w_{2j}) \exp(2\pi i z_3 w_{3j}) \\
&\simeq \lambda(z_1)\lambda(z_2)\lambda(z_3) \\
&\quad \times \sum_{k_1=-\infty}^{\infty} \sum_{k_2=-\infty}^{\infty} \sum_{k_3=-\infty}^{\infty} \sum_{j=1}^{N} q_j B(w_{1j}-k_1) B(w_{2j}-k_2) \\
&\quad \times B(w_{3j}-k_3) \exp[2\pi i (z_1 k_1 + z_2 k_2 + z_3 k_3)] \\
&= \lambda(z_1)\lambda(z_2)\lambda(z_3) \\
&\quad \times \sum_{k_1=-(M_1/2)+1}^{M_1/2} \sum_{k_2=-(M_2/2)+1}^{M_2/2} \sum_{k_3=-(M_3/2)+1}^{M_3/2} Q(k_1,k_2,k_3) \\
&\quad \times \exp\left[2\pi i \left(\frac{m_1 k_1}{M_1} + \frac{m_2 k_2}{M_2} + \frac{m_3 k_3}{M_3}\right)\right], \qquad (3.5.4.2)
\end{aligned}
$$

where $Q(k_1, k_2, k_3)$ is given by

$$
\begin{aligned}
Q(k_1,k_2,k_3) &= \sum_{j=1}^{N} q_j \sum_{l_1=-\infty}^{\infty} B(w_{1j}-k_1-l_1M_1) \\
&\quad \times \sum_{l_2=-\infty}^{\infty} B(w_{2j}-k_2-l_2M_2) \\
&\quad \times \sum_{l_3=-\infty}^{\infty} B(w_{3j}-k_3-l_3M_3) \qquad (3.5.4.3)
\end{aligned}
$$

and we have used the fact that $\exp[2\pi i m_\alpha (k_\alpha + M_\alpha)/M_\alpha] = \exp(2\pi i m_\alpha k_\alpha / M_\alpha)$ for $\alpha = 1, 2, 3$.

Next we turn to the general structure factors $S_l(\mathbf{m})$ from equation (3.5.3.12). Define $w_{\alpha j}, \alpha = 1, 2, 3$ as above for expansion points $\mathbf{R}_j \in U$, and note that

$$
\begin{aligned}
\frac{\partial}{\partial \mathbf{R}_{jx}} &= \frac{\partial}{\partial w_{1j}} \frac{\partial w_{1j}}{\partial \mathbf{R}_{jx}} + \frac{\partial}{\partial w_{2j}} \frac{\partial w_{2j}}{\partial \mathbf{R}_{jx}} + \frac{\partial}{\partial w_{3j}} \frac{\partial w_{3j}}{\partial \mathbf{R}_{jx}} \\
&= b_1 \frac{\partial}{\partial w_{1j}} + b_2 \frac{\partial}{\partial w_{2j}} + b_3 \frac{\partial}{\partial w_{3j}},
\end{aligned}
$$

where b_1, b_2, b_3 are constants depending on the reciprocal bases $\mathbf{a}_\alpha^*$ and on M_α, $\alpha = 1, 2, 3$. Similar expansions hold for the other partial derivatives. Thus we can approximate the general structure factor $S_l(\mathbf{m})$ by

$$
\begin{aligned}
S_l(\mathbf{m}) &= \sum_{j=1}^{N} \sum_{tuv} \mathbf{c}_{j,l,tuv} \left(\frac{\partial}{\partial \mathbf{R}_{jx}}\right)^t \left(\frac{\partial}{\partial \mathbf{R}_{jy}}\right)^u \left(\frac{\partial}{\partial \mathbf{R}_{jz}}\right)^v \\
&\quad \times \exp(2\pi i \mathbf{m} \cdot \mathbf{R}_j) \\
&= \sum_{j=1}^{N} \sum_{tuv} \mathbf{d}_{j,l,tuv} \left(\frac{\partial}{\partial w_{1j}}\right)^t \left(\frac{\partial}{\partial w_{2j}}\right)^u \left(\frac{\partial}{\partial w_{3j}}\right)^v \\
&\quad \times \exp(2\pi i z_1 w_{1j}) \exp(2\pi i z_2 w_{2j}) \exp(2\pi i z_3 w_{3j}) \\
&\simeq \lambda(z_1)\lambda(z_2)\lambda(z_3) \\
&\quad \times \sum_{k_1=-(M_1/2)+1}^{M_1/2} \sum_{k_2=-(M_2/2)+1}^{M_2/2} \sum_{k_3=-(M_3/2)+1}^{M_3/2} Q_l(k_1,k_2,k_3) \\
&\quad \times \exp\left[2\pi i \left(\frac{m_1 k_1}{M_1} + \frac{m_2 k_2}{M_2} + \frac{m_3 k_3}{M_3}\right)\right], \qquad (3.5.4.4)
\end{aligned}
$$

where $\mathbf{d}_{j,l,tuv}$ are the transformed Hermite coefficients obtained from $\mathbf{c}_{j,l,tuv}$ by change of variables, using b_1, b_2, b_3 and where $Q_l(k_1, k_2, k_3)$ is given by

$$
\begin{aligned}
Q_l(k_1,k_2,k_3) &= \sum_{j=1}^{N} \sum_{tuv} \mathbf{d}_{j,l,tuv} \\
&\quad \times \sum_{l_1=-\infty}^{\infty} \left(\frac{\partial}{\partial w_{1j}}\right)^t B(w_{1j}-k_1-l_1M_1) \\
&\quad \times \sum_{l_2=-\infty}^{\infty} \left(\frac{\partial}{\partial w_{2j}}\right)^t B(w_{2j}-k_2-l_2M_2) \\
&\quad \times \sum_{l_3=-\infty}^{\infty} \left(\frac{\partial}{\partial w_{3j}}\right)^t B(w_{3j}-k_3-l_3M_3).
\end{aligned}
$$

In equation (3.5.4.2) we recognize the approximation to $S(\mathbf{m})$ as $\lambda(z_1)\lambda(z_2)\lambda(z_3)$ times the three-dimensional discrete Fourier transform of $Q(k_1, k_2, k_3)$, which can be calculated rapidly by the 3DFFT. If the function $B(w)$ has finite support then $Q(k_1, k_2, k_3)$ can be calculated rapidly [in order(N) time] as well. Similarly we have the 3DFFT of $Q_l(k_1, k_2, k_3)$ in equation (3.5.4.4). Thus the efficient calculation of structure factors depends on the approximation given in equation (3.5.4.1), which in turn rests on the choice of $B(w)$. The smooth PME relies on B-splines.

3.5.4.2.1.1. Properties of B-splines

We proceed by deriving the facts needed about B-splines. The B-splines of order n, $B_n(w)$ are functions of a real variable defined as follows:

$$
B_1(w) = \begin{cases} 1 & \text{if } 0 \le w \le 1 \\ 0 & \text{otherwise} \end{cases}
$$

$$
B_2(w) = \begin{cases} w & \text{if } 0 \le w \le 1 \\ 2-w & \text{if } 1 \le w \le 2 \\ 0 & \text{otherwise} \end{cases}
$$

$$
\begin{aligned}
B_{n+1}(w) &= \int_{-\infty}^{\infty} B_n(w-v) B_1(v)\, \mathrm{d}v \\
&= \int_{0}^{1} B_n(w-v) B_1(v)\, \mathrm{d}v.
\end{aligned}
$$

We use the following properties of the B-splines:

(1) for $n \ge 1$ and all w, $0 \le B_n(w)$ and $B_n(w) = 0$ for $w < 0$ or $w > n$;

(2) for $n \ge 1$ and all w, $\sum_{j=-\infty}^{\infty} B_n(w-j) = 1$;

(3) for $n \ge 1$, $0 \le w \le n$, $B_n(n-w) = B_n(w)$;

(4) for $n \ge 2$, $0 \le w \le n$, $(\mathrm{d}/\mathrm{d}w) B_n(w) = B_{n-1}(w) - B_{n-1}(w-1)$;

(5) for $n \ge 2$, $0 \le w \le n$, $B_n(w) = [wB_{n-1}(w) + (n-w)B_{n-1}(w-1)]/(n-1)$.

The first property to be established is clearly true for $n = 1$ and if true for n, then in the above integral recursively defining B_{n+1} if $w < 0$ or $w > (n+1)$ the integrand must be zero for $0 \le v \le 1$, so $B_{n+1}(w) = 0$. Thus it is true in general by mathematical induction.

The second property is also clearly true for $n = 1$. Assume it is true for n. Then $\sum_{j=-\infty}^{\infty} B_{n+1}(w-j) = \int_0^1 [\sum_{j=-\infty}^{\infty} B_n(w-v-j)] B_1(v)\, \mathrm{d}v = \int_0^1 B_1(v)\, \mathrm{d}v = 1$. Thus it is true in general by mathematical induction.

Next we show symmetry: $B_n(n-w) = B_n(w)$, $0 \le w \le n$. Again this is clearly true for $n = 1$. Assuming it is true for n, we have

$$\begin{aligned}
B_{n+1}(n+1-w) &= \int_0^1 B_n(n+1-w-v)B_1(v)\,\mathrm{d}v \\
&= \int_0^1 B_n[n+1-w-(1-v')]B_1(1-v')\,\mathrm{d}v' \\
&= \int_0^1 B_n[n-(w-v')]B_1(1-v')\,\mathrm{d}v' \\
&= \int_0^1 B_n(w-v')B_1(v')\,\mathrm{d}v' \\
&= B_{n+1}(w),
\end{aligned}$$

where we substituted $v = (1 - v')$ in the second line above.

The fourth property is an efficient recursion for the derivatives of B-splines. It can be seen directly for $n = 2$ for $w \neq 0, 1$, or 2. Assume it is true for $n \geq 2$. Then for $0 \leq w \leq n + 1$,

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}w}B_{n+1}(w) &= \int_0^1 \frac{\mathrm{d}}{\mathrm{d}w}B_n(w-v)B_1(v)\,\mathrm{d}v \\
&= \int_0^1 B_{n-1}(w-v)B_1(v)\,\mathrm{d}v \\
&\quad - \int_0^1 B_{n-1}(w-1-v)B_1(v)\,\mathrm{d}v \\
&= B_n(w) - B_n(w-1),
\end{aligned}$$

thus it is true in general by induction.

The final property is an efficient recursion for $B_n(w)$. It can be seen directly for $n = 2$. Assume it is true for $n \geq 2$. Then for $0 \leq w \leq n + 1$,

$$\begin{aligned}
B_{n+1}(w) &= \int_0^1 \left[\frac{w-v}{n-1}B_{n-1}(w-v)\right. \\
&\quad \left. + \frac{n-(w-v)}{n-1}B_{n-1}(w-v-1)\right]B_1(v)\,\mathrm{d}v \\
&= \frac{n}{n-1}B_n(w-1) \\
&\quad + \frac{1}{n-1}\int_0^1 (w-v)\frac{\mathrm{d}}{\mathrm{d}w}B_n(w-v)B_1(v)\,\mathrm{d}v \\
&= \frac{n}{n-1}B_n(w-1) \\
&\quad - \frac{1}{n-1}\int_0^1 (w-v)\frac{\mathrm{d}}{\mathrm{d}v}B_n(w-v)B_1(v)\,\mathrm{d}v \\
&= \frac{n}{n-1}B_n(w-1) \\
&\quad - \frac{1}{n-1}[(w-1)B_n(w-1) - wB_n(w)] \\
&\quad + \frac{1}{n-1}\int_0^1 B_n(w-v)\frac{\mathrm{d}}{\mathrm{d}v}(w-v)B_1(v)\,\mathrm{d}v \\
&= \frac{n+1-w}{n-1}B_n(w-1) + \frac{w}{n-1}B_n(w) \\
&\quad - \frac{1}{n-1}B_{n+1}(w),
\end{aligned}$$

where we have used property (4) in the third line and integration by parts in the fifth and sixth lines. The induction step follows by moving the last term on the right-hand side over to the left side of the equation.

3.5.4.2.1.2. B-spline approximation to trigonometric functions

Next we examine properties of the B-spline approximations to the complex exponentials that appear in the structure factors. Let $g_n(w; z)$ be given by

$$g_n(w; z) = \lambda_n(z) \sum_{j=-\infty}^{\infty} B_n(w-j)\exp(2\pi i z j). \tag{3.5.4.5}$$

The complex number $\lambda_n(z)$ is chosen to optimize the approximation of $\exp(2\pi i z w)$ by $g_n(w; z)$ as shown below. It is convenient to first study the properties of the function $h_n(w; z)$ given by

$$\begin{aligned}
h_n(w; z) &= \exp(-2\pi i z w)g_n(u; z) \\
&= \lambda_n(z) \sum_{j=-\infty}^{\infty} B_n(w-j)\exp[-2\pi i z(w-j)],
\end{aligned}$$

which is an approximation to the constant one. From its definition it is clear that $h_n(w; z)$ is periodic in w with period one, *i.e.* $h_n(w + 1; z) = h_n(w; z)$. Therefore it can be expanded in a Fourier series:

$$h_n(w; z) = \sum_{k=-\infty}^{\infty} c_n(k; z)\exp(2\pi i k w). \tag{3.5.4.6}$$

The Fourier coefficients are given by

$$\begin{aligned}
c_n(k; z) &= \int_0^1 h_n(w; z)\exp(-2\pi i k w)\,\mathrm{d}w \\
&= \lambda_n(z)\int_0^1 \sum_{j=-\infty}^{\infty} B_n(w-j) \\
&\quad \times \exp[-2\pi i z(w-j)]\exp(-2\pi i k w)\,\mathrm{d}u \\
&= \lambda_n(z) \sum_{j=-\infty}^{\infty}\int_0^1 B_n(w-j) \\
&\quad \times \exp[-2\pi i(z+k)(w-j)]\,\mathrm{d}u \\
&= \lambda_n(z) \int_{-\infty}^{\infty} B_n(v)\exp[-2\pi i(z+k)v]\,\mathrm{d}v \\
&= \lambda_n(z)\ \hat{B}_n(z+k),
\end{aligned}$$

where $\hat{B}_n$ denotes the Fourier transform of B_n. Since B_n are defined recursively by convolutions, its Fourier transform is obtained simply from that of B_1: $\hat{B}_n = (\hat{B}_1)^n$. Here we are using the fact that if f, g and h are related by convolution, $h(w) = (f \star g)(w) = \int_{-\infty}^{\infty} f(w-v)g(v)\,\mathrm{d}v$, then $\hat{h} = \hat{f}\hat{g}$. Since $\hat{B}_1$ can be obtained by straightforward integration, we have

$$c_n(k; z) = \begin{cases} \lambda_n(z) & \text{if } z + k = 0 \\ \lambda_n(z)\left[\dfrac{1-\exp(-2\pi i z)}{2\pi i}\right]^n \left(\dfrac{1}{z+k}\right)^n & \text{otherwise.} \end{cases}$$

The original smooth PME method set $\lambda_n(z) = \bar{\lambda}_n(z)$, where $\bar{\lambda}_n(z)$ was chosen to enforce interpolation: $g_n(w; z) = \exp(2\pi i z w)$ or $h_n(w; z) = 1$ for integer values of w. This was related to the so-called Euler spline, studied for more general complex-valued interpolation problems by Schoenberg (1973). The special case of interpolating the function $\exp(2\pi i z w)$ is simpler, due to the Fourier-series representation, allowing us to to derive necessary properties in a self-contained way. From equations (3.5.4.6) and the above expression for $c_n(k; z)$, noting that $c_n(k; z) = 0$ for

integral z with $z + k \neq 0$, the interpolation condition can be written

$$1 = \begin{cases} \bar{\lambda}_n(z) & z \text{ an integer} \\ \bar{\lambda}_n(z)\left[\dfrac{1-\exp(-2\pi i z)}{2\pi i}\right]^n \displaystyle\sum_{k=-\infty}^{\infty}\left(\frac{1}{z+k}\right)^n & \text{otherwise.} \end{cases}$$

Note that except for $\bar{\lambda}_n(z)$, the expressions appearing in the interpolation condition are periodic in z with period one. The interpolation condition thus forces $\bar{\lambda}_n(z)$ to be periodic as well, and so we focus attention on the range $-\frac{1}{2} \leq z \leq \frac{1}{2}$. If $n \geq 2$ the sum in the above interpolation condition is bounded, so in order to be able to choose $\bar{\lambda}_n(z)$ to satisfy the interpolation condition it is sufficient to demonstrate that $\sum_{k=-\infty}^{\infty}[1/(z+k)]^n \neq 0$ for $-\frac{1}{2} \leq z \leq \frac{1}{2}$. If n is even, the terms in this sum are all positive so it is always possible to interpolate. If n is odd and $z = \frac{1}{2}$ then the sum is zero, since $(1/z)^n + [1/(-1+z)]^n = 0$, $[1/(1+z)^n + 1/(-2+z)]^n = 0$ *etc.* Similarly the interpolation condition fails for $z = -\frac{1}{2}$. However, for $0 < z < \frac{1}{2}$, $(1/z)^n + [1/(-1+z)]^n > 0$, $[1/(1+z)^n + 1/(-2+z)]^n > 0$ *etc.* Similarly for $-\frac{1}{2} < z < 0$. Thus we can say that for $n \geq 2$ and $-\frac{1}{2} < z < \frac{1}{2}$ the interpolation condition holds, and in this case we can write h_n as

$$h_n(w; z) = \sum_{k=-\infty}^{\infty} \gamma_n(k; z)\exp(2\pi i k w), \tag{3.5.4.7}$$

where

$$\gamma_n(k; z) = \left(\frac{1}{z+k}\right)^n \Bigg/ \sum_{j=-\infty}^{\infty}\left(\frac{1}{z+j}\right)^n. \tag{3.5.4.8}$$

The interpolating $g_n(w; z)$ is obtained from this h_n by multiplying by $\exp(2\pi i z w)$. Numerically, it is more convenient to use the alternative expression from equation (3.5.4.5), with $\bar{\lambda}_n(z)$ given by

$$\bar{\lambda}_n(z) = \left[\sum_{j=0}^{n} B_n(j)\exp(-2\pi i z j)\right]^{-1}.$$

Note that due to the above results for h_n, $\sum_{j=0}^{n} B_n(j)\exp(-2\pi i z j) \neq 0$ if $n \geq 2$ and $-\frac{1}{2} < z < \frac{1}{2}$.

Subsequent to the work by Essmann *et al.* (1995), we found (Darden *et al.*, 1997) that a more accurate approximation was given by least-squares fitting of $\exp(2\pi i z w)$ by $g_n(w; z)$, or equivalently 1 by $h_n(w; z)$. Thus, with h_n given by equation (3.5.4.7) we are looking for a complex number $\tilde{\lambda} = \tilde{\lambda}_n(z)$ that minimizes the mean-square error MSE, given by

$$\begin{aligned} \text{MSE} &= \int_0^1 [1 - \tilde{\lambda}h_n(w; z)][1 - \tilde{\lambda}h_n(w; z)]^* \, \mathrm{d}w \\ &= 1 - 2Re(\tilde{\lambda})\gamma_n(0; z) + [Re(\tilde{\lambda})^2 + Im(\tilde{\lambda})^2]\sum_{k=-\infty}^{\infty}\gamma_n^2(k; z), \end{aligned}$$

where $Re(\tilde{\lambda})$ and $Im(\tilde{\lambda})$ denote the real and imaginary parts of $\tilde{\lambda}$. Since $\sum_{k=-\infty}^{\infty}\gamma_n^2(k; z) > 0$, it is clear that we can set $Im(\tilde{\lambda})$ to zero, that is, restrict ourselves to real $\tilde{\lambda}$. Then, minimizing over real λ we have

$$\tilde{\lambda}_n(z) = \gamma_n(0; z) \Bigg/ \sum_{k=-\infty}^{\infty}\gamma_n^2(k; z),$$

with $\gamma_n(k; z)$ given in equation (3.5.4.8).

Thus we arrive at the least-squares optimal approximation to $\exp(2\pi i z u)$ by setting $\lambda_n(z) = \tilde{\lambda}_n(z)\bar{\lambda}_n(z)$ in equation (3.5.4.5). The mean-square error due to this can be seen to be

$$\begin{aligned} \text{MSE} &= 1 - \gamma_n^2(0; z) \Bigg/ \sum_{k=-\infty}^{\infty}\gamma_n^2(k; z) \\ &= \sum_{k\neq 0}\gamma_n^2(k; z) \Bigg/ \sum_{k=-\infty}^{\infty}\gamma_n^2(k; z) \end{aligned}$$

and thus the error in the approximation is seen to be small for small $|z|$ but increasing as $|z| \to \frac{1}{2}$, as discussed above (the reciprocal Ewald weight term compensates for the increased error by rapidly damping the larger $|z|$ terms). For $0 < |z| < \frac{1}{2}$ the error decreases to zero as the B-spline order $n \to \infty$. The accuracy of the PME is thus increased by raising the order of interpolation and/or the grid size M_1, M_2, M_3, which lowers $|z|$ for a given $\mathbf{m}$. When derivatives with respect to w of $g_n(w; z)$ are considered in this latter representation, their effect is to effectively lower the order of interpolation in the coefficients γ_n. Thus the order of interpolation needs to be higher, the higher the order of differentiation considered.

3.5.4.2.2. The fast Fourier Poisson approach

The fast Fourier Poisson (FFP) method (York & Yang, 1994) accelerates the calculation of the structure factors in equations (3.5.2.14) and (3.5.3.12) in much the same way as FFT methods accelerate structure-factor and density-map calculations in macromolecular structure determination. Originally the method was used to calculate structure factors appearing in Ewald sums over point charges. It is easier to see the basic idea if we rewrite the Ewald reciprocal sum from equation (3.5.2.15) as follows:

$$\begin{aligned} E_r(\underline{\mathbf{r}}^{\{\mathbf{N}\}}) &= \frac{1}{2\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{\exp(-\pi^2\mathbf{m}^2/\alpha)}{\mathbf{m}^2}S(\mathbf{m})S(-\mathbf{m}) \\ &= \frac{1}{2\pi V}\sum_{\mathbf{m}\neq\mathbf{0}}\frac{1}{\mathbf{m}^2}\tilde{S}(\mathbf{m})\tilde{S}(-\mathbf{m}), \end{aligned}$$

where the modified structure factor $\tilde{S}(\mathbf{m})$ is given by

$$\tilde{S}(\mathbf{m}) = \exp(-\pi^2\mathbf{m}^2/2\alpha)\sum_{j=1}^{N} q_j \exp(2\pi i \mathbf{m}\cdot\mathbf{r}_j).$$

We recognize $\tilde{S}(\mathbf{m})$ as the three-dimensional Fourier transform, evaluated at $\mathbf{m}$, of a density $\tilde{\rho}(\mathbf{r})$ given by

$$\tilde{\rho}(\mathbf{r}) = \sum_{j=1}^{N} q_j \rho_{2\alpha}(\mathbf{r} - \mathbf{r}_j),$$

where $\rho_{2\alpha}$ is a normalized Gaussian with Gaussian exponent 2α.

In turn we approximate this integral by a discrete Fourier transform. As above let M_1, M_2, M_3 be positive integers of the scale of the unit-cell dimensions. Let $\delta v = V/(M_1M_2M_3)$, where V is the volume of the unit cell. Recall the lattice basis vectors $\mathbf{a}_\alpha$, $\alpha = 1, 2, 3$. Given integers k_1, k_2, k_3 define $\tilde{\rho}_0(k_1, k_2, k_3)$ by $\tilde{\rho}_0(k_1, k_2, k_3) = \tilde{\rho}[(k_1/M_1)\mathbf{a}_1 + (k_2/M_2)\mathbf{a}_2 + (k_3/M_3)\mathbf{a}_3]$. Then we can approximate the modified structure factor $\tilde{S}(\mathbf{m})$ by

$$\tilde{S}(\mathbf{m}) \simeq \sum_{k_1=-(M_1/2)+1}^{M_1/2} \sum_{k_2=-(M_2/2)+1}^{M_2/2} \sum_{k_3=-(M_3/2)+1}^{M_3/2} Q(k_1,k_2,k_3) \times \exp\left[2\pi i\left(\frac{m_1k_1}{M_1}+\frac{m_2k_2}{M_2}+\frac{m_3k_3}{M_3}\right)\right],$$

where $Q(k_1,k_2,k_3)$ is given by

$$Q(k_1,k_2,k_3) = \sum_{l_1,l_2,l_3=-\infty}^{\infty} \tilde{\rho}_0(k_1+l_1M_1, k_2+l_2M_2, k_3+l_3M_3)\cdot \delta v.$$

The FFP can be generalized to Hermite Gaussians by sampling that density in place of the superposition of spherical Gaussians. In equation (3.5.3.11) the term

$$(1/2\pi V)\sum_{\mathbf{m}\neq\mathbf{0}}(1/\mathbf{m}^2)\exp(-\pi^2\mathbf{m}^2/2\beta)\sum_{l_1\in C}S_{l_1}(\mathbf{m}) \times \exp(-\pi^2\mathbf{m}^2/2\beta)\sum_{l_2\in C}S_{l_2}(-\mathbf{m})$$

can be handled by the methods just outlined. However the term

$$(1/2\pi V)\sum_{\mathbf{m}\neq\mathbf{0}}(1/\mathbf{m}^2)\sum_{(l_1,l_2)\notin C\times C}\exp(-\pi^2\mathbf{m}^2/\theta_{l_1})S_{l_1}(\mathbf{m}) \times \exp(-\pi^2\mathbf{m}^2/\theta_{l_2})S_{l_2}(-\mathbf{m})$$

can present problems. The difficulty comes in the case when, for example, l_1 is compact but l_2 is not. Then the combined Gaussian weights are sufficiently damping to efficiently converge the series, but it can be very inefficient to directly sample the superposition of Hermite Gaussians with a compact exponent. A similar problem was faced by Fusti-Molnar & Pulay (2002). Their solution was to filter out high frequencies in the Fourier-transformed compact densities and back transform them to obtain diffuse real-space densities. Instead, Cisneros *et al.* (2006) adjusted the exponents of both the compact and diffuse Gaussians. Choose a $\bar{\theta}$ such that if θ_l is diffuse $1/\theta_l > 1/\bar{\theta}$. For example, choose $\bar{\theta} = 1/(4\beta)$. As before, define $\tilde{S}_l(\mathbf{m})$ by $\tilde{S}_l(\mathbf{m}) = \exp(-\pi^2\mathbf{m}^2/\theta_l)S_l(\mathbf{m})$, and $\tilde{S}_{l+}(\mathbf{m})$, $\tilde{S}_{l-}(\mathbf{m})$ by

$$\tilde{S}_{l+}(\mathbf{M}) = \exp\left[-\pi^2\mathbf{m}^2\left(\frac{1}{\theta_l}+\frac{1}{4\beta}\right)\right]S_l(\mathbf{m})$$
$$\tilde{S}_{l-}(\mathbf{M}) = \exp\left[-\pi^2\mathbf{m}^2\left(\frac{1}{\theta_l}-\frac{1}{4\beta}\right)\right]S_l(\mathbf{m}).$$

Then, if $l_1 \in C$ and $l_2 \in D$,

$$\sum_{l_1\in C}\sum_{l_2\in D}\tilde{S}_{l_1}(\mathbf{m})\tilde{S}_{l_2}(\mathbf{m}) = \sum_{l_1\in C}\sum_{l_2\in D}\tilde{S}_{l_1+}(\mathbf{m})\tilde{S}_{l_2-}(\mathbf{m}).$$

Thus instead of approximating $\tilde{S}_l(\mathbf{m})$ by sampling the Gaussian followed by applying the 3DFFT, they approximated $\tilde{S}_{l+}(\mathbf{m})$ or $\tilde{S}_{l-}(\mathbf{m})$. Note that with the above choice of $\bar{\theta}$, for any $l \in C$, $\theta_{l+} < 4\beta$ and for any $l \in D$, $\theta_{l-} < 4\beta$. That is, all the modified Gaussians can be sampled on a uniform grid. Finally, note that for the diffuse–diffuse interactions

$$\sum_{l_1\in D}\sum_{l_2\in D}\tilde{S}_{l_1}(\mathbf{m})\tilde{S}_{l_2}(\mathbf{m}) = \sum_{l_1\in D}\sum_{l_2\in D}\tilde{S}_{l_1-}(\mathbf{m})\tilde{S}_{l_2-}(\mathbf{m})\exp(-\pi^2\mathbf{m}^2/2\beta),$$

i.e. the interaction between adjusted diffuse Gaussians can be corrected efficiently in reciprocal space.

Table 3.5.4.1. *Timing versus accuracy for smooth PME, FFP and regular Ewald sum reciprocal-space approaches*

(*a*) Time in seconds for A2 model density.

	RMS force error 10^{-3}			RMS force error 10^{-4}		
Box size	PME	FFP	Ewald	PME	FFP	Ewald
64	0.106	0.142	0.365	0.144	0.274	0.520
128	0.218	0.271	1.336	0.287	0.380	1.869
256	0.387	0.528	5.239	0.517	0.846	7.256
512	0.837	1.100	17.881	1.104	1.534	25.511
1024	1.701	2.236	71.513	2.249	3.152	108.158

(*b*) Time in seconds for P1 model density

	RMS force error 10^{-3}			RMS force error 10^{-4}		
Box size	PME	FFP	Ewald	PME	FFP	Ewald
64	0.310	0.399	2.321	0.478	0.688	3.858
128	0.591	0.832	7.706	0.923	1.576	11.056
256	1.186	1.920	35.178	1.805	2.736	49.107
512	2.549	3.825	119.863	3.794	5.684	183.487
1024	4.953	6.890	486.384	6.947	11.307	714.644

To test the efficiency of these reciprocal-space approaches, the electrostatic energy and intermolecular forces were calculated for a series of water boxes (64, 128, 256, 512 and 1024 water molecules) under periodic boundary conditions. Similar calculations were performed by Cisneros *et al.* (2006). As in that paper, the electron density of the water molecule was modelled by a five-site expansion consisting of the oxygen, the two hydrogens and the two bond midpoints, and using standard auxiliary basis functions, denoted A2 and P1, from the density-functional literature. These basis functions were obtained from the Environmental Molecular Sciences Laboratory at Pacific Northwest Laboratories (http://www.emsl.pnl.gov/forms/basisform.html). The A2 basis set expansion uses 21 Hermite primitives with 102 Hermite coefficients per water molecule, resulting in a root-mean-square relative molecular force error of about 8% compared to 6-31G* B3LYP intermolecular electrostatics (Cisneros *et al.*, 2006). The more complex P1 basis set expansion uses 38 Hermite primitives with 200 Hermite coefficients per water molecule, reducing the relative molecular force error to about 2%. For each water box the electrostatic energy and forces for the model A2 or P1 densities were calculated to a relative root-mean-square molecular force error of 10^{-3} or 10^{-4}, compared to exact Ewald summation of the respective model density.

The time to perform these calculations is given in Table 3.5.4.1. Note that the times given here are considerably faster than those reported in Figs. 13 and 14 of Cisneros *et al.* (2006). This is partly due to the faster processor used here (3.6 GHz Intel Xeon *versus* 3.2 GHz Xeon used previously; Intel compiler with similar options used in both cases) but mainly due to the more efficient algorithms described herein. Note that the PME and FFP timings increase in an approximately linear fashion as a function of box size whereas the Ewald sum timings behave quadratically. For each method the timings are a continuous function of the compact–diffuse separating exponent 2β described above in Section 3.5.3.1, except when 2β equals a Gaussian exponent in the model basis set. When this happens, a set of Hermite primitives change from compact to diffuse or *vice versa* and the relative

balance of direct-sum or reciprocal-sum calculation changes discontinuously. For the smooth PME calculations it was optimal to choose the separating exponent at one of these boundaries. This separating exponent value was then retained for the FFP and Ewald calculations, although the FFP method could be made slightly more efficient by further varying this parameter, and the Ewald summation could be considerably accelerated to an order $N^{3/2}$ method, where N is the number of water molecules, by making the separating exponent a decreasing function of system size. Neither of these optimizations would change the relative efficiencies, however.

The error in the FFP for a given Gaussian exponent is controlled by the size of the grid M_1, M_2, M_3 as in the PME method, and also by the completeness in the Gaussian sampling (the cutoff in the tails of the Gaussian). Typically, for equivalent accuracy, the FFP requires more extensive sampling onto grid points than does the smooth PME. That is, each Gaussian centred at an expansion point must be sampled over a considerably larger set of points than the tensor product B-spline in equation (3.5.4.3). The additional cost due to this has been ameliorated somewhat by the Gaussian split Ewald approach (Shan *et al.*, 2005). Additionally, in rectangular unit cells fast Poisson solvers such as multigrid (Beck, 2000; Sagui & Darden, 2001) can be applied, which in principle should parallelize more efficiently than the 3DFFT. Finally, although the smooth PME is typically more efficient for a single Gaussian exponent structure factor, the FFP approach has the strong advantage that the various Gaussian superpositions having possibly different exponents can be sampled and then fast Fourier transformed together, whereas they must be kept separate in the PME approach. Thus, as here Cisneros *et al.* (2006) found that the smooth PME approach was more efficient for smaller auxiliary basis sets, whereas they found that the FFP approach became more efficient for large auxiliary basis sets involving many different Gaussian exponents.

4.1. Thermal diffuse scattering of X-rays and neutrons

By B. T. M. Willis

4.1.1. Introduction

Thermal motion of the atoms in a crystal gives rise to a reduction in the intensities of the Bragg reflections and to a diffuse distribution of non-Bragg scattering in the rest of reciprocal space. This distribution is known as thermal diffuse scattering (TDS). Measurement and analysis of TDS give information about the lattice dynamics of the crystal, *i.e.* about the small oscillatory displacements of the atoms from their equilibrium positions which arise from thermal excitations. Lattice-dynamical models form the basis for interpreting many physical properties – for example, specific heat and thermal conductivity – which cannot be explained by a static model of the crystal.

Reference to a lattice-dynamical model is found in Newton's *Principia*, which contains a discussion of the vibrations of a linear chain of equidistant mass points connected by springs. The model was used to estimate the speed of sound in air. The vibrational properties of a one-dimensional crystal treated as a linear chain of atoms provide the starting point for several modern treatises on the lattice dynamics of crystals.

The classical theory of the dynamics of three-dimensional crystals is based on the treatment of Born & von Kármán (1912, 1913). In this theory, the restoring force on an atom is determined not by the displacement of the atom from its equilibrium position, but by its displacement relative to its neighbours. The atomic motion is then considered in terms of travelling waves, or 'lattice vibrations', extending throughout the whole crystal. These waves are the normal modes of vibration, in which each mode is characterized by a wavevector $\mathbf{q}$, an angular frequency $\omega(\mathbf{q})$ and certain polarization properties.

For twenty years after its publication the Born–von Kármán treatment was eclipsed by the theory of Debye (1912). In the Debye theory the crystal is treated as a continuous medium instead of a discrete array of atoms. The theory gives a reasonable fit to the integral vibrational properties (for example, the specific heat or the atomic temperature factor) of simple monatomic crystals. It fails to account for the form of the frequency distribution function which relates the number of modes and their frequency.

An even simpler model than Debye's is due to Einstein (1907), who considered the atoms in the crystal to be vibrating independently of each other and with the same frequency $\omega_{\rm E}$. By quantizing the energy of each atom in units of $\hbar\omega_{\rm E}$, Einstein showed that the specific heat falls to zero at $T = 0$ K and rises asymptotically to the Dulong and Petit value for T much larger than $\hbar\omega_{\rm E}/k_{\rm B}$. ($\hbar$ is Planck's constant divided by 2π and $k_{\rm B}$ is Boltzmann's constant.) His theory accounts satisfactorily for the breakdown of equipartition of energy at low temperatures, but it predicts a more rapid fall-off of specific heat with decreasing temperature than is observed.

Deficiencies in the Debye theory were noted by Blackman (1937), who showed that they are overcome satisfactorily using the more rigorous Born–von Kármán theory. Extensive X-ray studies of Laval (1939) on simple structures such as sylvine, aluminium and diamond showed that the detailed features of the TDS could only be explained in terms of the Born–von Kármán theory. The X-ray work on aluminium was developed further by Olmer (1948) and by Walker (1956) to derive the phonon dispersion relations (see Section 4.1.5) along various symmetry directions in the crystal.

It is possible to measure the vibrational frequencies directly with X-rays, but such measurements are very difficult as lattice vibrational energies are many orders of magnitude less than X-ray energies. The situation is much more favourable with thermal neutrons because their wavelength is comparable with interatomic spacings and their energy is comparable with a quantum of vibrational energy (or phonon). The neutron beam is scattered inelastically by the lattice vibrations, exchanging energy with the phonons. By measuring the energy change for different directions of the scattered beam, the dispersion relations $\omega(\mathbf{q})$ can be determined. Brockhouse & Stewart (1958) reported the first dispersion curves to be derived in this way; since then the neutron technique has become the principal experimental method for obtaining detailed information about lattice vibrations.

In this chapter we shall describe briefly the standard treatment of the lattice dynamics of crystals. There follows a section on the theory of the scattering of X-rays by lattice vibrations, and a similar section on the scattering of thermal neutrons. We then refer briefly to experimental work with X-rays and neutrons. The final section is concerned with the measurement of elastic constants: these constants are required in calculating the TDS correction to measured Bragg intensities (see Section 7.4.2 of *IT* C, 2004).

4.1.2. Dynamics of three-dimensional crystals

For modes of vibration of very long wavelength, the crystal can be treated as a homogeneous elastic continuum without referring to its crystal or molecular structure. The theory of the propagation of these elastic waves is based on Hooke's law of force and on Newton's equations of motion. As the wavelength of the vibrations becomes shorter and shorter and approaches the separation of adjacent atoms, the calculation of the vibrational properties requires a knowledge of the crystal structure and of the nature of the forces between adjacent atoms. The three-dimensional treatment is based on the formulation of Born and von Kármán, which is discussed in detail in the book by Born & Huang (1954) and in more elementary terms in the books by Cochran (1973) and by Willis & Pryor (1975).

Before setting up the equations of motion, it is necessary to introduce three approximations:

(i) *The harmonic approximation*. When an atom is displaced from its equilibrium position, the restoring force is assumed to be proportional to the displacement, measured relative to the neighbouring atoms. The approximation implies no thermal expansion and other properties not possessed by real crystals; it is a reasonable assumption in the lattice-dynamical theory provided the displacements are not too large.

(ii) *The adiabatic approximation*. We wish to set up a potential function for the crystal describing the binding between the atoms. However, the binding involves electronic motions whereas the dynamics involve nuclear motions. The adiabatic approximation, known as the Born–Oppenheimer approximation in the context of molecular vibrations, provides the justification for adopting the same potential function to describe both the binding and the dynamics. Its essence is that the electronic and nuclear motions may be considered separately. This is possible if the nuclei move very slowly compared with the electrons: the electrons can then instantaneously take up a configuration appropriate to that of the displaced nuclei without changing their quantum state. The approximation holds well for insulators, where electronic transition energies are high owing to the large energy gap between filled and unfilled electron states. Surprisingly, it even works for

Copyright © 2010 International Union of Crystallography

metals, because (on account of the Pauli principle) only a few electrons near the Fermi level can make transitions.

(iii) *Periodic boundary conditions*. These are introduced to avoid problems associated with the free surface. The system is treated as an infinite crystal made up of contiguous, repeating blocks of the actual crystal. The periodic (or cyclic) boundary conditions require that the displacements of corresponding atoms in different blocks are identical. The validity of the conditions was challenged by Raman (1941*a*,*b*), but these objections were safely disposed of by Ledermann (1944).

4.1.2.1. Equations of motion

As a result of thermal fluctuations, the atoms vibrate about their equilibrium positions, so that the actual position of the κth atom in the lth primitive cell is given by

$$\mathbf{R}(\kappa l) = \mathbf{r}(\kappa l) + \mathbf{u}(\kappa l)$$

with $\mathbf{r}$ representing the equilibrium position and $\mathbf{u}$ the thermal displacement. (In lattice-dynamical theory it is advantageous to deal with the primitive cell, as it possesses the fewest degrees of freedom.) The kinetic energy of the vibrating crystal is

$$(1/2)\sum_{\kappa l\alpha} m(\kappa)\dot{u}_\alpha^2(\kappa l),$$

where $m(\kappa)$ is the mass of atom κ and the index α (α = 1, 2, 3) refers to the Cartesian components of the displacement. (The dot denotes the time derivative.)

If the adiabatic approximation is invoked, the potential energy V of the crystal can be expressed as a function of the instantaneous atomic positions. Expanding V in powers of $\mathbf{u}(\kappa l)$, using the three-dimensional form of Taylor's series, we have

$$V = V^{(0)} + V^{(1)} + V^{(2)} + V^{(3)} + \ldots,$$

where $V^{(0)}$ is the static (equilibrium) potential and $V^{(1)}$, $V^{(2)}$ are given by

$$V^{(1)} = \sum_{\kappa l\alpha} \left.\frac{\partial V}{\partial u_\alpha(\kappa l)}\right|_0 u_\alpha(\kappa l)$$

$$V^{(2)} = \tfrac{1}{2}\sum_{\kappa l\alpha}\sum_{\kappa' l'\alpha'} \left.\frac{\partial^2 V}{\partial u_\alpha(\kappa l)\partial u_{\alpha'}(\kappa' l')}\right|_0 u_\alpha(\kappa l)u_{\alpha'}(\kappa' l').$$

The subscript zero indicates that the derivatives are to be evaluated at the equilibrium configuration. In the harmonic approximation, $V^{(3)}$ and all higher terms in the expansion are neglected.

At equilibrium the forces on an atom must vanish, so that

$$V^{(1)} = 0.$$

Ignoring the static potential $V^{(0)}$, the quadratic term $V^{(2)}$ only remains and the Hamiltonian for the crystal (the sum of the kinetic and potential energies) is then

$$H = \tfrac{1}{2}\sum_{\kappa l\alpha} m(\kappa)\dot{u}_\alpha^2(\kappa l) + \tfrac{1}{2}\sum_{\kappa l\alpha}\sum_{\kappa' l'\alpha'} \Phi_{\alpha\alpha'}\begin{pmatrix}\kappa & \kappa'\\ l & l'\end{pmatrix} u_\alpha(\kappa l)u_{\alpha'}(\kappa' l'), \qquad (4.1.2.1)$$

where $\Phi_{\alpha\alpha'}$ is an element of the 3 × 3 'atomic force-constant matrix' and is defined (for distinct atoms κl, $\kappa' l'$) by

$$\Phi_{\alpha\alpha'}\begin{pmatrix}\kappa & \kappa'\\ l & l'\end{pmatrix} = \left.\frac{\partial^2 V}{\partial u_\alpha(\kappa l)\partial u_{\alpha'}(\kappa' l')}\right|_0.$$

It is the negative of the force in the α direction imposed on the atom (κl) when atom $(\kappa' l')$ is displaced unit distance along α' with all the remaining atoms fixed at their equilibrium sites. $\Phi_{\alpha\alpha'}$ is defined differently for the self-term with $\kappa = \kappa'$ and $l = l'$:

$$\Phi_{\alpha\alpha'}\begin{pmatrix}\kappa & \kappa\\ l & l\end{pmatrix} = -\sum_{\kappa l}\sum_{\substack{\kappa' l'\\ \kappa l\neq\kappa' l'}} \Phi_{\alpha\alpha'}\begin{pmatrix}\kappa & \kappa'\\ l & l'\end{pmatrix}.$$

Thus the self-matrix describes the force on (κl) when the atom itself is displaced with all the remaining atoms kept stationary.

There are restrictions on the number of distinct force constants $\Phi_{\alpha\alpha'}$: these are imposed by symmetry and by the requirement that the potential energy is invariant under infinitesimal translations and rotations of the rigid crystal. Such constraints are discussed in the book by Venkataraman *et al.* (1975).

Applying Hamilton's equations of motion to equation (4.1.2.1) now gives

$$m(\kappa)\ddot{u}_\alpha(\kappa l) = -\sum_{\kappa' l'\alpha'} \Phi_{\alpha\alpha'}\begin{pmatrix}\kappa & \kappa'\\ l & l'\end{pmatrix} u_{\alpha'}(\kappa' l'). \qquad (4.1.2.2)$$

These represent $3nN$ coupled differential equations, where n is the number of atoms per primitive cell ($\kappa = 1, \ldots, n$) and N is the number of cells per crystal ($l = 1, \ldots, N$).

By applying the periodic boundary conditions, the solutions of equation (4.1.2.2) can be expressed as running, or travelling, plane waves extending throughout the entire crystal. The number of independent waves (or normal modes) is $3nN$. Effectively, we have transferred to a new coordinate system: instead of specifying the motion of the individual atoms, we describe the thermal motion in terms of normal modes, each of which contributes to the displacement of each atom. The general solution for the α component of the displacement of (κl) is then given by the superposition of the displacements from all modes:

$$u_\alpha(\kappa l) = [m(\kappa)]^{-1/2}\sum_{j\mathbf{q}} |A_j(\mathbf{q})| e_\alpha(\kappa|j\mathbf{q}) \times \exp\{i[\mathbf{q}\cdot\mathbf{r}(\kappa l) - \omega_j(\mathbf{q})t]\}. \qquad (4.1.2.3)$$

Here $\mathbf{q}$ is the wavevector of a mode (specifying both its wavelength and direction of propagation in the crystal) and $\omega(\mathbf{q})$ its frequency. There are N distinct wavevectors, occupying a uniformly distributed mesh of N points in the Brillouin zone (reciprocal cell); each wavevector is shared by $3n$ modes which possess, in general, different frequencies and polarization properties. Thus an individual mode is conveniently labelled $(j\mathbf{q})$, where j is an index ($j = 1, \ldots, 3n$) indicating the *branch*. The scalar quantity $|A_j(\mathbf{q})|$ in equation (4.1.2.3) is the amplitude of excitation of $(j\mathbf{q})$ and $e_\alpha(\kappa|j\mathbf{q})$ is the element of the eigenvector $\mathbf{e}(j\mathbf{q})$ referring to the displacement in the α direction of the atom κ. The eigenvector itself, with dimensions $n \times 1$, determines the pattern of atomic displacements in the mode $(j\mathbf{q})$ and its magnitude is fixed by the orthonormality and closure conditions

$$\sum_{\alpha\kappa} e_\alpha^*(\kappa|j\mathbf{q})e_\alpha(\kappa|j'\mathbf{q}) = \delta_{jj'}$$

and

$$\sum_j e_\alpha(\kappa|j\mathbf{q})e^*_{\alpha'}(\kappa'|j\mathbf{q}) = \delta_{\alpha\alpha'}\delta_{\kappa\kappa'}$$

with * indicating complex conjugate and δ the Kronecker delta.

The pre-exponential, or amplitude, terms in (4.1.2.3) are independent of the cell number. This follows from Bloch's (1928) theorem which states that, for corresponding atoms in different cells, the motions are identical as regards their amplitude and direction and differ only in phase. The theorem introduces an enormous simplification as it allows us to restrict attention to the $3n$ equations of motion of the n atoms in just one cell, rather than the $3nN$ equations of motion for all the atoms in the crystal.

Substitution of (4.1.2.3) into (4.1.2.2) gives the equations of motion in the form

$$\omega_j^2(\mathbf{q})e_\alpha(\kappa|j\mathbf{q}) = \sum_{\alpha'\kappa'} D_{\alpha\alpha'}(\kappa\kappa'|\mathbf{q})e_{\alpha'}(\kappa'|j\mathbf{q}), \qquad (4.1.2.4)$$

in which $D_{\alpha\alpha'}$ is an element of the dynamical matrix $\mathbf{D}(\mathbf{q})$. $D_{\alpha\alpha'}$ is defined by

$$D_{\alpha\alpha'}(\kappa\kappa'|\mathbf{q}) = [m(\kappa)m(\kappa')]^{-1/2}\exp\{i\mathbf{q}[r(\kappa') - r(\kappa)]\} \times \sum \Phi_{\alpha\alpha'}\begin{pmatrix}\kappa & \kappa'\\ 0 & L\end{pmatrix}\exp[i\mathbf{q}\cdot\mathbf{r}(L)], \qquad (4.1.2.5)$$

where $\mathbf{r}(\kappa)$ is the position of atom κ with respect to the cell origin, L is $l' - l$ and $\mathbf{r}(L)$ is the separation between cells l and l'. The element $D_{\alpha\alpha'}$ is obtained by writing down the $\alpha\alpha'$ component of the force constant between atoms κ, κ' which are L cells apart and multiplying by the phase factor $\exp[i\mathbf{q}\cdot\mathbf{r}(L)]$; this term is then summed over those values of L covering the range of interaction of κ and κ'.

The dynamical matrix is Hermitian and has dimensions $3n \times 3n$. Its eigenvalues are the squared frequencies $\omega_j^2(\mathbf{q})$ of the normal modes and its eigenvectors $\mathbf{e}(j\mathbf{q})$ determine the corresponding pattern of atomic displacements. The frequencies of the modes in three of the branches, j, go to zero as $\mathbf{q}$ approaches zero: these are the acoustic modes. The remaining $3n - 3$ branches contain the optic modes. There are N distinct $\mathbf{q}$ vectors, and so, in all, there are $3N$ acoustic modes and $(3n - 3)N$ optic modes. Thus copper has acoustic modes but no optic modes, silicon and rock salt have an equal number of both, and lysozyme possesses predominantly optic modes.

4.1.2.2. Quantization of normal modes. Phonons

Quantum concepts are not required in solving the equations of motion (4.1.2.4) to determine the frequencies and displacement patterns of the normal modes. The only place where quantum mechanics is necessary is in calculating the energy of the mode, and from this the amplitude of vibration $|A_j(\mathbf{q})|$.

It is possible to discuss the theory of lattice dynamics from the beginning in the language of quantum mechanics (Donovan & Angress, 1971). Instead of treating the modes as running waves, they are conceived as an assemblage of indistinguishable quasi-particles called phonons. Phonons obey Bose–Einstein statistics and are not limited in number. The number of phonons, each with energy $\hbar\omega_j(\mathbf{q})$ in the vibrational state specified by $\mathbf{q}$ and j, is given by

$$n_j(\mathbf{q}) = \{\exp[\hbar\omega_j(\mathbf{q})/k_B T] - 1\}^{-1} \qquad (4.1.2.6)$$

and the mode energy $E_j(\mathbf{q})$ by

$$E_j(\mathbf{q}) = \hbar\omega_j(\mathbf{q})[n_j(\mathbf{q}) + (1/2)]. \qquad (4.1.2.7)$$

Thus the quantum number $n_j(\mathbf{q})$ describes the degree of excitation of the mode $(j\mathbf{q})$. The relation between $E_j(\mathbf{q})$ and the amplitude $|A_j(\mathbf{q})|$ is

$$E_j(\mathbf{q}) = N\omega_j^2(\mathbf{q})|A_j(\mathbf{q})|^2. \qquad (4.1.2.8)$$

Equations (4.1.2.6) to (4.1.2.8) together determine the value of $|A_j(\mathbf{q})|$ to be substituted into equation (4.1.2.3) to give the atomic displacement in terms of the absolute temperature and the properties of the normal modes.

In solving the lattice-dynamical problem using the Born–von Kármán analysis, the first step is to set up a force-constant matrix describing the interactions between all pairs of atoms. This is followed by the assembly of the dynamical matrix $\mathbf{D}$, whose eigenvalues give the frequencies of the normal modes and whose eigenvectors determine the patterns of atomic displacement for each mode.

Before considering the extension of this treatment to molecular crystals, we shall comment briefly on the less rigorous treatments of Einstein and Debye.

4.1.2.3. Einstein and Debye models

In the Einstein model it is assumed that each atom vibrates in its private potential well, entirely unaffected by the motion of its neighbours. There is no correlation between the motion of different atoms, whereas correlated motion – in the form of collective modes propagating throughout the crystal – is a central feature in explaining the characteristics of the TDS. Nevertheless, the Einstein model is occasionally used to represent modes belonging to flat optic branches of the dispersion relations, with the frequency written symbolically as $\omega(\mathbf{q}) = \omega_E$ (constant).

In the Debye model the optic branches are ignored. The dispersion relations for the remaining three acoustic branches are assumed to be the same and represented by

$$\omega(\mathbf{q}) = \mathbf{v}_s q, \qquad (4.1.2.9)$$

where $\mathbf{v}_s$ is a mean sound velocity. The Brillouin zone is replaced by a sphere with radius q_D chosen to ensure the correct number of modes. The linear relationship (4.1.2.9) holds right up to the boundary of the spherical zone. In an improved version of the Debye model, (4.1.2.9) is replaced by the expression

$$\omega(\mathbf{q}) = \mathbf{v}_s(2q_D/\pi)\sin(\pi q/2q_D), \qquad (4.1.2.10)$$

which is the same as (4.1.2.9) at $q = 0$ but gives a sinusoidal dispersion relation with zero slope at the zone boundary.

4.1.2.4. Molecular crystals

The full Born–von Kármán treatment becomes excessively cumbersome when applied to most molecular crystals. For example, for naphthalene with two molecules or 36 atoms in the primitive cell, the dynamical matrix has dimensions 108×108. Moreover, the physical picture of molecules or of groups of atoms, vibrating in certain modes as quasi-rigid units, is lost in the full treatment.

To simplify the setting up of the dynamical matrix, it is assumed that the molecules vibrate as rigid units in the crystal with each molecule possessing three translational and three rotational (librational) degrees of freedom. The motion of these rigid groups as a whole is described by the *external modes* of motion, whereas the *internal modes* arise from distortions within

an individual group. The frequencies of these internal modes, which are largely determined by the strong intramolecular forces, are unaffected by the phase of the oscillation between neighbouring cells: the modes are taken, therefore, to be equivalent to those of the free molecule. The remaining external modes are calculated by applying the Born–von Kármán procedure to the crystal treated as an assembly of rigid molecules.

The dynamical matrix $\mathbf{D}(\mathbf{q})$ now has dimensions $6n' \times 6n'$, where n' is the number of molecules in the primitive cell: for naphthalene, $\mathbf{D}$ is reduced to 12×12. The elements of $\mathbf{D}$ can be expressed in the same form as equation (4.1.2.5) for an atomic system. κ, κ' refer to molecules which are L cells apart and the indices α, α' $(= 1, \ldots, 6)$ label the six components of translation and rotation. $m(\kappa)$ in equation (4.1.2.5) is replaced by $m_\alpha(\kappa)$ where m_α represents the 3×3 molecular-mass matrix for $\alpha = 1, 2, 3$ and represents the 3×3 moment-of-inertia matrix referred to the principal axes of inertia for $\alpha = 4, 5, 6$. The 6×6 force-torque constant matrices $\Phi_{\alpha\alpha'}$ are derived by taking the second derivative of the potential energy of the crystal with respect to the coordinates of translation and rotation.

4.1.3. Scattering of X-rays by thermal vibrations

The change of frequency, or energy, of X-rays on being scattered by thermal waves is extremely small. The differential scattering cross section, $\mathrm{d}\sigma/\mathrm{d}\Omega$, giving the probability that X-rays are scattered into the solid angle $\mathrm{d}\Omega$ is then

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \langle |Y(Q)|^2 \rangle,$$

where

$$Y(Q) = \sum_{\kappa l} f_\kappa(\mathbf{Q}) \exp\{i\mathbf{Q} \cdot [\mathbf{r}(\kappa l) + \mathbf{u}(\kappa l)]\}. \qquad (4.1.3.1)$$

The angled brackets indicate an average value over a period of time much longer than the period of oscillation of an atom. $\mathbf{Q}$ is the 'scattering vector' defined by

$$\mathbf{Q} = \mathbf{k} - \mathbf{k}_0,$$

where $\mathbf{k}$ and $\mathbf{k}_0$ are the wavevectors (each of magnitude $2\pi/\lambda$) of the scattered and incident beams, respectively. For Bragg scattering the magnitude of $\mathbf{Q}$ is $4\pi(\sin\theta)/\lambda$, where θ is the Bragg angle. $f_\kappa(\mathbf{Q})$ is the scattering factor of the κth atom in the unit cell.

The cross section $\mathrm{d}\sigma/\mathrm{d}\Omega$ can be expanded as a power series:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(0)} + \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(1)} + \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(2)} + \ldots. \qquad (4.1.3.2)$$

The individual terms on the right-hand side refer to the cross sections for zero-order, first-order, second-order scattering ..., *i.e.* for processes involving no exchange of energy between the incident radiation and the crystal (Bragg scattering), the exchange of one quantum of lattice vibrational energy (one-phonon scattering), the exchange of two quanta (two-phonon scattering) ....

The instantaneous thermal displacement $\mathbf{u}(\kappa l)$ of the atom (κl) can be expressed, using equations (4.1.2.3), (4.1.2.6), (4.1.2.7) and (4.1.2.8), as a superposition of the displacements of the $3nN$ ($\sim 10^{23}$) independent normal modes of vibration:

$$\mathbf{u}(\kappa l) = [Nm(\kappa)]^{-1/2} \sum_{j\mathbf{q}} \frac{E_j^{-1/2}(\mathbf{q})}{\omega_j^2(\mathbf{q})} \mathbf{e}(\kappa|j\mathbf{q}) \times \exp\{i[\mathbf{q} \cdot \mathbf{r}(\kappa l) - \omega_j(\mathbf{q})t]\}. \qquad (4.1.3.3)$$

Explicit expressions can now be given for the partial cross sections in equation (4.1.3.2). The cross section for Bragg scattering is

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(0)} = N|F(\mathbf{Q})|^2 \frac{(2\pi)^3}{\mathbf{v}} \sum_{\mathbf{h}} \delta(\mathbf{Q} - \mathbf{Q}_\mathbf{h}), \qquad (4.1.3.4)$$

where $\mathbf{v}$ is the cell volume. The delta function requires that

$$\mathbf{Q} = \mathbf{Q}_\mathbf{h},$$

where $\mathbf{Q}_\mathbf{h}$ is a reciprocal-lattice vector, so that scattering is restricted to the points $\mathbf{h}$ of the reciprocal lattice. The structure factor $F(\mathbf{Q})$ is

$$F(\mathbf{Q}) = \sum_\kappa f_\kappa(\mathbf{Q}) \exp[i\mathbf{Q} \cdot \mathbf{r}(\kappa)] \exp(-W_\kappa),$$

where the exponent W_κ of the temperature factor of the atom κ is calculated by summing over the normal modes:

$$W_\kappa = \frac{1}{2Nm(\kappa)} \sum_{j\mathbf{q}} |\mathbf{Q}_h \cdot \mathbf{e}(\kappa|j\mathbf{q})|^2 \frac{E_j(\mathbf{q})}{\omega_j^2(\mathbf{q})}. \qquad (4.1.3.5)$$

The last equation shows that the acoustic modes, with frequencies approaching zero as $\mathbf{q} \to 0$, make the largest contribution to the temperature factor.

The one-phonon cross section is

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(1)} = \frac{(2\pi)^3}{\mathbf{v}} \sum_{j\mathbf{q}} \frac{|G_j(\mathbf{Q}, \mathbf{q})|^2 E_j(\mathbf{q})}{\omega_j^2(\mathbf{q})} \times \sum_\mathbf{h} \delta(\mathbf{Q} \pm \mathbf{q} - \mathbf{Q}_\mathbf{h}), \qquad (4.1.3.6)$$

where $G_j(\mathbf{Q}, \mathbf{q})$ is the 'structure factor for one-phonon scattering' by the mode $(j\mathbf{q})$ and is given by

$$G_j(\mathbf{Q}, \mathbf{q}) = \sum_\kappa \frac{\mathbf{Q} \cdot \mathbf{e}(\kappa|j\mathbf{q})}{[m(\kappa)]^{1/2}} \cdot f_\kappa(\mathbf{Q}) \times \exp[i\mathbf{Q} \cdot \mathbf{r}(\kappa)] \exp(-W_\kappa).$$

The delta function in equation (4.1.3.6) implies that

$$\mathbf{Q} = \mathbf{Q}_\mathbf{h} \pm \mathbf{q}, \qquad (4.1.3.7)$$

so that the scattering from the $3n$ modes with the same wavevector $\mathbf{q}$ is restricted to pairs of points in reciprocal space which are displaced by $\pm\mathbf{q}$ from the reciprocal-lattice points. (These satellite reflections are analogous to the pairs of 'ghosts' near the principal diffraction maxima in a grating ruled with a periodic error.) There is a huge number, N, of $\mathbf{q}$ vectors which are uniformly distributed throughout the Brillouin zone, and each of these vectors gives a cross section in accordance with equation (4.1.3.6). Thus the one-phonon TDS is spread throughout the

whole of reciprocal space, rising to a maximum at the reciprocal-lattice points where $\omega \rightarrow 0$ for the acoustic modes.

For two-phonon scattering, involving modes with wavevectors $\mathbf{q}_1$ and $\mathbf{q}_2$, the scattering condition becomes

$$\mathbf{Q} = \mathbf{Q}_\mathbf{h} \pm \mathbf{q}_1 \pm \mathbf{q}_2. \qquad (4.1.3.8)$$

The intensity at any point in reciprocal space is now contributed by a very large number of pairs of elastic waves with wavevectors satisfying equation (4.1.3.8). These vectors span the entire Brillouin zone, and so the variation of the two-phonon intensity with location in reciprocal space is less pronounced than for one-phonon scattering.

Expressions for $(\mathrm{d}\sigma/\mathrm{d}\Omega)^{(2)}$ and for higher terms in equation (4.1.3.2) will not be given, but a rough estimate of their relative magnitudes can be derived by using the Einstein model of the crystal. All frequencies are the same, $\omega_j(\mathbf{q}) = \omega_\mathrm{E}$, and for one atom per cell ($n = 1$) the exponent of the temperature factor, equation (4.1.3.5), becomes

$$W = \frac{Q^2 k_\mathrm{B} T}{2m\omega_\mathrm{E}^2}, \qquad (4.1.3.9)$$

assuming classical equipartition of energy between modes: $E_j(\mathbf{q}) = k_\mathrm{B}T$. The cross sections for zero-order, first-order, second-order ... scattering are then

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(0)} = Nf^2 \exp(-2W)$$
$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(1)} = Nf^2 \exp(-2W)2W$$
$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{(2)} = Nf^2 \exp(-2W)\tfrac{1}{2}(2W)^2$$
$$\vdots$$

and the total cross section is

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = Nf^2 \exp(-2W)\big\{1 + 2W + \tfrac{1}{2}(2W)^2 + \tfrac{1}{6}(2W)^3 + \ldots\big\}.$$

The expression in curly brackets is the expansion of $\exp(2W)$. The nth term in the expansion, associated with the nth-order (n-phonon) process, is proportional to W^n or to $Q^{2n}T^n$. The higher-order processes are more important, therefore, at higher values of $(\sin\theta)/\lambda$ and at higher temperatures.

Our treatment so far applies to the TDS from single crystals. It can be extended to cover the TDS from polycrystalline samples, but the calculations are more complicated as the first-order scattering at a fixed value of $(\sin\theta)/\lambda$ is contributed by phonon wavevectors extending over the whole of the Brillouin zone. For a fuller discussion of the TDS from powders see Section 7.4.2 in *IT* C (2004).

4.1.4. Scattering of neutrons by thermal vibrations

The amplitude of the X-ray beam scattered by a single atom is denoted by the atomic scattering factor $f(\mathbf{Q})$. The corresponding quantity in neutron scattering is the scattering amplitude or scattering length b of an atom. b is independent of scattering angle and is also independent of neutron wavelength apart from for a few isotopes (*e.g.* ^{113}Cd, ^{149}Sm) with resonances in the thermal neutron region.

The scattering amplitude for atoms of the same chemical element can vary randomly from one atom to the next, as different amplitudes are associated with different isotopes. If the nucleus has a nonzero spin, even a single isotope has two different amplitudes, dependent on whether the nuclear spin is parallel or antiparallel to the spin of the incident neutron. If there is a variation in the amplitude associated with a particular type of atom, some of the waves scattered by the atoms will interfere with one another and some will not. The first part is called coherent scattering and the second incoherent scattering. The amplitude of the coherent scattering is determined by the mean atomic scattering amplitude, averaged over the various isotopes and spin states of the atom, and is known as the coherent scattering length, $\bar{b}$.

A crucial difference between neutrons and X-rays concerns their energies:

$$E = \hbar^2 k^2/2m_\mathrm{n} \quad \text{(neutrons)}$$
$$= c\hbar k \quad \text{(X-rays)},$$

where m_n is the neutron mass and c the velocity of light. At $\lambda = 1$ Å, neutrons have an energy of 0.08 eV or a temperature of about 800 K; for X-rays of this wavelength the corresponding temperature exceeds 10^8 K! Thermal neutrons have energies comparable with phonon energies, and so inelastic scattering processes, involving the exchange of energy between neutrons and phonons, produce appreciable changes in neutron energy. (These changes are readily determined from the change in wavelength or velocity of the scattered neutrons.) It is customary to refer to the thermal diffuse scattering of neutrons as 'inelastic neutron scattering' to draw attention to this energy change.

For a scattering process in which energy is exchanged with just one phonon, energy conservation gives

$$E_0 - E = \varepsilon\hbar\omega_j(\mathbf{q}), \qquad (4.1.4.1)$$

where E_0 and E are the energies of the neutron before and after scattering and $\varepsilon = \pm 1$. If $\varepsilon = +1$ the neutron loses energy by creating a phonon ('phonon emission'), and if $\varepsilon = -1$ it gains energy by annihilating a phonon ('phonon absorption').

The partial differential scattering cross section $\mathrm{d}^2\sigma/\mathrm{d}\Omega\,\mathrm{d}\omega$ gives the probability that neutrons will be scattered into a small solid angle $\mathrm{d}\Omega$ about the direction $\mathbf{k}$ with a change of energy between $\hbar\omega$ and $\hbar(\omega + \mathrm{d}\omega)$. This cross section can be split into two terms, known as the coherent and incoherent cross sections:

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega} = \left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)_\mathrm{coh} + \left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)_\mathrm{incoh}.$$

The coherent cross section depends on the correlation between the positions of all the atoms at different times, and so gives interference effects. The incoherent cross section depends only on the correlation between the positions of the same atom at different times, giving no interference effects. Incoherent inelastic scattering is the basis of a powerful technique for studying the dynamics of molecular crystals containing hydrogen (Boutin & Yip, 1968).

The coherent scattering cross section $(\mathrm{d}^2\sigma/\mathrm{d}\Omega\,\mathrm{d}\omega)_\mathrm{coh}$ can be expanded, as in the X-ray case [equation (4.1.3.2)], into terms representing the contributions from zero-phonon, one-phonon, two-phonon ... scattering. To determine phonon dispersion relations, we measure the one-phonon contribution and this arises from both phonon emission and phonon absorption:

$$\left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)^{(1)}_{\mathrm{coh}} = \left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)^{(1)}_{\mathrm{coh}+1} + \left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)^{(1)}_{\mathrm{coh}-1}.$$

The superscript (1) denotes a one-phonon process, and the subscript +1 (−1) indicates emission (absorption).

The emission cross section is given by (Squires, 1978)

$$\begin{aligned}\left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)^{(1)}_{\mathrm{coh}+1} = {} & \frac{\hbar k}{k_0}\frac{4\pi^3}{\mathbf{v}}\sum_{j\mathbf{q}}\sum_{\mathbf{Q_h}}\frac{[n_j(\mathbf{q})+1]}{\omega_j(\mathbf{q})} \\ & \times \left|\frac{b_\kappa}{[m(\kappa)]^{1/2}}\exp[i\mathbf{Q}\cdot\mathbf{r}(\kappa)]\right. \\ & \left.\times\,\mathbf{Q}\cdot\mathbf{e}(\kappa|j\mathbf{q})\exp(-W_\kappa)\right|^2 \\ & \times\,\delta[\omega-\omega_j(\mathbf{q})]\delta(\mathbf{Q}-\mathbf{Q_h}+\mathbf{q}),\end{aligned} \tag{4.1.4.2}$$

whereas for phonon absorption

$$\begin{aligned}\left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)^{(1)}_{\mathrm{coh}-1} = {} & \frac{\hbar k}{k_0}\frac{4\pi^3}{\mathbf{v}}\sum_{j\mathbf{q}}\sum_{\mathbf{Q_h}}\frac{[n_j(\mathbf{q})]}{\omega_j(\mathbf{q})} \\ & \times \left|\frac{b_\kappa}{[m(\kappa)]^{1/2}}\exp[i\mathbf{Q}\cdot\mathbf{r}(\kappa)]\right. \\ & \left.\times\,\mathbf{Q}\cdot\mathbf{e}(\kappa|j\mathbf{q})\exp(-W_\kappa)\right|^2 \\ & \times\,\delta[\omega+\omega_j(\mathbf{q})]\delta(\mathbf{Q}-\mathbf{Q_h}-\mathbf{q}).\end{aligned} \tag{4.1.4.3}$$

The first delta function in these two expressions embodies energy conservation,

$$\hbar\omega \equiv \frac{\hbar^2}{2m_{\mathrm{n}}}(k_0^2-k^2) = \varepsilon\hbar\omega_j(\mathbf{q}),$$

and the second embodies conservation of momentum,

$$\mathbf{Q} \equiv \mathbf{k}-\mathbf{k}_0 = \mathbf{Q_h}-\varepsilon\mathbf{q}. \tag{4.1.4.4}$$

The phonon population number, $n_j(\mathbf{q})$, tends to zero as $T \to 0$ [see equation (4.1.2.6)], so that the one-phonon absorption cross section is very small at low temperatures where there are few phonons for the radiation to absorb. Comparison of equations (4.1.4.2) and (4.1.4.3) shows that there is always a greater probability that the neutrons are scattered with energy loss rather than with energy gain.

Normally it is not possible in X-ray experiments to distinguish between phonon emission and phonon absorption, and the measured cross section is obtained by summing over all energy transfers. The cross section for X-rays can be derived from the neutron formulae, equations (4.1.4.2) and (4.1.4.3), by putting $k = k_0$ and by replacing b_κ with $f_\kappa(\mathbf{Q})$. Integration over ω and addition of the parts for emission and absorption gives the X-ray formula (4.1.3.6).

The theory of neutron scattering can also be formulated in terms of thermal averages known as Van Hove correlation functions (Van Hove, 1954). For example, the partial differential cross section for coherent scattering is

$$\left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega}\right)_{\mathrm{coh}} = \frac{k}{k_0}S(\mathbf{Q},\omega),$$

where

$$S(\mathbf{Q},\omega) = \frac{1}{2\pi\hbar}\int G(\mathbf{r},t)\exp[i(\mathbf{Q}\cdot\mathbf{r}-\omega t)]\,\mathrm{d}\mathbf{r}\,\mathrm{d}t.$$

$S(\mathbf{Q},\omega)$ is the Fourier transform in space and time of $G(\mathbf{r},t)$, the time-dependent pair-correlation function. The classical interpretation of $G(\mathbf{r},t)$ is that it is the probability of finding any atom at time t in a volume $\mathrm{d}\mathbf{r} = \mathrm{d}^3r$, if there is an atom at the origin at time zero.

4.1.5. Phonon dispersion relations

Both X-rays and neutrons are used for determining crystal structures, but the X-ray method plays the dominant role. The reverse is true for the measurement of phonon dispersion relations: the experimental determination of $\omega(\mathbf{q})$ *versus* $\mathbf{q}$ was first undertaken with X-rays, but the method has been superseded by the technique of coherent inelastic neutron scattering (or neutron spectroscopy). For phonon wavevectors lying anywhere within the first Brillouin zone, it is necessary to employ radiation of wavelength comparable with interatomic distances and of energy comparable with lattice vibrational energies. X-rays satisfy the first of these conditions, but not the second, whereas the opposite holds for infrared radiation. Thermal neutrons satisfy both conditions simultaneously.

4.1.5.1. Measurement with X-rays

Frequencies can be derived indirectly with X-rays from the intensity of the thermal diffuse scattering. For a monatomic crystal with one atom per primitive cell, there are no optic modes and the one-phonon TDS intensity, equation (4.1.3.6), reduces to

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = Q^2f^2e^{-2W}\sum_{j=1}^{3}\frac{E_j(\mathbf{q})}{\omega^2(\mathbf{q})}\cos^2\alpha_j(\mathbf{q})\delta(\mathbf{Q}\pm\mathbf{q}-\mathbf{Q_h}), \tag{4.1.5.1}$$

where $\alpha_j(\mathbf{q})$ is the angle between $\mathbf{Q}$ and the direction of polarization of the mode $(j\mathbf{q})$. There are three acoustic modes associated with each wavevector $\mathbf{q}$, but along certain directions of $\mathbf{Q}$ it is possible to isolate the intensities contributed by the individual modes by choosing $\alpha_j(\mathbf{q})$ to be close to 0 or 90°. Equation (4.1.5.1) can then be employed to derive the frequency $\omega_j(\mathbf{q})$ for just one mode. The measured intensity must be corrected for multiphonon and Compton scattering, both of which can exceed the intensity of the one-phonon scattering. The correction for two-phonon scattering involves an integration over the entire Brillouin zone, and this in turn requires an approximate knowledge of the dispersion relations. The correction for Compton scattering can be made by repeating the measurements at low temperature.

This X-ray method is hardly feasible for systems with several atoms in the primitive cell. It comes into its own for those few materials which cannot be examined by neutrons. These include boron, cadmium and samarium with high absorption cross sections for thermal neutrons, and vanadium with a very small coherent (and a large incoherent) cross section for the scattering of neutrons. An important feature of TDS measurements with X-rays is in providing an independent check on interatomic or intermolecular force constants derived from measurements with inelastic neutron scattering. The force model is used to generate

phonon frequencies and eigenvectors, which are then employed to compute the one-phonon and multi-phonon contributions to the X-ray TDS. Any discrepancy between calculated and observed X-ray intensities might be ascribed to such features as ionic deformation (Buyers *et al.*, 1968) or anharmonicity (Schuster & Weymouth, 1971).

With the availability of dedicated beamlines at third-generation synchrotrons, inelastic X-ray scattering is an alternative method of determining phonon dispersion relations in crystals (Burkel, 2000). The basic design of the X-ray instrument is the same as the three-axis spectrometer for neutron scattering (see Section 4.1.5.2 below): however, it is necessary to measure the minute change in energy of the scattered X-rays to a resolution of a few meV. This *tour de force* is achieved by adopting some novel experimental procedures. These include the use of a monochromator and analyser of perfect silicon crystals, both of which are operated under extreme conditions of Bragg back reflection ($\theta \simeq 89.95^\circ$). Also, energy scans are performed by varying the relative temperature (and thereby the relative lattice spacing) between the monochromator and analyser with millikelvin precision. The X-ray spot size is in the submillimetre range, and so very small samples can be examined. A good example of this X-ray method is the study by Ruf *et al.* (2001) of the optic and acoustic modes of GaN, which possesses the wurtzite structure: crystals of GaN are too small to be examined by the traditional neutron method.

4.1.5.2. Measurement with neutrons

The inelastic scattering of neutrons by phonons gives rise to changes of energy which are readily measured and converted to frequencies $\omega_j(\mathbf{q})$ using equation (4.1.4.1). The corresponding wavevector $\mathbf{q}$ is derived from the momentum conservation relation (4.1.4.4). Nearly all phonon dispersion relations determined to date have been obtained in this way. Well over 200 materials have been examined, including half the chemical elements, a large number of alloys and diatomic compounds, and rather fewer molecular crystals (Dolling, 1974; Bilz & Kress, 1979). Phonon dispersion curves have been determined in crystals with up to ten atoms in the primitive cell, for example, tetracyanoethylene (Chaplot *et al.*, 1983).

The principal instrument for determining phonon dispersion relations with neutrons is the triple-axis spectrometer, first designed and built by Brockhouse (Brockhouse & Stewart, 1958). The modern instrument is unchanged apart from running continuously under computer control. A beam of thermal neutrons falls on a single-crystal monochromator, which Bragg reflects a single wavelength on to the sample in a known orientation. The magnitude of the scattered wavevector, and hence the change of energy on scattering by the sample, is found by measuring the Bragg angle at which the neutrons are reflected by the crystal analyser. The direction of $\mathbf{k}$ is defined by a collimator between the sample and analyser.

In the 'constant $\mathbf{Q}$' mode of operating the triple-axis spectrometer, the phonon wavevector is kept fixed while the energy transfer $\hbar\omega$ is varied. This allows the frequency spectrum to be determined for all phonons sharing the same $\mathbf{q}$; the spectrum will contain up to $3n$ frequencies, corresponding to the $3n$ branches of the dispersion relations.

In an inelastic neutron scattering experiment, where the TDS intensity is of the order of one-thousandth of the Bragg intensity, it is necessary to use a large sample with a volume of 1 cm^3, or more. The sample should have a high cross section for coherent scattering as compared with the cross sections for incoherent scattering and for true absorption. Crystals containing hydrogen should be deuterated.

Dolling (1974) has given a comprehensive review of the measurement of phonon dispersion relations by neutron spectroscopy.

4.1.5.3. Interpretation of dispersion relations

The usual procedure for analysing dispersion relations is to set up the Born–von Kármán formalism with an assumed set of interatomic force constants Φ. The calculated frequencies $\omega_j(\mathbf{q})$ are then derived from the eigenvalues of the dynamical matrix $\mathbf{D}$ (Section 4.1.2.1) and the force constants fitted, by least squares, to the observed frequencies. Several sets of force constants may describe the frequencies equally well, and to decide which set is preferable it is necessary to compare eigenvectors as well as eigenvalues (Cochran, 1971).

The main interest in the curves is in testing different models of interatomic potentials, whose derivatives are related to the interatomic force constants. For the solid inert gases the curves are reproduced reasonably well using a two-parameter Lennard–Jones 6–12 potential, although calculated frequencies are systematically higher than the experimental points near the Brillouin-zone boundary (Fujii *et al.*, 1974). To reproduce the dispersion relations in metals it is necessary to use a large number of interatomic force constants, extending to at least fifth neighbours. The number of independent constants is then too large for a meaningful analysis with the Born–von Kármán theory, but in the pseudo-potential approximation (Harrison, 1966) only two parameters are required to give good agreement between calculated and observed frequencies of simple metals such as aluminium. In the rigid-ion model for ionic crystals, the ions are treated as point charges centred on the nuclei and polarization of the outermost electrons is ignored. This is unsatisfactory at high frequencies. In the shell model, polarization is accounted for by representing the ion as a rigid core connected by a flexible spring to a polarizable shell of outermost electrons. There are many variants of this model – extended shell, overlap shell, deformation dipole, breathing shell ... (Bilz & Kress, 1979). For molecular crystals the contributions to the force constants from the intermolecular forces can be derived from the nonbonded atomic pair potential of, say, the 6-exponential type:

$$\varphi(r) = -\frac{A_{ij}}{r^6} + B_{ij}\exp(-C_{ij}r).$$

Here, i, j label atoms in different molecules. The values of the parameters A, B, C depend on the pair of atomic species i, j only. For hydrocarbons they have been tabulated for different atom pairs by Kitaigorodskii (1966) and Williams (1967). The 6-exponential potential is applicable to molecular crystals that are stabilized mainly by London–van der Waals interactions; it is likely to fail when hydrogen bonds are present.

4.1.6. Measurement of elastic constants

There is a close connection between the theory of lattice dynamics and the theory of elasticity. Acoustic modes of vibration of long wavelength propagate as elastic waves in a continuous medium, with all the atoms in one unit cell moving in phase with one another. These vibrations are sound waves with velocities which can be calculated from the macroscopic elastic constants and from the density. The sound velocities are also given by the slopes, at $q = 0$, of the acoustic branches of the phonon dispersion relations. A knowledge of the velocities, or of the elastic constants, is necessary in estimating the TDS contribution to measured Bragg intensities.

The elastic constants relate the nine components of stress and nine components of strain, making 81 constants in all. This large number is reduced to 36, because there are only six independent components of stress and six independent components of strain. An economy of notation is now possible, replacing the indices 11 by 1, 22 by 2, 33 by 3, 23 by 4, 31 by 5 and 12 by 6, so that the

elastic constants are represented by c_{ij} with $i, j = 1, \ldots, 6$. Applying the principle of conservation of energy gives

$$c_{ij} = c_{ji}$$

and the number of constants is reduced further to 21. Crystal symmetry effects yet a further reduction. For cubic crystals there are just three independent constants (c_{11}, c_{12}, c_{44}) and the 6×6 matrix of elastic constants is

$$\begin{pmatrix} c_{11} & c_{12} & c_{12} & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{12} & 0 & 0 & 0 \\ c_{12} & c_{12} & c_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{44} \end{pmatrix}.$$

In principle, the elastic constants can be derived from static measurements of the four quantities – compressibility, Poisson's ratio, Young's modulus and rigidity modulus. The measurements are made along different directions in the crystal: at least six directions are needed for the orthorhombic system. The accuracy of the static method is limited by the difficulty of measuring small strains.

Dynamic methods are more accurate as they depend on measuring a frequency or velocity. For a cubic crystal, the three elastic constants can be derived from the three sound velocities propagating along the single direction [110]; for non-cubic crystals the velocities must be measured along a number of non-equivalent directions.

Sound velocities can be determined in a number of ways. In the ultrasonic pulse technique, a quartz transducer sends a pulse through the crystal; the pulse is reflected from the rear surface back to the transducer, and the elapsed time for the round trip of several cm is measured. Brillouin scattering of laser light is also used (Vacher & Boyer, 1972). Fluctuations in dielectric constant caused by (thermally excited) sound waves give rise to a Doppler shift of the light frequency. The sound velocity is readily calculated from this shift, and the elastic constants are then obtained from the velocities along several directions, using the Christoffel relations (Hearmon, 1956). The Brillouin method is restricted to transparent materials. This restriction does not apply to neutron diffraction methods, which employ the inelastic scattering of neutrons (Willis, 1986; Schofield & Willis, 1987; Popa & Willis, 1994).

Tables of elastic constants of cubic and non-cubic crystals have been compiled by Hearmon (1946, 1956) and by Huntingdon (1958).

4.2. Disorder diffuse scattering of X-rays and neutrons

By F. Frey, H. Boysen and H. Jagodzinski

4.2.1. Introduction

Diffuse scattering of X-rays, neutrons and other particles is an accompanying effect in all diffraction experiments aimed at structure analysis with the aid of elastic scattering. In this case, the momentum exchange of the scattered photon or particle includes the crystal as a whole; the energy transfer involved becomes negligibly small and need not be considered in diffraction theory. Static distortions as a consequence of structural changes cause typical elastic diffuse scattering. Many structural phenomena and processes contribute to diffuse scattering, and a general theory has to include all of them. Hence the exact treatment of diffuse scattering becomes very complex.

Inelastic scattering is due to dynamical fluctuations or ionization processes and may become observable as a 'diffuse' contribution in a diffraction pattern. A separation of elastic from inelastic diffuse scattering is generally possible, but difficulties may result from small energy exchanges that cannot be resolved for experimental reasons. The latter is true for scattering of X-rays by phonons, which have energies of the order of 10^{-2}–10^{-3} eV, values which are considerably smaller than 10 keV, a typical value for X-ray quanta. Another equivalent explanation, frequently forwarded in the literature, is the high speed of X-ray photons, such that the rather slow motion of atoms cannot be 'observed' by them during diffraction. Hence, all movements appear as static displacement waves of atoms, and temperature diffuse scattering is pseudo-elastic for X-rays. This is not true in the case of thermal neutrons, which have energies comparable to those of phonons. Phonon-related or thermal diffuse scattering is discussed separately in Chapter 4.1, *i.e.* the present chapter is mainly concerned with the elastic (or pseudo-elastic other than thermal) part of diffuse scattering. A particularly important aspect concerns diffuse scattering related to phase transitions, in particular the critical diffuse scattering observed at or close to the transition temperature. In simple cases, a satisfactory description may be given with the aid of a 'soft phonon', which freezes at the critical temperature, thus generating typical temperature-dependent diffuse scattering. If the geometry of the lattice is maintained during the transformation (*i.e.* there is no breakdown into crystallites of different cell geometry), the diffuse scattering is very similar to diffraction phenomena described in this chapter. Sometimes, however, very complicated interim stages (ordered or disordered) are observed, demanding a complicated theory for their full explanation (see, *e.g.*, Dorner & Comes, 1977).

Obviously, there is a close relationship between thermodynamics and diffuse scattering in disordered systems representing a stable or metastable thermal equilibrium. From the thermodynamical point of view, the system is then characterized by its grand partition function, which is intimately related to the correlation functions used in the interpretation of diffuse scattering. The latter is nothing other than a kind of 'partial partition function' where two atoms, or two cell occupancies, are fixed such that the sum of all partial partition functions represents the grand partition function. This fact yields the useful correlation between thermodynamics and diffuse scattering mentioned above, which may well be used for a determination of thermodynamical properties of the crystal. This important subject shall not be included here for the following reason: real three-dimensional crystals generally exhibit diffuse scattering by defects and/or disordering effects that are not in thermal equilibrium. They are created during crystal growth, or are frozen-in defects formed at higher temperatures. Hence a thermodynamical interpretation of diffraction data needs a careful study of diffuse scattering as a function of temperature or some other thermodynamical parameters. This can be done in very rare cases only, so the omission of this subject seems justified.

As shown in this chapter, electron-density fluctuations and distribution functions of defects play an important role in the complete interpretation of diffraction patterns. Both quantities may best be studied in the low-angle scattering range. Hence many problems cannot be solved without a detailed interpretation of low-angle diffraction (also called small-angle scattering).

Disorder phenomena in magnetic structures are also not specifically discussed here. Magnetic diffuse neutron scattering and special experimental techniques constitute a large subject by themselves. Many aspects, however, may be analysed along similar lines to those given here.

Glasses, liquids or liquid crystals show typical diffuse diffraction phenomena. Particle-size effects and strains have an important influence on the diffuse scattering. The same is true for dislocations and point defects such as interstitials or vacancies. These defects are mainly described by their strain field, which influences the intensities of sharp reflections like an artificial temperature factor: the Bragg peaks diminish in intensity while the diffuse scattering increases predominantly close to them. These phenomena are less important from a structural point of view, at least in the case of metals or other simple structures. This statement is true as long as the structure of the 'kernel' of defects may be neglected when compared with the influence of the strain field. Whether dislocations in more complicated structures meet this condition is not yet known.

Commensurate and incommensurate modulated structures and quasicrystals frequently show a typical diffuse scattering, a satisfactory explanation of which demands extensive experimental and theoretical study. A reliable structure determination becomes very difficult in cases where the interpretation of diffuse scattering has not been incorporated. Many erroneous structural conclusions have been published in the past. The solution of problems of this kind needs careful thermodynamical consideration as to whether a plausible explanation of the structural data can be given.

For all of the reasons mentioned above, this article cannot be complete. It is hoped, however, that it will provide a useful guide for those who need a full understanding of the crystal chemistry of a given structure.

The study of disorder in crystals by diffuse-scattering techniques can be performed with X-rays, neutrons or electrons. Each of these methods has its own advantages (and disadvantages) and they often can (or have to) be used in a complementary way (*cf.* Chapter 4.3 of this volume). Electron diffraction and microscopy are usually restricted to relatively small regions in space and thus supply information on a local scale, *i.e.* local defect structures. Moreover, electron-microscopy investigations are carried out on thin samples (films), where the disorder could be different from the bulk, and, in addition, could be affected by the high heat load deposited by the impinging electron beam. X-rays and neutrons sample larger crystal volumes and thus provide thermodynamically more important information on *averages* of the disorder. These methods are also better suited to the analysis of long-range correlated cooperative disorder phenomena. On the other hand, electron microscopy and diffraction often allow more direct access to disorder and can therefore provide valuable

Copyright © 2010 International Union of Crystallography

information about the underlying model, which can then be used for a successful interpretation of X-ray and neutron diffuse scattering. Basic aspects of electron diffraction and microscopy in structure determination are treated in Chapter 2.5 of this volume.

There is no comprehensive treatment of all aspects of diffuse scattering. Essential parts are treated in the textbooks by James (1954), Wilson (1962), Wooster (1962), Krivoglaz (1969, 1996*a*,*b*), Schwartz & Cohen (1977), Billinge & Thorpe (1998), Schweika (1998), Nield & Keen (2001), Fultz & Howe (2002), Frey (2003) and Welberry (2004); handbook articles have been written by Jagodzinski (1963, 1964*a*,*b*, 1987), Schulz (1982), Welberry (1985) and Moss *et al.* (2003), and a series of relevant papers has been collected by Collongues *et al.* (1977).

Finally, we mention that different symbols and 'languages' are used in the various diffraction methods. Quite a few of the new symbols in use are not really necessary, but some are caused by differences in the experimental techniques. For example, the neutron scattering length b may usually be equated with the atomic form factor f in X-ray diffraction. The differential cross section introduced in neutron diffraction represents the intensity scattered into an angular range dΩ and an energy range dE. The 'scattering law' in neutron work corresponds to the square of an (extended) structure factor; the 'static structure factor', a term used by neutron diffractionists, is nothing other than the conventional Patterson function. The complicated resolution functions in neutron work correspond to the well known Lorentz factors in X-ray diffraction. These have to be derived in order to include all the techniques used in diffuse-scattering work. In this article we try to preserve the most common symbols. In particular, the scattering vector will be denoted as $\mathbf{H}$, which is more commonly used in crystallography than $\mathbf{Q} = 2\pi\mathbf{H}$.

4.2.2. Basic scattering theory

4.2.2.1. General

Diffuse scattering results from deviations from the identity of translationally invariant scattering objects and from long-range correlations in space and time. Fluctuations of scattering amplitudes and/or phase shifts of the scattered wavetrains reduce the maximum capacity of interference (leading to Bragg reflections) and are responsible for the diffuse scattering, *i.e.* scattering parts that are not located in distinct spots in reciprocal space. Unfortunately, the terms 'coherent' and 'incoherent' scattering used in this context are not uniquely defined in the literature. Since all scattering processes are correlated in space and time, there is no incoherent scattering at all in its strict sense. A similar relationship exists for 'elastic' and 'inelastic' scattering. Here pure inelastic scattering would take place if the momentum and the energy were transferred to a single scatterer; on the other hand, an elastic scattering process would demand a uniform exchange of momentum and energy with the whole crystal. Obviously, both cases are idealized and the truth lies somewhere in between. In spite of this, many authors use the term 'incoherent' systematically for the diffuse scattering away from the Bragg peaks when all diffuse maxima or minima are due to structure factors of molecules or atoms only. Although this definition is unequivocal as such, it is physically incorrect. Other authors use the term 'coherent' for Bragg scattering only; all diffuse contributions are then called 'incoherent'. This definition is clear and unique since it considers space and time, but it does not differentiate between incoherent and inelastic. In the case of neutron scattering, both terms are essential and neither can be abandoned.

In neutron diffraction, the term 'incoherent scattering' refers to scattering by uncorrelated nuclear spin orientations or by a random distribution of isotopes of the same element. Hence another definition of 'incoherence' is proposed for scattering processes that are uncorrelated in space and time. In fact, there may be correlations between the spins *via* their magnetic field, but the correlation length in space (and time) may be very small, such that the scattering process appears to be incoherent. Even in these cases, the nuclei contribute to coherent (average structure) and incoherent scattering (diffuse background). Hence the scattering process cannot really be understood by assuming nuclei that scatter independently. For this reason, it seems to be useful to restrict the term 'incoherent' to cases where a random contribution to scattering is realized or, in other words, a continuous function exists in reciprocal space. This corresponds to a δ function in real four-dimensional space. The randomness may be attributed to a nucleus (neutron diffraction) or an atom (molecule). It follows from this definition that the scattering need not be constant, but may be modulated by structure factors of molecules. In this sense we shall use the term 'incoherent', remembering that it is incorrect from a physical point of view.

As mentioned in Chapter 4.1, the theory of thermal neutron scattering must be treated quantum mechanically. In principle, this is also true in the X-ray case. In the classical limit, however, the final expressions have a simple physical interpretation. Generally, the quantum-mechanical nature of the scattering function of thermal neutrons is negligible at higher temperatures and in those cases where energy or momentum transfers are not too large. In almost all disorder problems this classical interpretation is sufficient for the interpretation of diffuse-scattering phenomena. This is not quite true in the case of orientational disorder (plastic crystals) where H atoms are involved.

The basic formulae given below are valid in either the X-ray or the neutron case: the atomic form factor f replaces the coherent scattering length $b_{\rm coh}$ (abbreviated as b). The formulation in the frame of the van Hove correlation function $G(\mathbf{r}, t)$ (classical interpretation, coherent part) corresponds to a treatment by a four-dimensional Patterson function $P(\mathbf{r}, t)$.

The basic equations for the differential cross sections are

$$\frac{\mathrm{d}^2\sigma_{\rm coh}}{\mathrm{d}\Omega\ \mathrm{d}(\hbar\omega)} = N\frac{|\mathbf{k}|}{|\mathbf{k}_0|}\frac{\langle b\rangle^2}{2\pi\hbar}\int_{\mathbf{r}}\int_{t} G(\mathbf{r}, t) \times \exp\{2\pi i(\mathbf{H}\cdot\mathbf{r} - \nu t)\}\ \mathrm{d}\mathbf{r}\,\mathrm{d}t, \quad (4.2.2.1a)$$

$$\frac{\mathrm{d}^2\sigma_{\rm inc}}{\mathrm{d}\Omega\ \mathrm{d}(\hbar\omega)} = N\frac{|\mathbf{k}|}{|\mathbf{k}_0|}\frac{\langle b^2\rangle - \langle b\rangle^2}{2\pi\hbar}\int_{\mathbf{r}}\int_{t} G_{\rm s}(\mathbf{r}, t) \times \exp\{2\pi i(\mathbf{H}\cdot\mathbf{r} - \nu t)\}\ \mathrm{d}\mathbf{r}\,\mathrm{d}t, \quad (4.2.2.1b)$$

where N is the number of scattering nuclei of same chemical species; $\mathbf{k}$, $\mathbf{k}_0$ are the wavevectors after/before scattering and $\omega = 2\pi\nu$.

The integrations over space may be replaced by summations in disordered crystals, except in cases where structural elements exhibit a liquid-like behaviour. Then the van Hove correlation functions are

$$G(\mathbf{r}, t) = \frac{1}{N}\sum_{\mathbf{r}_j,\,\mathbf{r}_{j'}} \delta\{\mathbf{r} - [\mathbf{r}_{j'}(t) - \mathbf{r}_j(0)]\}, \quad (4.2.2.2a)$$

$$G_{\rm s}(\mathbf{r}, t) = \frac{1}{N}\sum_{\mathbf{r}_j} \delta\{\mathbf{r} - [\mathbf{r}_j(t) - \mathbf{r}_j(0)]\}. \quad (4.2.2.2b)$$

$G(\mathbf{r}, t)$ gives the probability that if there is an atom j at $\mathbf{r}_j(0)$ at time zero, there is an *arbitrary* atom j' at $\mathbf{r}_{j'}(t)$ at an *arbitrary* time t, while $G_{\rm s}(\mathbf{r}, t)$ refers to the *same* atom j at $\mathbf{r}_j(t)$ at time t.

Equations (4.2.2.1) may be rewritten using the four-dimensional Fourier transforms of G and $G_{\rm s}$, respectively:

$$S_{\rm coh}(\mathbf{H},\omega)=\frac{1}{2\pi}\int_{\mathbf{r}}\int_{t} G(\mathbf{r},t)\exp\{2\pi i(\mathbf{H}\cdot\mathbf{r}-\nu t)\}\,\mathrm{d}\mathbf{r}\,\mathrm{d}t, \quad (4.2.2.3a)$$

$$S_{\rm inc}(\mathbf{H},\omega)=\frac{1}{2\pi}\int_{\mathbf{r}}\int_{t} G_{\rm s}(\mathbf{r},t)\exp\{2\pi i(\mathbf{H}\cdot\mathbf{r}-\nu t)\}\,\mathrm{d}\mathbf{r}\,\mathrm{d}t, \quad (4.2.2.3b)$$

$$\frac{\mathrm{d}^2\sigma_{\rm coh}}{\mathrm{d}\Omega\,\mathrm{d}(\hbar\omega)}=N\frac{k}{k_0}\langle b\rangle^2 S_{\rm coh}(\mathbf{H},\omega), \quad (4.2.2.4a)$$

$$\frac{\mathrm{d}^2\sigma_{\rm inc}}{\mathrm{d}\Omega\,\mathrm{d}(\hbar\omega)}=N\frac{k}{k_0}[\langle b^2\rangle-\langle b\rangle^2]S_{\rm inc}(\mathbf{H},\omega). \quad (4.2.2.4b)$$

Incoherent scattering cross sections [(4.2.2.3*b*), (4.2.2.4*b*)] refer to one and the same particle (at different times). In particular, plastic crystals (see Section 4.2.5.5) may be studied by means of this incoherent scattering. It should be emphasized, however, that for reasons of intensity only disordered crystals with strong incoherent scatterers can be investigated by this technique. In practice, mostly samples that contain H atoms have been investigated. This topic will not be treated further in this article (see, *e.g.*, Springer, 1972; Lechner & Riekel, 1983). The following considerations are restricted to *coherent* scattering only.

Essentially the same formalism as given by equations (4.2.2.1*a*)–(4.2.2.4*a*) may be described using a generalized Patterson function, which is more familiar to crystallographers:

$$P(\mathbf{r},t)=\int_{\mathbf{r}'}\int_{t'=0}^{\tau}\rho(\mathbf{r}',t')\rho(\mathbf{r}'+\mathbf{r},t'+t)\,\mathrm{d}\mathbf{r}'\,\mathrm{d}t', \quad (4.2.2.5)$$

where ρ is the scattering density and τ denotes the time of observation. The only difference between $G(\mathbf{r},t)$ and $P(\mathbf{r},t)$ is the inclusion of the scattering weight (f or b) in $P(\mathbf{r},t)$. $P(\mathbf{r},t)$ is an extension of the usual spatial Patterson function $P(\mathbf{r})$. Similarly, S is replaced by another function,

$$\begin{aligned}2\pi S(\mathbf{H},\omega)&\equiv|F(\mathbf{H},\omega)|^2\\&=\int_{\mathbf{r}}\int_{t}P(\mathbf{r},t)\exp\{2\pi i(\mathbf{H}\cdot\mathbf{r}-\nu t)\}\,\mathrm{d}\mathbf{r}\,\mathrm{d}t,\end{aligned} \quad (4.2.2.6)$$

which is the Fourier transform of $P(\mathbf{r},t)$. One difficulty arises from neglecting the time of observation. Just as $S(\mathbf{H})$ [$\simeq|F(\mathbf{H})|^2$] is always proportional to the scattering volume V in the framework of kinematical theory or within Born's first approximation [*cf.* equation (4.2.2.1*a*)], so $S(\mathbf{H},\omega)$ [$\simeq|F(\mathbf{H},\omega)|^2$] is proportional to volume *and* observation time. In general, one does not make S proportional to τ, but one normalizes S to be independent of τ as $\tau\rightarrow\infty$: $2\pi S=(1/\tau)|F|^2$. Averaging over time τ gives therefore

$$\begin{aligned}S(\mathbf{H},\omega)=\frac{1}{2\pi}\int_{\mathbf{r}}\int_{t}\left\langle\int_{\mathbf{r}'}\rho(\mathbf{r}',t')\rho(\mathbf{r}'+\mathbf{r},t'+t)\,\mathrm{d}r'\right\rangle_{t'}\\\times\exp\{2\pi i(\mathbf{H}\cdot\mathbf{r}-\nu t)\}\,\mathrm{d}\mathbf{r}\,\mathrm{d}t.\end{aligned} \quad (4.2.2.7)$$

Special cases (see, *e.g.*, Cowley, 1981) are:

(1) *Pure elastic measurement*

$$\begin{aligned}I_{\rm e}\simeq S(\mathbf{H},0)&=\int_{\mathbf{r}}\left[\int_{t}P(\mathbf{r},t)\,\mathrm{d}t\right]\exp\{2\pi i\mathbf{H}\cdot\mathbf{r}\}\,\mathrm{d}\mathbf{r}\\&=\left|\sum_j f_j\langle\exp\{2\pi i\mathbf{H}\cdot\mathbf{r}_j(t)\}\rangle_t\right|^2.\end{aligned} \quad (4.2.2.8)$$

In this type of measurement, the time-averaged 'structure' is determined:

$$\langle\rho(\mathbf{r},t)\rangle_t=\int_{\mathbf{H}}|F(\mathbf{H},0)|\exp\{2\pi i\mathbf{H}\cdot\mathbf{r}\}\,\mathrm{d}\mathbf{H}.$$

The projection along the time axis in real (Patterson) space gives a section in Fourier space at $\omega=0$. True elastic measurement is a domain of neutron scattering. To determine the time-averaged structure of a statistically disordered crystal, dynamical disorder (phonon scattering) may be separated. For liquids or liquid-like systems this kind of scattering technique is rather ineffective, as the time-averaging procedure gives only a uniform particle distribution.

(2) *Integration over frequency (or energy)*

$$\begin{aligned}I_{\rm tot}\simeq\int_{\omega}|F(\mathbf{H},\omega)|^2\,\mathrm{d}\omega&=\int_{\omega}\int_{\mathbf{r}}\int_{t}P(\mathbf{r},t)\\&\times\exp\{2\pi i(\mathbf{H}\cdot\mathbf{r}-\nu t)\}\,\mathrm{d}\mathbf{r}\,\mathrm{d}t\,\mathrm{d}\omega\\&=\int_{\mathbf{r}}P(\mathbf{r},0)\exp\{2\pi i\mathbf{H}\cdot\mathbf{r}\}\,\mathrm{d}\mathbf{r}\end{aligned} \quad (4.2.2.9)$$

(*cf.* the properties of δ functions). In such an experiment, one determines the Patterson function for $t=0$, *i.e.* the instantaneous structure (a 'snapshot' of the correlation function): a projection in Fourier space along the energy axis gives a section in direct (Patterson) space at $t=0$. An energy integration is automatically performed in a conventional X-ray diffraction experiment ($|\mathbf{k}|\simeq|\mathbf{k}_0|$). One should bear in mind that in a real experiment there is, of course, an average over both the sample volume and the time of observation.

In most practical cases, averaging over time is equivalent to averaging over space: the total diffracted intensity may be regarded as the sum of the intensities from a large number of independent regions due to the limited coherence of a beam. At any time these regions take all possible configurations. Therefore, this sum of intensities is equivalent to the sum of intensities from any one region at different times,

$$\begin{aligned}\langle I_{\rm tot}\rangle_t&=\left\langle\sum_j\sum_{j'}f_jf_{j'}\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_j-\mathbf{r}_{j'})\}\right\rangle_t\\&=\sum_{j,j'}f_jf_{j'}\langle\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_j-\mathbf{r}_{j'})\}\rangle_t.\end{aligned} \quad (4.2.2.9a)$$

From the basic formulae one also derives the well known results for X-ray or neutron scattering by a periodic arrangement of particles in space [*cf.* equation (4.1.3.2) of Chapter 4.1]:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}=N\frac{(2\pi)^3}{V_{\rm c}}\sum_{\mathbf{h}}|F(\mathbf{H})|^2\delta(\mathbf{H}-\mathbf{G}), \quad (4.2.2.10)$$

$$F(\mathbf{H})=\sum_j f_j(\mathbf{H})\exp\{-W_j\}\exp\{2\pi i\mathbf{H}\cdot\mathbf{r}_j\}. \quad (4.2.2.11)$$

$F(\mathbf{H})$ denotes the Fourier transform of one cell (structure factor); $\mathbf{G}$ is the reciprocal-lattice vector and W is the Debye–Waller factor; the f's are assumed to be real.

The evaluation of the intensity expressions (4.2.2.6), (4.2.2.8) or (4.2.2.9), (4.2.2.9*a*) for a disordered crystal must be performed in terms of statistical relationships between scattering factors and/or atomic positions.

4.2.2.2. X-ray and neutron scattering

From these basic scattering formulae some conclusions on the relative merits of X-rays and neutrons can be drawn. Both X-rays and thermal neutrons possess wavelengths of the order of interatomic distances and are thus well suited to the study of the atomic structure of condensed matter. Besides this, there are fundamental differences that make one or the other the radiation of choice for a particular problem or enable them to be used with advantage in a complementary manner. These differences are well documented in a number of textbooks on diffraction and are widely exploited in the determination of average structures. One fundamental difference is related to the interaction with matter: while X-rays are scattered by the electrons, neutrons are scat-

tered by the atomic nuclei (we are disregarding magnetic interactions in this chapter), *i.e.* X-rays probe the distribution of charges, which (in particular for light atoms) may not coincide with that of the nuclei. This fact forms the basis for the well known X − N technique in the analysis of Bragg intensities. No such studies of disorder diffuse scattering have been performed up to now, but may be a challenge for the future. As a consequence of the different size of the scattering objects, the scattering amplitude falls off with increasing scattering vector $|\mathbf{H}| = (\sin\theta)/\lambda$ for X-rays (the form factor), while it is constant for neutrons. Since for a complete interpretation of diffuse scattering high Q values are generally required, neutrons have their advantages in this respect. The scattering intensity varies as Z^2 (Z = number of electrons) for X-rays and more-or-less erratically for neutrons, for which it also depends on the specific isotope. This imposes problems for X-rays when trying to detect light elements (in particular H and O) in the presence of heavy elements or discriminating neighbouring elements in the periodic table (*e.g.* Al/Si/Mg, Fe/Co/Ni). On the other hand, these differences in scattering power can be used to identify the atomic species taking part in the disorder by comparing the intensity distributions observed with both methods. The contrast can be further enhanced by marking selected atoms by isotope substitution for neutrons or by using anomalous dispersion for X-rays.

In many practical cases, the complementarities of the two methods can be exploited by using them simultaneously. Some illustrative examples can be found in Boysen & Frey (1998).

Another important difference is in the energies given by the dispersion laws $E_x = \hbar ck$ and $E_n = (\hbar^2/2m)k^2$ for X-rays and neutrons, respectively, where c is the velocity of light, m is the neutron mass and $k = 2\pi/\lambda$ is the wavevector. For a typical wavelength, λ =1.54 Å (Cu $K\alpha$) ($k = 4.08$ Å^{-1}), $E_x = 8$ keV and E_n = 35 meV, *i.e.* the energies differ by almost six orders of magnitude. This means that neutron energies are similar to those of typical collective lattice excitations, which may therefore be determined more easily by neutron spectroscopy. The basic question of whether the underlying disorder is of static or dynamic origin can be answered using neutrons alone, *e.g.* by comparing the 'integral' (= elastic + inelastic) scattered intensity (*i.e.* without energy analysis, using a two-axis diffractometer) with the purely elastic intensity by placing an analyser crystal set to zero energy transfer in the diffracted beam (using a triple-axis diffractometer) or using time-of-flight methods. The high energy resolution of Mössbauer radiation can also be used for this purpose. Owing to the very low available intensities, however, this technique has only been applied occasionally. In the elastic mode, diffracted neutron intensities are also usually rather weak. The decision can, however, also be made simply by comparing the positions of the intensity maxima in reciprocal space. This follows from a consideration of the relative changes of the momentum transfer (the wavevector) in the two cases. For example, for an energy change $\Delta E = E_f - E_i$ (the subscripts refer to final and incident energies) of 1 meV, one obtains a change in the scattered wavevector Δk_f of 2×10^{-6} Å^{-1} for X-rays and 0.06 Å^{-1} for neutrons. In a two-axis experiment where the detector does not discriminate energies, *i.e.* without prior knowledge of the real energies, the distribution of diffuse intensities has to be drawn as if the scattering had been elastic ($\Delta E = 0$). In other words, the signal appears at a position displaced by Δk_f. From the estimations above it is clear that only in the neutron case can a measurable effect be expected.

Other specific features of neutrons include their magnetic moment (magnetic scattering is still a domain of neutrons, although progress is now being made with synchrotron radiation) and (nuclear) spin and isotope incoherent scattering processes (which allow the determination of the self-correlation functions). It is possible to separate the spin-incoherent part and distinguish between nuclear and magnetic scattering using polarization analysis. For most elements scattering and absorption is much weaker for neutrons, allowing larger samples to be analysed and sample environments (furnaces, pressure cells, electric and magnetic fields, special atmospheres *etc.*) to be handled much more easily. Differences in the experimental techniques for X-ray and neutron scattering are discussed in Section 4.2.8.

4.2.3. Qualitative treatment of structural disorder

4.2.3.1. Basic mathematics

Any structure analysis of disordered structures should start with a qualitative interpretation of diffuse scattering. This may be achieved with the aid of Fourier transforms and convolutions. A thorough mathematical treatment of Fourier transforms is given in Chapter 1.3 of this volume; here we give a simple short overview of the practical use of Fourier transforms, convolutions, their algebraic operations and examples of functions which are frequently used in diffraction physics (see, *e.g.*, Patterson, 1959; Jagodzinski, 1987). For simplicity, the following modified notation is used in this section: functions in real space are represented by lower-case letters, *e.g.* $a(\mathbf{r})$, $b(\mathbf{r})$, ... except for $F(\mathbf{r})$ [also, more frequently, denoted as $\rho(\mathbf{r})$] and $P(\mathbf{r})$, which are used as general symbols for a structure and the Patterson function, respectively; functions in reciprocal space are represented by capital letters $A(\mathbf{H})$, $B(\mathbf{H})$; and $\mathbf{r}$ and $\mathbf{H}$ are general vectors in real and reciprocal space, respectively. H, K, L denote continuous variables in reciprocal space; integer values are given by the commonly used symbols h, k, l. $Hx + Ky + Lz$ is the scalar product $\mathbf{H}\cdot\mathbf{r}$; d$\mathbf{r}$ and d$\mathbf{H}$ indicate integrations in three dimensions in real and reciprocal space, respectively. Even for X-rays, the electron density $\rho(\mathbf{r})$ will generally be replaced by the scattering potential $a(\mathbf{r})$. Consequently, anomalous contributions to scattering may be included if complex functions $a(\mathbf{r})$ are admitted. In the neutron case $a(\mathbf{r})$ refers to a quasi-potential. Using this notation we obtain the scattered amplitude

$$A(\mathbf{H}) = \int_{\mathbf{r}} a(\mathbf{r}) \exp\{2\pi i \mathbf{H}\cdot\mathbf{r}\}\, \mathrm{d}\mathbf{r}, \qquad (4.2.3.1a)$$

$$a(\mathbf{r}) = \int_{\mathbf{H}} A(\mathbf{H}) \exp\{-2\pi i \mathbf{H}\cdot\mathbf{r}\}\, \mathrm{d}\mathbf{H} \qquad (4.2.3.1b)$$

(constant factors are omitted).

$a(\mathbf{r})$ and $A(\mathbf{H})$ are reversibly and uniquely determined by Fourier transformation. Consequently, equations (4.2.3.1) may simply be replaced by $a(\mathbf{r}) \leftrightarrow A(\mathbf{H})$, where the double-headed arrow represents the two integrations given by (4.2.3.1) and means: $A(\mathbf{H})$ is the Fourier transform of $a(\mathbf{r})$ and *vice versa.* The following relations may easily be derived from (4.2.3.1):

$$a(\mathbf{r}) + b(\mathbf{r}) \leftrightarrow A(\mathbf{H}) + B(\mathbf{H}) \quad \text{(law of addition)}, \qquad (4.2.3.2)$$

$$\beta a(\mathbf{r}) \leftrightarrow \beta A(\mathbf{H}) \quad \text{(law of scalar multiplication)}, \qquad (4.2.3.3)$$

where β is a scalar quantity.

On the other hand, the multiplication of two functions does not yield a relation of similar symmetrical simplicity:

$$a(\mathbf{r})b(\mathbf{r}) \leftrightarrow \int A(\mathbf{H}')B(\mathbf{H}-\mathbf{H}')\, \mathrm{d}\mathbf{H}' = A(\mathbf{H}) * B(\mathbf{H}), \qquad (4.2.3.4a)$$

$$a(\mathbf{r}) * b(\mathbf{r}) = \int a(\mathbf{r}')b(\mathbf{r}-\mathbf{r}')\, \mathrm{d}\mathbf{r}' \leftrightarrow A(\mathbf{H})B(\mathbf{H}) \qquad (4.2.3.4b)$$

(the laws of convolution and multiplication).

For simplicity, the complete convolution integral is abbreviated as $a(\mathbf{r}) * b(\mathbf{r})$. Since $a(\mathbf{r})b(\mathbf{r}) = b(\mathbf{r})a(\mathbf{r})$,

$$\int A(\mathbf{H}')B(\mathbf{H}-\mathbf{H}')\, \mathrm{d}\mathbf{H}' = \int B(\mathbf{H}')A(\mathbf{H}-\mathbf{H}')\, \mathrm{d}\mathbf{H}'$$

and *vice versa.* The convolution operation is commutative in either space.

The distribution law $a(b+c) = ab + ac$ is valid for the convolution as well:

$$a(\mathbf{r}) * [b(\mathbf{r}) + c(\mathbf{r})] = a(\mathbf{r}) * b(\mathbf{r}) + a(\mathbf{r}) * c(\mathbf{r}). \quad (4.2.3.5)$$

The associative law of multiplication does not hold if mixed products (convolution and multiplication) are used:

$$a(\mathbf{r}) * [b(\mathbf{r})c(\mathbf{r})] \neq [a(\mathbf{r}) * b(\mathbf{r})]c(\mathbf{r}). \quad (4.2.3.6)$$

From equations (4.2.3.1) one has

$$\begin{aligned} a(\mathbf{r} - \mathbf{r}_0) &\leftrightarrow A(\mathbf{H}) \exp\{2\pi i \mathbf{H} \cdot \mathbf{r}_0\}, \\ A(\mathbf{H} - \mathbf{H}_0) &\leftrightarrow a(\mathbf{r}) \exp\{-2\pi i \mathbf{H}_0 \cdot \mathbf{r}\} \end{aligned} \quad (4.2.3.7)$$

(the law of displacements).

Since symmetry operations are well known to crystallographers in reciprocal space as well, the law of inversion is only mentioned here:

$$a(-\mathbf{r}) \leftrightarrow A(-\mathbf{H}). \quad (4.2.3.8)$$

Consequently, if $a(\mathbf{r}) = a(-\mathbf{r})$, then $A(\mathbf{H}) = A(-\mathbf{H})$. In order to calculate the intensity, the complex conjugate $A^+(\mathbf{H})$ is needed:

$$a^+(\mathbf{r}) \leftrightarrow A^+(-\mathbf{H}), \quad (4.2.3.9a)$$

$$a^+(-\mathbf{r}) \leftrightarrow A^+(\mathbf{H}). \quad (4.2.3.9b)$$

Equations (4.2.3.9) yield the relationship $A^+(-\mathbf{H}) = A(\mathbf{H})$ ('Friedel's law') if $a(\mathbf{r})$ is a *real* function. The multiplication of a function with its conjugate is given by

$$a(\mathbf{r}) * a^+(-\mathbf{r}) \leftrightarrow |A(\mathbf{H})|^2,$$

with

$$a(\mathbf{r}) * a^+(-\mathbf{r}) = \int a(\mathbf{r}')a(\mathbf{r}' - \mathbf{r})\,\mathrm{d}\mathbf{r}' = P(\mathbf{r}). \quad (4.2.3.10)$$

Note that $P(\mathbf{r}) = P(-\mathbf{r})$ is not valid if $a(\mathbf{r})$ is complex. Consequently $|A(-\mathbf{H})|^2 \neq |A(\mathbf{H})|^2$. This is shown by evaluating $A(-\mathbf{H})A^+(-\mathbf{H})$,

$$A(-\mathbf{H})A^+(-\mathbf{H}) \leftrightarrow a(-\mathbf{r}) * a^+(\mathbf{r}) = P(-\mathbf{r}). \quad (4.2.3.11)$$

Equation (4.2.3.11) is very useful for the determination of the contribution of anomalous scattering to diffuse reflections.

Most of the diffuse-diffraction phenomena observed may be interpreted qualitatively or even semiquantitatively in a very simple manner using a limited number of important Fourier transforms, which are given below.

4.2.3.2. Fourier transforms

(1) *Normalized Gaussian function*

$$(\pi^{3/2}\alpha\beta\gamma)^{-1} \exp\{-(x/\alpha)^2 - (y/\beta)^2 - (z/\gamma)^2\}. \quad (4.2.3.12)$$

This plays an important role in statistics. Its Fourier transform is again a Gaussian:

$$\exp\{-\pi^2(\alpha^2H^2 + \beta^2K^2 + \gamma^2L^2)\}. \quad (4.2.3.12a)$$

The three parameters α, β, γ determine the width of the curve. Small values of α, β, γ represent a broad maximum in reciprocal space but a narrow one in real space and *vice versa*. The constant has been chosen such that the integral of the Gaussian is unity in real space. The product of two Gaussians in reciprocal space,

$$\begin{aligned} &\exp\{-\pi^2(\alpha_1^2H^2 + \beta_1^2K^2 + \gamma_1^2L^2)\} \\ &\quad \times \exp\{-\pi^2(\alpha_2^2H^2 + \beta_2^2K^2 + \gamma_2^2L^2)\} \\ &\quad = \exp\{-\pi^2[(\alpha_1^2 + \alpha_2^2)H^2 + (\beta_1^2 + \beta_2^2)K^2 \\ &\qquad + (\gamma_1^2 + \gamma_2^2)L^2]\} \end{aligned} \quad (4.2.3.12b)$$

again represents a Gaussian of the same type, but with a sharper profile. Consequently, its Fourier transform, which is given by the convolution of the transforms of the two Gaussians, is itself a Gaussian with a broader maximum. It may be concluded from this discussion that the Gaussian with $\alpha, \beta, \gamma \to 0$ is a δ function in real space and its Fourier transform is unity in reciprocal space.

(2) δ *'functions'*

For a proper definition see, *e.g.*, Cowley (1981). Here the term is used with the relaxed definition $\delta(\mathbf{r}) = 1$ if $\mathbf{r} = 0$ and zero elsewhere.

$$\delta(\mathbf{r}) \leftrightarrow 1 \text{ and } \delta(\mathbf{H}) \leftrightarrow 1$$

and

$$\delta(\mathbf{r} - \mathbf{r}_0) \leftrightarrow \exp\{2\pi i \mathbf{H} \cdot \mathbf{r}_0\}.$$

The convolution of two δ functions is again a δ function.

(3) *Lattices*

Lattices in real and reciprocal space may be described by δ functions:

$$l(\mathbf{r}) = \sum_{\mathbf{n}} \delta(\mathbf{r} - \mathbf{n})$$

and

$$L(\mathbf{H}) = \sum_{\mathbf{h}} \delta(\mathbf{H} - \mathbf{G}),$$

where $\mathbf{n} = n_1\mathbf{a} + n_2\mathbf{b} + n_3\mathbf{c}$ and $\mathbf{G} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$ represent the components of the translation vectors in real and reciprocal space, respectively. The Fourier transforms of lattices with orthogonal basis vectors of unit length and an infinite number of points in all three dimensions correspond to each other. In the following the relation $l(\mathbf{r}) \leftrightarrow L(\mathbf{H})$ is used in this generalized sense.

The Fourier transforms of *finite* lattices with N_1, N_2, N_3 nodes in the basic directions $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$ are given by

$$\frac{\sin \pi N_1 H}{\sin \pi H} \frac{\sin \pi N_2 K}{\sin \pi K} \frac{\sin \pi N_3 L}{\sin \pi L}, \quad (4.2.3.13)$$

which is a periodic function in reciprocal space, but, strictly speaking, nonperiodic in real space. It should be pointed out that the correspondence of lattices in either space is valid only if the origin coincides with a δ function. This fact may easily be understood by applying the law of displacement given in equation (4.2.3.7).

(4) *Box functions*

The Fourier transform of a box function $b(\mathbf{r})$ with unit height is

$$b(\mathbf{r}) \leftrightarrow \frac{\sin \pi\alpha H}{\pi H} \frac{\sin \pi\beta K}{\pi K} \frac{\sin \pi\gamma L}{\pi L}. \quad (4.2.3.14)$$

α, β, γ describe its extension in the three dimensions. This function is real as long as the centre of symmetry is placed at the origin, otherwise the law of displacement has to be used. The convolution of the box function with its inverse is needed for the calculation of intensities:

$$\begin{aligned} t(\mathbf{r}) &= b(\mathbf{r}) * b(-\mathbf{r}) \\ &\leftrightarrow \left(\frac{\sin \pi\alpha H}{\pi H}\right)^2 \left(\frac{\sin \pi\beta K}{\pi K}\right)^2 \left(\frac{\sin \pi\gamma L}{\pi L}\right)^2. \end{aligned} \quad (4.2.3.15)$$

$t(\mathbf{r})$ is a generalized three-dimensional 'pyramid' of doubled basal length when compared with the corresponding length of the box function. The top of the pyramid has a height given by the number of unit cells covered by the box function. Obviously, the box function generates a particle size in real space by multiplying the infinite lattice $l(\mathbf{r})$ by $b(\mathbf{r})$. Fourier transformation yields a particle-size effect well known in diffraction. Correspondingly, the termination effect of a Fourier synthesis is caused by multiplication by a box function in reciprocal space, which causes a broadening of maxima in real space.

(5) *Convolutions*

It is often very useful to elucidate the convolution given in equations (4.2.3.4) by introducing the corresponding pictures in real or reciprocal space. Since $1 \cdot f(\mathbf{r}) = f(\mathbf{r})$, $\delta(\mathbf{H}) * F(\mathbf{H}) = F(\mathbf{H})$, the convolution with a δ function must result in an identical picture of the second function, although the function is used as $f(-\mathbf{r})$ in the integrals of equations (4.2.3.4), $f(\mathbf{r} - \mathbf{r}')$ with $\mathbf{r}'$ as variable in the integral of convolution. The convolution with $f(-\mathbf{r})$ brings the integral into the form

$$\int f(\mathbf{r}')\, f(\mathbf{r}' - \mathbf{r})\, \mathrm{d}\mathbf{r}', \tag{4.2.3.16}$$

which is known as the Patterson (or self- or auto-convolution) function and represents the generalized Patterson function including anomalous scattering [*cf.* equation (4.2.3.10)].

The change of the variable in the convolution integral may sometimes lead to confusion if certain operations are applied to the arguments of the functions entering the integral. Hence it is useful to mention the invariance of the convolution integral with respect to a change of sign, or a displacement, respectively, if applied to $\mathbf{r}'$ in both functions. Consequently, the convolution with the inverted function $a(\mathbf{r}) * b(-\mathbf{r})$ may be determined as follows:

$$\begin{aligned} b'(\mathbf{r}) &= b(-\mathbf{r}), \\ a(\mathbf{r}) * b(-\mathbf{r}) &= a(\mathbf{r}) * b'(\mathbf{r}) = \int a(\mathbf{r}')b'(\mathbf{r} - \mathbf{r}')\, \mathrm{d}\mathbf{r}', \\ &= \int a(\mathbf{r}')b(\mathbf{r}' - \mathbf{r})\, \mathrm{d}\mathbf{r}' = P'(\mathbf{r}). \end{aligned} \tag{4.2.3.17}$$

This equation means that the second function is displaced into the positive direction by $\mathbf{r}$, then multiplied by the first function and integrated. In the original meaning of the convolution, the operation represents a displacement of the second function in the positive direction and an inversion at the displaced origin before multiplication and subsequent integration. On comparing the two operations it may be concluded that $P'(\mathbf{r}) \neq P'(-\mathbf{r})$ if the second function is acentric. For real functions both have to be acentric. In a similar way, it may be shown that the convolution

$$\begin{aligned} a(\mathbf{r} - \mathbf{m}) * b(\mathbf{r} - \mathbf{m}') &= \int_{\mathbf{r}'} a(\mathbf{r}' - \mathbf{m})b(\mathbf{r} - \mathbf{m}' - \mathbf{r}')\, \mathrm{d}\mathbf{r}' \\ &= \int_{\mathbf{r}''} a(\mathbf{r}'')b(\mathbf{r} - \mathbf{m}' - \mathbf{m} - \mathbf{r}'')\, \mathrm{d}\mathbf{r}''. \end{aligned} \tag{4.2.3.18}$$

Equation (4.2.3.18) indicates a displacement by $\mathbf{m}' + \mathbf{m}$ with respect to the convolution of the undisplaced functions. Consequently,

$$\delta(\mathbf{r} - \mathbf{m}) * \delta(\mathbf{r} - \mathbf{m}') = \delta(\mathbf{r} - \mathbf{m} - \mathbf{m}'). \tag{4.2.3.19}$$

Obviously, the commutative law of convolution is obeyed; on the other hand, the convolution with the inverted function yields

$$\delta(\mathbf{r} - \mathbf{m}' + \mathbf{m}),$$

indicating that the commutative law (interchange of $\mathbf{m}$ and $\mathbf{m}'$) is violated because of the different signs of $\mathbf{m}$ and $\mathbf{m}'$.

The effectiveness of the method outlined above may be greatly improved by introducing further Fourier transforms of useful functions in real and reciprocal space (Patterson, 1959).

4.2.3.3. General formulation of a disorder problem

From these basic concepts the generally adopted method in a disorder problem is to try to separate the scattering intensity into two parts, namely one part $\langle\rho\rangle$ from an average periodic structure where formulae (4.2.2.10), (4.2.2.11) apply and a second part $\Delta\rho$ resulting from fluctuations from this average (see, *e.g.*, Schwartz & Cohen, 1977). One may write this formally as

$$\rho = \langle\rho\rangle + \Delta\rho, \tag{4.2.3.20}$$

where $\langle\rho\rangle = \langle\rho_\mathrm{c}\rangle * l$ is defined to be time-independent and periodic in space and $\langle\Delta\rho\rangle = 0$. $\langle\rho_\mathrm{c}\rangle = (1/N)\sum_i \rho_i$ is the density of the average unit cell obtained by the projection of all unit cells into a single one. Fourier transformation gives the average amplitude,

$$\langle A\rangle = \langle F\rangle L = \sum_i \langle F\rangle \exp\{2\pi i\mathbf{H}\cdot\mathbf{r}_i\}, \tag{4.2.3.21a}$$

where $\langle F\rangle$ is the usual structure factor (4.2.2.11). The difference structure $\Delta\rho$ leads to the difference amplitude,

$$\begin{aligned} \Delta A = A - \langle A\rangle &= \sum_i (F_i - \langle F\rangle)\exp\{2\pi i\mathbf{H}\cdot\mathbf{r}_i\} \\ &= \sum_i \Delta F_i \exp\{2\pi i\mathbf{H}\cdot\mathbf{r}_i\}. \end{aligned} \tag{4.2.3.21b}$$

Because cross terms $\langle\rho\rangle * \Delta\rho$ vanish by definition, the Patterson function is

$$\begin{aligned} &[\langle\rho(\mathbf{r})\rangle + \Delta\rho(\mathbf{r})] * [\langle\rho(-\mathbf{r})\rangle + \Delta\rho(-\mathbf{r})] \\ &\quad = [\langle\rho(\mathbf{r})\rangle * \langle\rho(-\mathbf{r})\rangle] + [\Delta\rho(\mathbf{r}) * \Delta\rho(-\mathbf{r})]. \end{aligned} \tag{4.2.3.22}$$

Fourier transformation gives

$$I \simeq |\langle F\rangle|^2 + |\Delta F|^2, \tag{4.2.3.23a}$$

$$|\Delta F|^2 \simeq \langle |F|^2\rangle - |\langle F\rangle|^2. \tag{4.2.3.23b}$$

Since $\langle\rho\rangle$ is periodic, the first term in (4.2.3.23*a*) describes Bragg scattering,

$$I_\mathrm{B} = \langle A\rangle\langle A^*\rangle = |\langle F\rangle|^2 L, \tag{4.2.3.24}$$

where $\langle F\rangle$ plays the normal role of a structure factor of *one* cell of the averaged structure. The second term corresponds to diffuse scattering,

$$I_\mathrm{D} = \langle \Delta A \Delta A^*\rangle = \left\langle \sum_i \sum_j \Delta F_i \Delta F_j^* \exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_i - \mathbf{r}_j)\}\right\rangle. \tag{4.2.3.25}$$

In many cases, diffuse interferences are centred exactly at the positions of the Bragg reflections. It is then a serious experimental problem to decide whether the observed intensity distribution is due to Bragg scattering obscured by crystal-size limitations or due to other scattering phenomena.

If disordering is exclusively time-dependent, $\langle\rho\rangle$ represents the time average, whereas $\langle F\rangle$ gives the pure elastic scattering part [*cf.* (4.2.2.8)] and ΔF refers to inelastic scattering only.

4.2.3.4. General aspects of diffuse scattering

Diffuse scattering may be classified in various ways which may be related to specific aspects of the intensity distribution, *e.g.* according to the type of disorder: substitutional (or density or chemical) or displacive. The general expression (4.2.3.25), which may be rewritten as

$$I_{\rm D} = \left\langle \sum_k \left(\sum_i \Delta F_i \Delta F_{i+k} \right) \exp\{2\pi i \mathbf{H}\cdot\mathbf{r}_k\} \right\rangle = \sum_k \langle \Delta F \Delta F^* \rangle_k \exp\{2\pi i \mathbf{H}\cdot\mathbf{r}_k\}, \quad (4.2.3.26)$$

where $\mathbf{r}_k = \mathbf{r}_i - \mathbf{r}_j$, contains the difference structure factor ΔF, which may formally be written as

$$\Delta F = (\Delta f)\exp\{2\pi i \mathbf{H}\cdot(\mathbf{r}+\Delta\mathbf{r})\},$$

where (Δf) denotes a fluctuation of the scattering density (the form factor in the case of X-rays and the scattering length in the case of neutrons; note that this may include vacancies) and $\Delta\mathbf{r}$ denotes a fluctuation of the position, *i.e.* they refer to substitutional and displacive disorder, respectively. Although the two types often occur together in real crystals, they may be discriminated through their different dependence on the modulus of the scattering vector $\mathbf{H}$. This may be seen by considering the diffuse scattering of completely random fluctuations, *i.e.* without any correlations. For substitutional disorder one easily derives from (4.2.3.26)

$$I_{\rm D} = N\langle \Delta F^2 \rangle = N\langle \Delta f^2 \rangle,$$

while for displacive fluctuations with small amplitudes $\Delta\mathbf{r}$ the exponential may be expanded:

$$\exp\{2\pi i \mathbf{H}\cdot\Delta\mathbf{r}_i\} \simeq (1 + 2\pi i \mathbf{H}\cdot\Delta\mathbf{r}_i + \ldots),$$

leading to

$$I_{\rm D} = Nf^2 \sum_k \sum_i (2\pi\mathbf{H}\cdot\Delta\mathbf{r}_i)(2\pi\mathbf{H}\cdot\Delta\mathbf{r}_{i+k}) \exp\{2\pi i \mathbf{H}\cdot\mathbf{r}_k\} \quad (4.2.3.27)$$

and

$$I_{\rm D} = Nf^2 4\pi^2 H^2 \langle \Delta r_i^2 \rangle_i. \quad (4.2.3.28)$$

Hence in the substitutional case the diffuse intensity is constant throughout reciprocal space, while in the displacive case it increases with H^2, *i.e.* it is zero near the origin. Any correlations will modulate this intensity, but will not change this general behaviour.

A second classification is related to the dimensionality of the disorder: one-dimensional disorder between two-dimensionally ordered objects (planes) leading to diffuse streaks perpendicular to the planes, two-dimensional disorder between one-dimensionally ordered objects (chains) leading to diffuse planes and general three-dimensional disorder.

These different types of disorder will be further discussed separately in the next paragraphs.

From the derivation in Section 4.2.3.3, one may note that information about an averaged disordered structure is contained in the Bragg scattering governed by

$$\langle F \rangle = \sum_i n_i f_i \exp\{2\pi\mathbf{H}\cdot\mathbf{r}_i\} T_i(\mathbf{H}), \quad (4.2.3.29)$$

where $T_i(\mathbf{H})$ is the Debye–Waller factor. Back-transformation to real space gives

$$\langle \rho \rangle = \sum_i n_i f_i \delta(\mathbf{r}-\mathbf{r}_i) * \text{p.d.f.}_i(\mathbf{r}-\mathbf{r}_i), \quad (4.2.3.30)$$

i.e. each average position is convoluted with p.d.f.$_i(\mathbf{r}-\mathbf{r}_i)$, the probability density function, which is the Fourier transform of $T_i(\mathbf{H})$. Any disorder model derived from the diffuse scattering must therefore comply with the p.d.f., *i.e.* this may and should be used to validate these models.

4.2.3.5. Types of diffuse scattering

4.2.3.5.1. Substitutional fluctuations, occupational disorder

As mentioned above, a completely random distribution of chemical species leads to a uniform distribution of diffuse intensity, which is also called monotonic Laue scattering. For example, for a binary alloy with scattering densities f_1 and f_2 and concentrations c_1 and c_2 this is simply given by $I_{\rm D} \propto c_1 c_2 (f_1 - f_2)^2$. Several authors use this, *i.e.* the intensity of a random distribution of occupancies, to define a so-called Laue unit, and therewith to put the general diffuse scattering on a relative scale.

Any deviations from the monotonic Laue scattering may be due either to the scattering factor of the objects (*e.g.* molecules) or to short-range-order correlations. For example, for a simple defect pair with distance $\mathbf{R}$ we have

$$I_{\rm D} \propto c_1 c_2 (f_1 - f_2)^2 [1 + \cos(2\pi\mathbf{H}\cdot\mathbf{R})], \quad (4.2.3.31a)$$

or for more general short-range order

$$I_{\rm D} \propto c_1 c_2 (f_1 - f_2)^2 \sum_n \alpha_n \cos(2\pi\mathbf{H}\cdot\mathbf{r}_n), \quad (4.2.3.31b)$$

where α_n are Warren–Cowley short-range-order parameters, as will be discussed in more detail in Section 4.2.5.4.

For a periodic modulation $\Delta f_n = f_A \cos(2\pi\mathbf{K}\cdot\mathbf{r}_n)$

$$I_{\rm D} \propto f_A^2 \left| \sum_n \left[\exp\{2\pi i(\mathbf{H}+\mathbf{K})\cdot\mathbf{r}_n\} + \exp\{2\pi i(\mathbf{H}-\mathbf{K})\cdot\mathbf{r}_n\} \right] \right|^2 \propto f_A^2 \sum_G \delta(\mathbf{H} - \mathbf{G} \pm \mathbf{K}), \quad (4.2.3.32)$$

where $\mathbf{G}$ is a reciprocal-lattice vector.

Hence a harmonic density modulation of a structure in real space leads to pairs of satellites in reciprocal space. Each main reflection is accompanied by a pair of satellites in the directions $\mp\Delta\mathbf{H}$ with phases $\mp 2\pi\varphi$. The reciprocal lattice may then be written in the following form:

$$L(\mathbf{H}) + \frac{\alpha}{2} L(\mathbf{H}+\Delta\mathbf{H}) \exp\{2\pi i \Phi\} + \frac{\alpha}{2} L(\mathbf{H}-\Delta\mathbf{H}) \exp\{2\pi i(-\Phi)\}, \quad (4.2.3.33)$$

where $0 \le \alpha \le 1$. Fourier transformation yields

$$l(\mathbf{r})\left[1 + \frac{\alpha}{2}\exp\{2\pi i(\Delta\mathbf{H}\cdot\mathbf{r}+\Phi)\} + \frac{\alpha}{2}\exp\{-2\pi i(\Delta\mathbf{H}\cdot\mathbf{r}+\Phi)\}\right] = l(\mathbf{r})[1 + \alpha\cos(2\pi\Delta\mathbf{H}\cdot\mathbf{r}+\Phi)]. \quad (4.2.3.34)$$

Equation (4.2.3.34) describes the lattice modulated by a harmonic density wave. Since phases cannot be determined by intensity measurements, there is no possibility of obtaining any information on the phase relative to the sublattice. From (4.2.3.34) it is obvious that the use of higher orders of harmonics does not change the situation. If $\Delta\mathbf{H}$ is not rational, such that no $n\Delta\mathbf{H}$ (n = integer) coincides with a main reflection in reciprocal space, the modulated structure is incommensurate with the basic lattice and the phase of the density wave becomes meaningless. The same is true for the relative phases of the various orders of harmonic modulations of the density. This uncertainty even remains valid for commensurate density modulations of the sublattice, because coinciding higher-order harmonics in reciprocal space cause the same difficulty; higher-order coefficients cannot uniquely be separated from lower ones, consequently structure determination becomes impossible unless phase-determination methods are applied. Fortunately, density modulations of pure harmonic character are impossible for chemical reasons; they may be approximated by disorder phenomena for the averaged structure only. If diffuse scattering is taken into

account, the situation is changed considerably: A careful study of the diffuse scattering alone, although difficult in principle, will yield the necessary information about the relative phases of density waves (Korekawa, 1967).

4.2.3.5.2. Displacement fluctuations, displacive disorder

Displacement modulations are more complicated, even in a primitive structure. The Fourier transform of a longitudinal or a transverse displacement wave has to be calculated and this procedure does not result in a function of similar simplicity. Formally, a periodic modulation $\Delta\mathbf{r}_n = \mathbf{a}\cos(2\pi\mathbf{K}\cdot\mathbf{r}_n)$ leads to

$$I_{\rm D} \propto (2\pi\mathbf{H}\cdot\mathbf{a})^2 \sum_{\mathbf{G},\nu} A_\nu \delta(\mathbf{H}-\mathbf{G}\pm\nu\mathbf{K}), \qquad (4.2.3.35)$$

where $\mathbf{a}$ is the amplitude of the displacement wave with $\mathbf{a}=\alpha\mathbf{e}$ and $\mathbf{e}$ is the polarization vector: $|\mathbf{e}|=1$. Equation (4.2.3.35) denotes a set of satellites whose amplitudes are described by Bessel functions of νth order, where ν represents the order of the satellites. The intensity of the satellites increases with the magnitude of the product $\mathbf{H}\cdot\mathbf{a}$. This means that a single harmonic displacement causes an infinite number of satellites. They may be unobservable at low diffraction angles as long as the amplitudes are small. If the displacement modulation is incommensurate there are no coincidences with reflections of the sublattice. Consequently, the reciprocal space is completely covered with an infinite number of satellites, or, in other words, with diffuse scattering. This is a clear indication that incommensurate displacement modulations belong to the category of disordered structures. Statistical fluctuations of amplitudes of the displacement waves cause additional diffuse scattering, regardless of whether the period is commensurate or incommensurate (Overhauser, 1971; Axe, 1980). Fluctuations of 'phases' (*i.e.* periods) cause a broadening of satellites in reciprocal space but no change in their integrated intensities as long as the changes are not correlated with fluctuation periods. The broadening of satellite reflections increases with the order of the satellites and $(\mathbf{H}\cdot\mathbf{a})$. Obviously, there is no fundamental difference in the calculation of diffuse scattering with an ordered supercell of sufficient size.

4.2.3.5.3. Clusters and domains

Many disorder problems may be treated qualitatively in terms of coarsened structures that are made up of clusters or domain-like order extending along one or more directions in space. Common crystals are made up of 'mosaic individuals' which are separated irregularly by unspecified defects such as dislocations, small-angle boundaries, micro-strain fields and other defects. This 'real' crystallinity is not covered by the term 'disorder'. Clustering is, in a structural sense, not a very well defined term, but refers to general agglomerations of atoms, vacancies, defects or atomic groups due to preferred chemical bonding or due to some kind of exsolution processes. In general, the term 'cluster' is used to describe some inhomogeneity in a basic matrix structure. The term 'domain' usually implies either a spatially varying structure forming separate blocks, such as occurring in twin domains, or a spatial variation of a physical property (*e.g.* magnetic moment), which may be visualized by different configurations (see, *e.g.*, Frey, 1997). Structural domains may be chemically homogeneous, as is the case in twin domain structures, or heterogeneous, which occurs, *e.g.*, in feldspars with their complicated Ca/Na and Al/Si distributions. A definition of a domain structure may be given by symmetry arguments or, equivalently, by the order-parameter concept. Individual domains of the coarsened structure may be derived from a, possibly hypothetical, high-symmetry aristophase obeying the concept of symmetry groups. A lower symmetry of the domain is either due to loss of a point-group symmetry element (twin domains) or due to loss of a translational symmetry element of the aristophase, giving rise to the formation of out-of-phase domains. The special case of antiphase domains is related to a violation of a translational vector $\mathbf{t}$ in the aristophase by regular or irregular insertion of lattice displacements $\frac{1}{2}\mathbf{t}$. Shear domains, which are related by other fractional parts of $\mathbf{t}$, may be explained by cooperative gliding of structural building blocks, for example coordination polyhedra. Colour (black-and-white) symmetry has to be used for magnetic domain structures and may also be used for chemical domain ordering. While preserving the same lattice, the disordered (usually high-temperature) phase, which is specified by grey, decomposes into black and white domains, possibly embedded in the grey matrix. However, the term 'atomic cluster' is frequently used in this context. Domains can exhibit a new order by themselves, thus creating new symmetries of the superstructure. The boundaries between different domains are apparently essential and may even be used for a definition of a domain. This does not mean that the boundaries or domain walls are simple atomic planes rather than extended intermediate structural states which mellow the transition from one domain to the next one. Thus extended walls may carry a 'gradient' structure between neighbouring differently oriented domains and may be treated as new domains with their own structure. If misfits at the planes of coincidence are accompanied by remarkable straining, an array of dislocations may destroy the exact symmetry relation between the individuals. There is a stepwise transition from fully coherent domains to fully incoherent crystal parts. As long as coherency between the individuals is preserved, domain structures can be treated simply by means of Fourier transforms and characteristic features of the disorder problem may be extracted from diffuse patterns.

Quite generally, the scattering density for a general arrangement of domains may be written as (Boysen, 1995; Frey, 1997)

$$[\rho_1 * l_1][b_1^1 * d_1^1 + b_1^2 * d_1^2 + \ldots] + [\rho_2 * l_2][b_2^1 * d_2^1 + b_2^2 * d_2^2 + \ldots] + \ldots, \qquad (4.2.3.36)$$

where $\rho_i = \rho_i(\mathbf{r})$ is the structure of the unit cell of domain i, $l_i(\mathbf{r})$ is the lattice function, $b_i^j(\mathbf{r})$ is the shape function (which is unity in the region of domain i with size j and zero elsewhere) and $d_i^j(\mathbf{r}) = \sum \delta(\mathbf{r}-\mathbf{m}_i^j)$ is the distribution function ($\mathbf{m}_i^j$ are the centres of the domains). Note again that domain walls may be included in this formulation as separate 'domains'. Fourier transformation yields the scattering amplitude

$$[F_1 L_1] * [B_1^1 D_1^1 + B_1^2 D_1^2 + \ldots] + [F_2 L_2] * [B_2^1 D_2^1 + B_2^2 D_2^2 + \ldots] + \ldots, \qquad (4.2.3.37)$$

where $F_i = F_i(\mathbf{H})$ is the usual structure factor, $L_i(\mathbf{H})$ is the lattice function in reciprocal space, $B_i^j(\mathbf{H})$ and $D_i^j(\mathbf{H})$ are the Fourier transforms of the shape and distribution function, respectively, and the intensity is

$$\sum_i \Big|[F_i L_i] * \Big[\sum_j B_i^j D_i^j\Big]\Big|^2 + 2\sum_{i\neq k}[F_i L_i] * \Big[\sum_j B_i^j D_i^j\Big][F_k^+ L_k^+] * \Big[\sum_j B_k^{j+} D_k^{j+}\Big]. \qquad (4.2.3.38)$$

The first term represents sharp or diffuse reflections that are modified by the convolution with the Fourier transforms of the shape and distribution function (more correctly, with the Fourier transforms of the corresponding Patterson functions), while the second (cross) term generally leads to smaller additional changes. It should be emphasized that this separation does not correspond to the separation into Bragg and diffuse scattering. Although a further mathematical treatment of this very general expression does not seem to be easy, some qualitative or even semi-quantitative conclusions may be drawn:

(1) If the d_i^j are coherent with l_i (*i.e.* the $\mathbf{m}_i^j$ coincide with lattice points $\sum m_i\mathbf{a}_i$), the convolution with the second term in (4.2.3.38) is meaningless and we obtain sharp (basic) Bragg

reflections. This means that domain sizes and distributions cannot be determined from the widths of the Bragg reflections. One has to rely on the second term in this case.

(*a*) If, in addition, the d_i^j are strictly periodic (which implies equal sizes b_i), superlattice reflections occur that accompany the basic reflections as *satellites*. If the periodicity is *commensurate* with the basic lattice, higher-order satellites may coincide with basic reflections. Hence care must be taken even in the determination of the average structure.

(*b*) If the periodicity in (*a*) is not perfect (there are small fluctuations of domain sizes), the satellites will be broadened.

(*c*) If the distribution of domain sizes is completely random, this will degenerate into a continuous intensity distribution (diffuse streaks). Note, however, that a completely random distribution cannot be realized, since the domains have a *finite* size, *i.e.* there will always be some kind of modulation of the streak.

(2) If the d_i^j are incoherent, the second terms vanish and the broadening effect of the convolution in the first term becomes effective, *i.e.* the domain size and distribution can be determined directly from the widths of the basic Bragg reflections. This situation may be encountered more frequently in real systems, as usually the fluctuating widths of the domain walls lead to a loss of coherence between different domains of the same type. Nevertheless, one has to be careful if relatively small domain sizes are present, since accidental coincidences may occur that lead to different broadening of different reflections. The problem of coherence effects in these cases is discussed and exemplified by Boysen (2007).

(3) Interferences between domains of *different* kinds may lead to specific extinction rules (governing the distribution of sharp and diffuse reflections). Some examples are given below.

(4) The general reciprocity between direct and reciprocal space means that narrow objects in real space correspond to broad features in reciprocal space and *vice versa*. In particular, for domain walls, which are usually thin in one direction and extended in the other two, we expect a broad feature in one direction (perpendicular to the wall) and narrow ones in the perpendicular directions, *i.e.* streaks. For a single layer (with an ideal interface) this streak will be uniform, *i.e.* without modulations. In order to estimate domain sizes W, the square of the Fourier transform of a box function (for a special direction $\mathbf{H}$)

$$B^2(H) = [\sin(\pi WH)/\pi H]^2 \qquad (4.2.3.39)$$

may be used to estimate the half widths of the peaks. Hence measuring the peak broadening in all directions of reciprocal space will give full information about the shape of the domains.

(5*a*) The situation becomes slightly more complicated when strain effects are present. For small extensions of the strained volume, *e.g.* inside a domain wall, it may be convenient to treat the whole wall as one unit cell, *i.e.* simply calculate the sum over all atoms directly. A strained lattice may generally be written

$$l_s(\mathbf{r}) = \sum_m \delta\big[\mathbf{r} - \textstyle\sum m_i \mathbf{a}_i - \mathbf{s}(m)\big], \qquad (4.2.3.40)$$

where the function $\mathbf{s}(m)$ describes the displacement variation in the different cells. Fourier transformation gives

$$L_s(\mathbf{H}) = \sum_m \exp\{2\pi i \mathbf{H} \cdot \textstyle\sum m_i \mathbf{a}_i\} \exp\{2\pi i \mathbf{H} \cdot \mathbf{s}(m)\}. \qquad (4.2.3.41)$$

For a harmonic (sinusoidal) wave $\mathbf{s} = \mathbf{z}_0 \sin(2\pi m/M + \varphi)$, where $\mathbf{z}_0$, φ and M are the amplitude, the phase and the period of the wave, one gets (Korekawa, 1967)

$$L_s(\mathbf{H}) = \sum_m J_m(2\pi \mathbf{H} \cdot \mathbf{z}_0) \exp\{2\pi i m\varphi\} L(H - m/M), \quad (4.2.3.41a)$$

i.e. a set of satellites m weighted by Bessel functions of order m. The intensity of the zeroth order (Bragg peak) thus decreases with $\mathbf{H}$, while higher orders become more important. Again, one has to be careful with possible coincidences. This dependence on the scattering vector $\mathbf{H}$ holds for all other functional forms of $\mathbf{s}(m)$ as well and is therewith fundamentally different to the behaviour of the size effect, which gives the same contribution to all Bragg reflections, like in the case of density fluctuations. This difference may therefore be used to distinguish between the two effects.

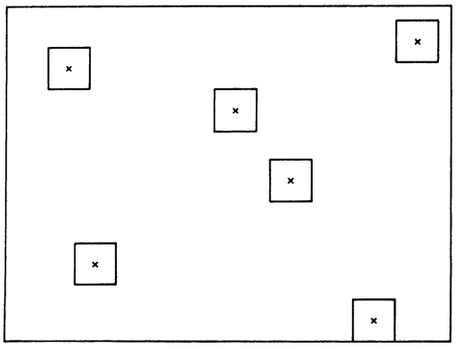

Fig. 4.2.3.1. Model of the two-dimensional distribution of point defects, causing changes in the surroundings.

(5*b*) Again, fluctuations of amplitude and phase lead to a broadening (diffuse tails) of the satellites. A general function $\mathbf{s}(m)$ may be analysed by expanding it into a Fourier series. For very long wavelengths (M) the satellites approach the basic Bragg peaks and cannot be observed easily. The case of a linear strain may be approximated by a sinusoidal modulation with very large wavelength, *i.e.* we will essentially observe a broadening of the Bragg peaks only. Then the strain ε may be estimated from the measured width $\Delta\mathbf{H}$:

$$\varepsilon = \Delta d/d = \Delta H/H.$$

Example: Clusters in a periodic lattice (low concentrations)

The exsolution of clusters of equal sizes is considered. The lattice of the host is undistorted, structure F_1, and the clusters have the same lattice but a different structure, F_2. A schematic drawing is shown in Fig. 4.2.3.1. Two different structures are introduced:

$$F_1(\mathbf{r}) = \sum_\nu \delta(\mathbf{r} - \mathbf{r}_\nu) * F_\nu(\mathbf{r}),$$

$$F_2(\mathbf{r}) = \sum_\mu \delta(\mathbf{r} - \mathbf{r}_\mu) * F_\mu(\mathbf{r}).$$

Their Fourier transforms are the structure factors $F_1(\mathbf{H})$, $F_2(\mathbf{H})$ of the matrix and the exsolved clusters, respectively. The boxes in Fig. 4.2.3.1 indicate the clusters, which may be represented by box functions $b(\mathbf{r})$ in the simplest case. It should be pointed out, however, that a more complicated shape means nothing other than a replacement of $b(\mathbf{r})$ by another shape function $b'(\mathbf{r})$ and its Fourier transform $B'(\mathbf{H})$. The distribution of clusters is represented by

$$d(\mathbf{r}) = \sum_{\mathbf{m}} \delta(\mathbf{r} - \mathbf{m}),$$

where $\mathbf{m}$ refers to the centres of the box functions (the crosses in Fig. 4.2.3.1). The problem is therefore defined by

$$l(\mathbf{r}) * F_1(\mathbf{r}) + [l(\mathbf{r})b(\mathbf{r})] * [F_2(\mathbf{r}) - F_1(\mathbf{r})] * d(\mathbf{r}). \qquad (4.2.3.42a)$$

The incorrect addition of $F_1(\mathbf{r})$ to the areas of clusters $F_2(\mathbf{r})$ is compensated by subtracting the same contribution from the second term in equation (4.2.3.42*a*). In order to determine the diffuse scattering, the Fourier transformation of (4.2.3.42*a*) is performed:

$$L(\mathbf{H})F_1(\mathbf{H}) + [L(\mathbf{H}) * B(\mathbf{H})][F_2(\mathbf{H}) - F_1(\mathbf{H})]D(\mathbf{H}). \quad (4.2.3.42b)$$

The intensity is given by

$$\left|L(\mathbf{H})F_1(\mathbf{H}) + [L(\mathbf{H}) * B(\mathbf{H})][F_2(\mathbf{H}) - F_1(\mathbf{H})]D(\mathbf{H})\right|^2. \quad (4.2.3.42c)$$

Evaluation of equation (4.2.3.42*c*) yields three terms (where c.c. means complex conjugate):

(i) $|L(\mathbf{H})F_1(\mathbf{H})|^2$

(ii) $\{[L(\mathbf{H})F_1(\mathbf{H})][L(\mathbf{H}) * B(\mathbf{H})] \times [F_2(\mathbf{H}) - F_1(\mathbf{H})]D(\mathbf{H}) + \text{c.c.}\}$

(iii) $|[L(\mathbf{H}) * B(\mathbf{H})][F_2(\mathbf{H}) - F_1(\mathbf{H})]D(\mathbf{H})|^2$.

The first two terms represent modulated lattices [multiplication of $L(\mathbf{H})$ by $F_1(\mathbf{H})$]. Consequently, they cannot contribute to diffuse scattering, which is completely determined by the third term. Fourier transformation of this term gives

$$\begin{aligned}&[l(\mathbf{r})b(\mathbf{r})] * \Delta F(\mathbf{r}) * d(\mathbf{r}) * [l(\mathbf{r})b(\mathbf{r})] * \Delta F^+(-\mathbf{r}) * d(-\mathbf{r})\\ &\quad = [l(\mathbf{r})b(\mathbf{r})] * [l(\mathbf{r})b(\mathbf{r})] * \Delta F(\mathbf{r}) * \Delta F^+(-\mathbf{r}) * d(\mathbf{r}) * d(-\mathbf{r})\\ &\quad = [l(\mathbf{r})t(\mathbf{r})] * \Delta F(\mathbf{r}) * \Delta F^+(-\mathbf{r}) * d(\mathbf{r}) * d(-\mathbf{r}), \quad (4.2.3.43a)\end{aligned}$$

where $l(\mathbf{r}) = l(-\mathbf{r})$, $b(\mathbf{r}) = b(-\mathbf{r})$ and $\Delta F = F_2 - F_1$. According to equation (4.2.3.15) and its subsequent discussion, the convolution of the two expressions in square brackets was replaced by $l(\mathbf{r})t(\mathbf{r})$, where $t(\mathbf{r})$ represents the 'pyramid' of n-fold height discussed above and n is the number of unit cells within $b(\mathbf{r})$. $d(\mathbf{r}) * d(-\mathbf{r})$ is the Patterson function of the distribution function $d(\mathbf{r})$. Its usefulness may be recognized by considering the two possible extreme solutions, namely the random and the strictly periodic distribution.

If no fluctuations of domain sizes are admitted, the minimum distance between two neighbouring domains is equal to the length of the domain in the corresponding direction. This means that the distribution function cannot be completely random. In one dimension, the solution of a random distribution of particles of a given size on a finite length shows that the distribution functions exhibit periodicities that depend on the average free volume of one particle (Zernike & Prins, 1927). Although the problem is more complicated in three dimensions, there should be no fundamental difference in the exact solutions.

On the other hand, it may be shown that the convolution of a pseudo-random distribution may be obtained if the average free volume is large. This is shown in Fig. 4.2.3.2(*a*) for the particular case of a cluster smaller than one unit cell. A strictly periodic distribution function (a superstructure) may result, however, if the volume of the domain and the average free volume are equal. Obviously, the practical solution for the self-convolution of the distribution function (which is the Patterson function) lies somewhere in between, as shown in Fig. 4.2.3.2(*b*). If a harmonic periodicity damped by a Gaussian is assumed, this self-convolution of the distribution in real space may be considered to consist of two parts, as shown in Figs. 4.2.3.2(*c*), (*d*). Note that the two different solutions result in completely different diffraction patterns:

(i) The geometrically perfect lattice extends to distances that are large when compared with the correlation length of the distribution function. Then the Patterson function of the distribution function concentrates at the positions of the basic lattice, which is given by multiplication by the lattice $l(\mathbf{r})$. The corresponding convolution in reciprocal space gives the same contribution to all Bragg reflections (Fig. 4.2.3.2*e*).

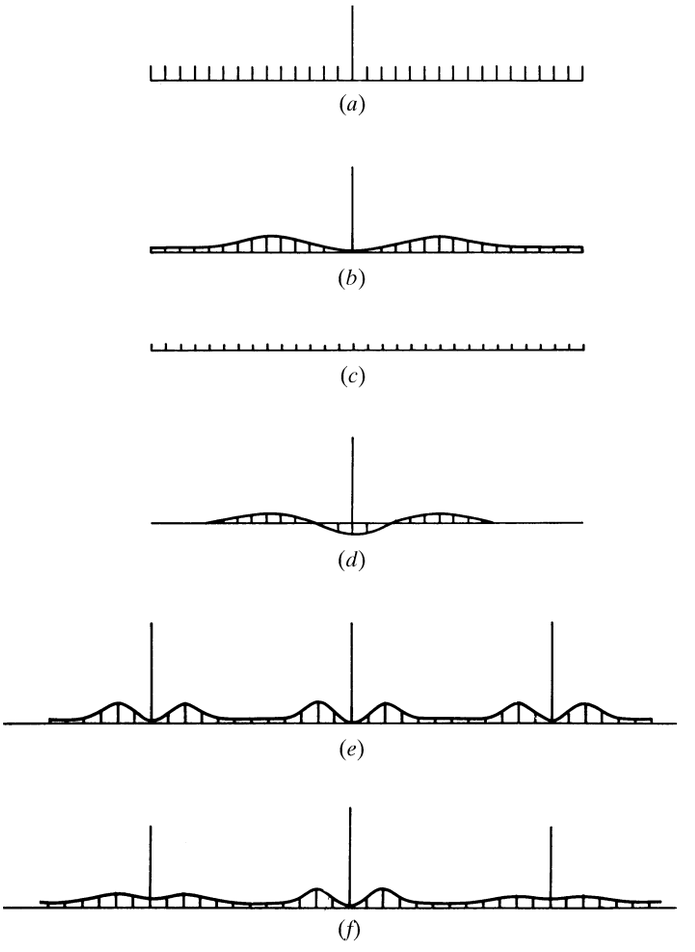

Fig. 4.2.3.2. One-dimensional Patterson functions of various point-defect distributions: (*a*) random distribution; (*b*) influence of finite volume of defects on the distribution function; (*c*), (*d*) decomposition of (*b*) into a periodic (*c*) and a convergent (*d*) part; (*e*) Fourier transform of (*c*) + (*d*); (*f*) changes of (*e*) if the centres of the defects show major deviations from the origins of the lattice.

(ii) There is no perfect lattice geometry. In this case, a continuous Patterson function results. Fourier transformation yields an influence that is now restricted primarily to the reflection 000, *i.e.* to the low-angle diffraction range.

Figs. 4.2.3.2(*e*), (*f*) show the different diffraction patterns of the diffuse scattering that is concentrated around the Bragg maxima. Although the discussion of the diffuse scattering was restricted to the case of identical domains, the introduction of a distribution of domain sizes does not influence the diffraction pattern essentially, as long as the fluctuation of sizes is small compared with the average volume of domain sizes and no strong correlation exists between domains of any size (a size-independent random distribution).

A complete qualitative discussion of the diffraction pattern may be carried out by investigating the Fourier transform of (4.2.3.43*a*):

$$[L(\mathbf{H}) * T(\mathbf{H})]|\Delta F(\mathbf{H})|^2|D(\mathbf{H})|^2. \quad (4.2.3.43b)$$

The first factor in (4.2.3.43*b*) describes the particle-size effect of a domain containing the influence of a surrounding strain field and the new structure of the domains precipitated from the bulk. $D(\mathbf{H})$ has its characteristic variation near the Bragg peaks (Figs. 4.2.3.2*e*,*f*) and is less important in between. For domain structure determination, intensities near the Bragg peaks should be avoided. Note that equation (4.2.3.43*b*) may be used for measurements using anomalous scattering in both the centric and the acentric case.

Solution of the diffraction problem. In equation (4.2.3.43*b*) $\Delta F(\mathbf{H})$ is replaced by its average,

$$\langle \Delta F(\mathbf{H}) \rangle = \sum_{\mu} p_{\mu} \Delta F_{\mu}(\mathbf{H}),$$

where p_{μ} represents the *a priori* probability of a domain of type μ. This replacement becomes increasingly important if small clusters (domains) have to be considered. Applications of the formulae to Guinier–Preston zones are given by Guinier (1942) and Gerold (1954); a similar application to clusters of vacancies in spinels with an excess of Al_2O_3 was outlined by Jagodzinski & Haefner (1967).

Although refinement procedures are possible in principle, the number of parameters entering the diffraction problem becomes increasingly large if more clusters or domains (of different sizes) have to be introduced. Another difficulty results from the large number of diffraction data which must be collected to perform a reliable structure determination. There is no need to calculate the first two terms in equation (4.2.3.42*c*) which contribute to the sharp Bragg peaks only, because their intensity is simply described by the averaged structure factor $|\langle F(\mathbf{H}) \rangle|^2$. These terms may therefore be replaced by

$$|L(\mathbf{H})|^2 |\langle F(\mathbf{H}) \rangle|^2$$

with

$$|\langle F(\mathbf{H}) \rangle|^2 = \Big| \sum_{\mu} p_{\mu} F_{\mu}(\mathbf{H}) \Big|^2, \qquad (4.2.3.43c)$$

where p_{μ} is the *a priori* probability of the structure factor $F_{\mu}(\mathbf{H})$. It should be emphasized here that (4.2.3.43*c*) is independent of the distribution function $d(\mathbf{r})$ or its Fourier transform $D(\mathbf{H})$.

While a number of solutions to the diffraction problem may be found in the literature for one-dimensional (1D) disorder (1D distribution functions) (see, *e.g.*, Jagodzinski, 1949*a*,*b*,*c*; Cowley, 1976*a*,*b*; Adlhart, 1981; Pflanz & Moritz, 1992), these become increasingly more complicated with increasing dimensionality. These types are therefore discussed separately in the following.

4.2.3.5.4. One-dimensional disorder

This lamellar (1D) type of disorder is common in many crystals for energetic reasons. For example, most of the important rock-forming minerals exhibit such disorder behaviour. Therefore we give some extended introduction to this field. To illustrate the application of the formalism outlined above, we start with a simple example of domains of an identical structure $\rho(\mathbf{r})$ displaced relative to each other by an arbitrary fault vector $\mathbf{\Delta}$ (Boysen *et al.*, 1991). If $t(\mathbf{r})$ describes the regions of one domain, then $1 - t(\mathbf{r})$ describes those of the displaced domains and the complete structure may be written

$$t(\mathbf{r})[l(\mathbf{r}) * \rho(\mathbf{r})] + [1 - t(\mathbf{r})][l(\mathbf{r} - \mathbf{\Delta}) * \rho(\mathbf{r})].$$

Introducing $t'(\mathbf{r}) = 2t(\mathbf{r}) - 1$, this may be rewritten as

$$[l(\mathbf{r}) + l(\mathbf{r} - \mathbf{\Delta})] * \rho(\mathbf{r})/2 = t'(\mathbf{r})\{[l(\mathbf{r}) - l(\mathbf{r} - \mathbf{\Delta})] * \rho(\mathbf{r})\}/2.$$

Fourier transformation yields

$$L(\mathbf{H})[1 + \exp\{2\pi i \mathbf{\Delta} \cdot \mathbf{r}\}]F(\mathbf{H})/2 + T'(\mathbf{H}) * L(\mathbf{H})[1 - \exp\{2\pi i \mathbf{\Delta} \cdot \mathbf{r}\}]F(\mathbf{H})/2.$$

The first term describes sharp reflections due to the multiplication with the lattice function $L(\mathbf{H})$, while the second term gives diffuse reflections due to the convolution with $T'(\mathbf{H})$. The corresponding intensities are

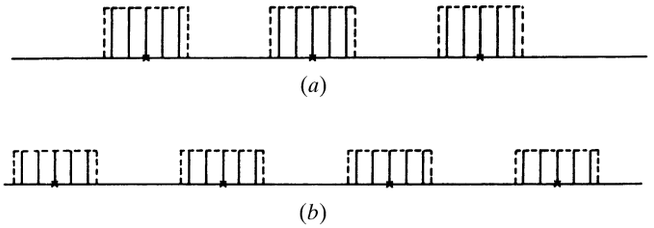

Fig. 4.2.3.3. Periodic array of domains consisting of two different atoms, represented by different heights. (*a*) Distribution of domain type 1, (*b*) distribution of domain type 2.

$$I_S \propto 1 + \cos(2\pi \mathbf{\Delta} \cdot \mathbf{H}) \text{ and } I_D \propto 1 - \cos(2\pi \mathbf{\Delta} \cdot \mathbf{H}).$$

In the general case, all reflections consist of a superposition of sharp and diffuse intensities. Note that the well known separation of sharp and diffuse intensities for antiphase domains is obtained if $\mathbf{\Delta}$ equals $\frac{1}{2}$ times a lattice vector.

(1) *Periodic distribution of lamellar domains*

Here $d(\mathbf{r})$ is one-dimensional and can easily be calculated: a periodic array of two types of lamellae having the same basic lattice $l(\mathbf{r})$ but different structures is shown in Fig. 4.2.3.3. The sizes of the two types of lamellae may be different. The structure of the first domain type is given by a convolution with $F_1(\mathbf{r})$ (Fig. 4.2.3.3*a*) and that of the second domain type by $F_2(\mathbf{r})$ (Fig. 4.2.3.3*b*). Introducing $\langle F(\mathbf{r}) \rangle$ and $\Delta F(\mathbf{r})$, the structure in real space is described by

$$\begin{aligned}[l(\mathbf{r})b_1(\mathbf{r})] * d(\mathbf{r}) * F_1(\mathbf{r}) + [l(\mathbf{r})b_2(\mathbf{r})] * d(\mathbf{r}) * F_2(\mathbf{r}) \\ = \{[l(\mathbf{r})b_1(\mathbf{r}) + l(\mathbf{r})b_2(\mathbf{r})] * d(\mathbf{r})\} * \langle F(\mathbf{r}) \rangle \\ + [l(\mathbf{r})b_1(\mathbf{r}) - l(\mathbf{r})b_2(\mathbf{r})] * d(\mathbf{r}) * \Delta F(\mathbf{r}). \qquad (4.2.3.44a)\end{aligned}$$

Obviously, the first term in curly brackets in equation (4.2.3.44*a*) is no more than $l(\mathbf{r})$ itself and $d(\mathbf{r})$ is strictly periodic. $b_1(\mathbf{r})$ and $b_2(\mathbf{r})$ are box functions, mutually displaced by $\pm(n_1 + n_2)/2$ unit cells in the stacking direction [n_1, n_2 are the numbers of cells covered by $b_1(\mathbf{r})$ and $b_2(\mathbf{r})$, respectively].

Fourier transformation of equation (4.2.3.44*a*) yields

$$L(\mathbf{H})\langle F(\mathbf{H}) \rangle + \{L(\mathbf{H}) * [B_1(\mathbf{H}) - B_2(\mathbf{H})]\} D(\mathbf{H}) \Delta F(\mathbf{H}). \qquad (4.2.3.44b)$$

The first term in equation (4.2.3.44*b*) gives the normal sharp reflections of the average structure, while the second describes superlattice reflections [sublattice $L_s(\mathbf{H}) = D(\mathbf{H})$ in reciprocal space], multiplied by $\Delta F(\mathbf{H})$ and another 'structure factor' generated by the convolution of the reciprocal lattice $L(\mathbf{h})$ with $[B_1(\mathbf{H}) - B_2(\mathbf{H})]$ (*cf.* Fig. 4.2.3.3). Since the centres of $b_1(\mathbf{r})$ and $b_2(\mathbf{r})$ are mutually displaced, the expression in square brackets includes extinctions if $b_1(\mathbf{r})$ and $b_2(\mathbf{r})$ represent boxes equal in size. These extinctions are discussed below. It should be pointed out that $L_s(\mathbf{H})$ and its Fourier transform $l_s(\mathbf{r})$ are commensurate with the basic lattice as long as no change of the translation vector at the interface of the lamellae occurs. Obviously, $L_s(\mathbf{H})$ becomes incommensurate in the general case of a slightly distorted interface. Considerations of this kind play an important role in the discussion of modulated structures.

No assumption has been made so far about the position of the interface. This point is meaningless only in the case of a strictly periodic array of domains (with no diffuse scattering). Therefore it seems to be convenient to introduce two basis vectors parallel to the interface in real space, which demand a new reciprocal vector perpendicular to them defined by $(\mathbf{a}' \times \mathbf{b}')/V'$, where $\mathbf{a}'$, $\mathbf{b}'$ are the new basis vectors and V' is the volume of the supercell. As long as the new basis vectors are commensurate with the original lattice, the direction of the new reciprocal vector $\mathbf{c}'^*$, perpendicular to $\mathbf{a}'$, $\mathbf{b}'$, passes through the Bragg points of the original reciprocal lattice and the reciprocal lattice of the superlattice

remains commensurate as long as V' is a multiple of V ($V' = mV$, m = integer). Since the direction of **c** is arbitrary to some extent, there is no clear rule about the assignment of superlattice reflections to the original Bragg peaks. This problem becomes very important if extinction rules of the basic lattice and the superlattice have to be described together.

Example

We consider a b.c.c. structure with two kinds of atoms (1, 2) with a strong tendency towards superstructure formation (CsCl-type ordering). According to equations (4.2.3.43*b*,*c*) and (4.2.3.44*b*), in the case of negligible short-range order we obtain the following expressions for sharp and diffuse scattering (where c = concentration):

$$I_S = |cf_1(\mathbf{H}) + (1-c)f_2(\mathbf{H})|^2 \quad \text{for } h+k+l = 2n,$$
$$I_D = c(1-c)|f_1(\mathbf{H}) - f_2(\mathbf{H})|^2 \quad \text{elsewhere.}$$

With increasing short-range order the sharp reflections remain essentially unaffected, while the diffuse ones concentrate into diffuse maxima at **h** with $h+k+l = 2n+1$. This process is treated more extensively below. As long as the domains exhibit no clear interface, it is useful to describe the ordering process with the two possible cell occupations of a pair of different atoms; then contributions of equal pairs may be neglected with increasing short-range order. Now the two configurations 1, 2 and 2, 1 may be given with the aid of the translation $\frac{1}{2}(\mathbf{a}+\mathbf{b}+\mathbf{c})$. Hence the two structure factors are

$$F_1 \text{ and } F_2 = F_1 \exp\{\pi i(h+k+l)\}.$$

Since the two structure factors occur with the same probability, the equations for sharp and diffuse reflections become

$$I_S = \tfrac{1}{4}|F_1(\mathbf{H})|^2[1 + \exp\{\pi i(h+k+l)\}]^2,$$
$$I_D = \tfrac{1}{4}|F_1(\mathbf{H})|^2[1 - \exp\{\pi i(h+k+l)\}]^2.$$

It is well recognized that no sharp reflections may occur for $h+k+l = 2n+1$, and the same holds for the diffuse scattering if $h+k+l = 2n$. This extinction rule for diffuse scattering is due to suppression of the contributions of equal pairs. The situation becomes different for lamellar structures. Let us first consider the case of lamellae parallel to (100). The ordered structure is formed by an alternating sequence of monoatomic layers consisting of atoms of types 1 or 2. Hence the interface between two neighbouring domains is a pair of equal layers 1, 1 or 2, 2, which are not equivalent. Each interface of type 1 (2) may be described by an inserted layer of type 1 (2) and the chemical composition differs from 1:1 if one type of interface is preferred. Since the contribution of equal pairs has been neglected in deriving the extinction rule of diffuse scattering (see above), this rule is no longer valid. Because of the lamellar structure the diffuse intensity is concentrated into streaks parallel to (00l). Starting from the diffuse maximum (010), the diffuse streak passes over the sharp reflection 011 to the next diffuse one 012 *etc.*, and the extinction rule is violated as long as one of the two interfaces is predominant. Therefore, the position of the interface determines the extinction rule in this orientation.

A completely different behaviour is observed for lamellae parallel to (110). This structure is described by a sequence of equal layers containing atoms 1 and 2. The interface between two domains (exchange of the two different atoms) is now nothing other than the displacement parallel to the layer of the original one in the ordered sequence. Calculation of the two structure factors would involve displacements $\pm\frac{1}{2}(\mathbf{a}-\mathbf{b})$. Starting from the diffuse reflection 001, the diffuse streak parallel to (HH0) passes through (111), (221), (331), ...; *i.e.* through diffuse reflections only. On the other hand, rows (HH2) going through (002), (112), (222), ... do not show any diffuse scattering. Hence we have a new extinction rule for diffuse scattering originating from the orientation of interfaces. This fact is rather important in structure determination. For various reasons, lamellar interfaces show a strong tendency towards a periodic arrangement. In diffraction the diffuse streak then concentrates into quite sharp superstructure reflections. These are not observed on those rows of the reciprocal lattice that are free from diffuse scattering. The same extinction law is not valid in the case of the (100) orientation of the interfaces. Summarizing, we may state that three types of extinction rules have to be considered:

(*a*) Normal extinctions for the average structure.

(*b*) Extinction of the difference structure factors for diffuse scattering.

(*c*) Extinctions caused by the ordering process itself.

(2) *Lamellar system with two different structures, where* $\langle F(\mathbf{H})\rangle$ *and* $\Delta F(\mathbf{H})$ *do not obey any systematic extinction law*

The convolution of the second term in equation (4.2.3.44*b*) (*cf.* Fig. 4.2.3.3) may be represented by a convolution of the Fourier transform of a box function $B_1(\mathbf{H})$ with the reciprocal superlattice. Since $B_1(\mathbf{H})$ is given by $\sin(\pi m_s H)/(\pi H)$, where m_s is the number of cells in the supercell, the reader might believe that the result of the convolution may easily be determined quantitatively: this assumption is not correct because of the slow convergence of $B_1(\mathbf{H})$. The systematic concidences of the maxima, or minima, of $B_1(\mathbf{H})$ with the points of the superlattice in the commensurate case cause considerable changes in intensities, especially in the case of a small domain thickness. For this reason, an accurate calculation of the amplitudes of the satellites is necessary (Jagodzinski & Penzkofer, 1981):

(*a*) Bragg peaks of the basic lattice

$$I \simeq |\langle F(\mathbf{H})\rangle|^2; \qquad (4.2.3.45a)$$

(*b*) satellites: $\nu = 2n$ (n = integer except 0)

$$I \simeq |2\sin\pi\nu C/[\sin\pi\nu/(N_1+N_2)]\Delta F(\mathbf{H})|^2; \qquad (4.2.3.45b)$$

(*c*) satellites: $\nu = 2n+1$

$$I \simeq |2\cos\pi\nu C/[\sin\pi\nu/(N_1+N_2)]\Delta F(\mathbf{H})|^2. \qquad (4.2.3.45c)$$

Here ν is the order of the satellites, $C = \frac{1}{2}(N_1 - N_2)/(N_1 + N_2)$, and N_1 and N_2 are the number of cells within $b_1(\mathbf{r})$ and $b_2(\mathbf{r})$, respectively.

Obviously, there is again a systematic extinction rule for even satellites if $N_1 = N_2$.

Equation (4.2.3.45*b*) indicates an increasing intensity of first even-order satellites with increasing C. Intensities of first even and odd orders become nearly equal if $N_2 \simeq \frac{1}{2}N_1$. Smaller values of N_2 result in a decrease of intensities of both even and odd orders (no satellites occur if $N_2 = 0$). The denominators in equations (4.2.3.45*b*,*c*) indicate a decrease in intensity with increasing order of the satellites. The quantitative behaviour of the intensities needs a more detailed discussion of the numerator in equations (4.2.3.45*b*,*c*) with increasing order of the satellites. Obviously, there are two kinds of extinction rules to be taken into account: systematic absences for the various orders of satellites, and the usual extinctions for $\langle F(\mathbf{H})\rangle$ and $\Delta F(\mathbf{H})$. Each has to be considered separately in order to arrive at reliable conclusions. This different behaviour of the superlattice reflections (satellites) and that of the basic lattice may be represented by a multidimensional group-theoretical representation, as has been shown by de Wolff (1974), Janner & Janssen (1980*a*,*b*), de Wolff *et al.* (1981) and others.

(3) *Nonperiodic system of lamellar domains*

Following the discussion of equations (4.2.3.43), one may conclude that the fluctuations of domain sizes cause a broadening of satellites if the periodic distribution function has to be

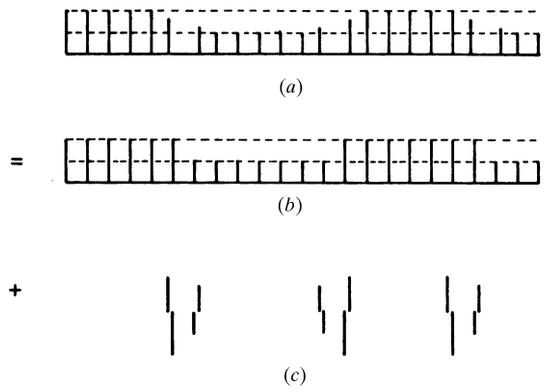

Fig. 4.2.3.4. Influence of distortions at the boundary of domains and separation into two parts; for discussion see text.

replaced by a statistical one. In this case, the broadening effect increases with the order of the satellites. The intensities, however, are completely determined by the distribution function and can be estimated by calculating the intensities of the perfectly ordered array, as approximated by the distribution function.

A careful check of $\langle F(\mathbf{H})\rangle$ and $\Delta F(\mathbf{H})$ in equations (4.2.3.45) shows that the position of the interface plays an important role in the intensities of the satellites. Since this position determines the origin of the unit cells in the sublattice, we have to choose this origin for the calculation of $F(\mathbf{H})$ and $\Delta F(\mathbf{H})$. This involves phase factors which are meaningless for integral values of $\mathbf{H}$ (i) if the average $\langle F(\mathbf{H})\rangle$ refers to different structures with arbitrary origin or (ii), which is important for practical cases, where no change occurs in the origin of related structures for neighbouring domains that are bound to an origin by general convention (*e.g.* a centre of symmetry). This statement is no longer true for non-integral values of $\mathbf{H}$, which are needed for the calculation of intensities of satellites. The intensities of satellites become different for different positions of the interface even in the absence of a relative displacement between neighbouring domains with respect to an origin by convention. This statement may be extended to nonperiodic distribution functions. Consequently, one may conclude that the study of diffuse scattering yields information on the interfacial scattering. For slightly different structures at the interface two cases are important:

(i) the two structures are related by symmetry (*e.g.* by a twin law); and

(ii) the difference between the two structures cannot be described by a symmetry operation.

In structures based on the same sublattice, the first case seems to be more important, because two different structures with the same sublattice are improbable. In the first case there is an identical sublattice if the symmetry operation in question does not influence the plane of intergrowth, *e.g.* a mirror plane should coincide with the plane of intergrowth. Since we have two inequivalent mirror planes in any sublattice, there are two such planes. It is assumed that no more than one unit cell of both domains at the interface has a slightly different structure without any change of geometry of the unit cell, and the number of unit cells is equal because of the equivalence of both domain structures (twins). Fig. 4.2.3.4(*a*) shows a picture of this model; Figs. 4.2.3.4(*b*), (*c*) explain that this structure may be described by two contributions:

(i) The first term is already given by equation (4.2.3.45) for $N_1 = N_2$, consequently only odd orders of satellites are observed.

(ii) The second term may be described by a superlattice containing $2N_1$ cells with an alternating arrangement of interfaces, correlated by the relevant plane of symmetry.

In real space, the second term may be constructed by convolution of the one-dimensional superlattice with two difference structures displaced by $\mp N_1/2$ units of the sublattice; its Fourier transformation yields

$$L_s(\mathbf{H})[\Delta F_i(\mathbf{H})\exp\{2\pi i N_1 H/2\} + \Delta F_i'(\mathbf{H})\exp\{-2\pi i N_1 H/2\}], \quad (4.2.3.46)$$

where ΔF_i, $\Delta F_i'$ correspond to the Fourier transforms of the contributions shown in Fig. 4.2.3.4(*c*). Since $H = \nu/N_1$, there are alternating contributions to the νth satellite which may be calculated more accurately by taking into account the symmetry operations. The important difference between equations (4.2.3.45) and (4.2.3.46) is the missing decrease in intensity with increasing order of the satellites. Consequently, one may conclude that the interface contributes to low- and high-order satellites as well, but its influence prevails for high-order satellites. Similar considerations may be made for two- and three-dimensional distributions of domains. A great variety of extinction rules may be found depending on the type of order approximated by the distribution under investigation.

(4) *Two kinds of lamellar domains with variable size distribution*

The preceding discussion of the diffuse scattering from domains is obviously restricted to relatively small fluctuations of domain sizes. This is specifically valid if the most probable domain size does not differ markedly from the average size. This condition is violated in the case of order–disorder phenomena. It may happen that the smallest ordered area is the most probable one, although the average is considerably larger. This may be shown for a lamellar structure of two types of layers correlated by a (conditional) pair probability $p_{\mu\mu'}(\mathbf{1})$. As shown below, a pair at distance $\mathbf{m}$ occurs with the probability $p_\mu p_{\mu\mu'}(\mathbf{m})$, which may be derived from the pair probability of nearest neighbours $p_\mu p_{\mu\mu'}(\mathbf{1})$. (In fact only one component of vector $\mathbf{m}$ is relevant in this context.) The problem will be restricted to two kinds of layers (μ, $\mu' = 1, 2$). Furthermore, it will be symmetric in the sense that the pair probabilities obey the following rules:

$$p_{11}(\mathbf{m}) = p_{22}(\mathbf{m}), \quad p_{12}(\mathbf{m}) = p_{21}(\mathbf{m}). \quad (4.2.3.47)$$

It may be derived from equation (4.2.3.47) that the *a priori* probabilities p_μ of a single layer are $\frac{1}{2}$ and

$$p_{11}(\mathbf{0}) = p_{22}(\mathbf{0}) = 1, \quad p_{12}(\mathbf{0}) = p_{21}(\mathbf{0}) = 0.$$

With these definitions and the general relation

$$p_{11}(\mathbf{m}) + p_{12}(\mathbf{m}) = p_{22}(\mathbf{m}) + p_{21}(\mathbf{m}) = 1,$$

the *a priori* probability of a domain containing m layers of type 1 may be calculated with the aid of $p_{11}(\mathbf{1})$ [$0 \le p_{11}(\mathbf{1}) \le 1$]:

$$p_\mu = \tfrac{1}{2}p_{11}(\mathbf{1})^{m-1}[1 - p_{11}(\mathbf{1})]. \quad (4.2.3.48)$$

Hence the most probable size of domains is a single layer, because a similar relation holds for layers of type 2. Since the average thickness of the domains is strongly dependent on $p_{11}(\mathbf{1})$ [infinite for $p_{11}(\mathbf{1}) = 1$ and one layer for $p_{11}(\mathbf{1}) = 0$], it may become very large in the latter case. Consequently, there are extremely large fluctuations if $p_{11}(\mathbf{1})$ is small but different from zero.

It may be concluded from equation (4.2.3.48) that the function $p_{11}(\mathbf{m})$ decreases monotonically with increasing $\mathbf{m}$, approaching $\frac{1}{2}$ with $\mathbf{m} \to \infty$. It is apparent that this cannot be true for a finite crystal if $p_{11}(\mathbf{m})$ is unity (a structure of two types of domains) or zero (a superstructure of alternating layers). In either case, the crystal should consist of a single domain of type 1 or 2, or one of the possible superstructures 1212 ..., 2121 ..., respectively. Hence one has to differentiate between long-range order, where two equivalent solutions have to be considered, and short-range order, where $p_{11}(\mathbf{m})$ approaches the *a priori* probability $\frac{1}{2}$ for large m. This behaviour of $p_{11}(\mathbf{m})$ and $p_{12}(\mathbf{m})$, which may also be

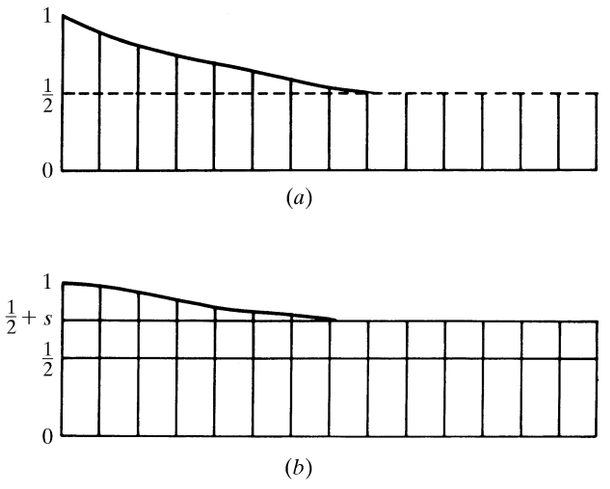

Fig. 4.2.3.5. Behaviour of $p_{11}(\mathbf{m})$ and $p_{12}(\mathbf{m})$ in mixed crystals (unmixing): (*a*) upper curve: short-range order only; (*b*) lower curve: long-range order.

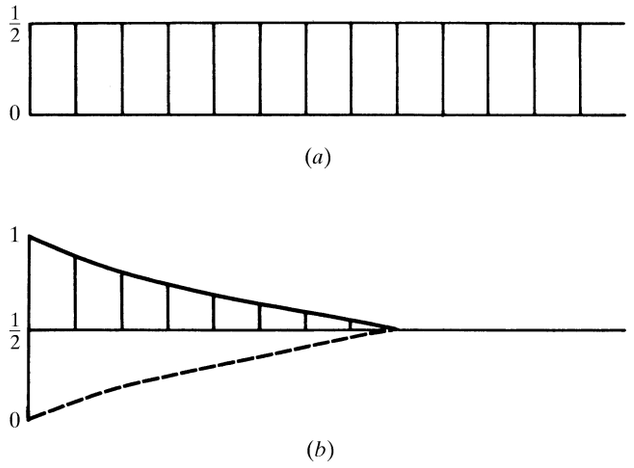

Fig. 4.2.3.6. Decomposition of Fig. 4.2.3.5(*a*) into (*a*) a periodic and (*b*) a rapidly convergent part.

expressed by equivalent correlation functions, is shown in Figs. 4.2.3.5(*a*) (short-range order) and 4.2.3.5(*b*) (long-range order, quantified by the parameter s). $p_{11}(\mathbf{m})$ approaches $\frac{1}{2}+s$ for large m with $s = 0$ in the case of short-range order, while $p_{12}(\mathbf{m})$ becomes $\frac{1}{2}-s$. Obviously, a strict correlation between $p_{11}(\mathbf{1})$ and s exists, and this has to be calculated. For a qualitative interpretation of the diffraction pictures this correlation may be derived from the diffraction pattern itself. The $p_{\mu\mu'}(\mathbf{m})$ are separable into a strictly periodic and a monotonically decreasing term approaching zero in both cases. This behaviour is shown in Figs. 4.2.3.6(*a*), (*b*). The periodic term contributes to sharp Bragg scattering. In the case of short-range order, the symmetry relations given in equation (4.2.3.47) are valid. The convolution in real space yields with factors $t(\mathbf{r})$ (equation 4.2.3.43*a*):

$$\begin{aligned}
&\tfrac{1}{2}t(\mathbf{r})\left[\sum_{\mathbf{m}}\delta(\mathbf{r}+\mathbf{m})p'_{11}(\mathbf{m})\right] * F_1(\mathbf{r}) * F_1(-\mathbf{r})\\
&\quad+\tfrac{1}{2}t(\mathbf{r})\left[\sum_{\mathbf{m}}\delta(\mathbf{r}+\mathbf{m})p'_{12}(\mathbf{m})\right] * F_1(\mathbf{r}) * F_2(-\mathbf{r})\\
&\quad+\tfrac{1}{2}t(\mathbf{r})\left[\sum_{\mathbf{m}}\delta(\mathbf{r}+\mathbf{m})p'_{21}(\mathbf{m})\right] * F_2(\mathbf{r}) * F_1(-\mathbf{r})\\
&\quad+\tfrac{1}{2}t(\mathbf{r})\left[\sum_{\mathbf{m}}\delta(\mathbf{r}+\mathbf{m})p'_{22}(\mathbf{m})\right] * F_2(\mathbf{r}) * F_2(-\mathbf{r}),
\end{aligned}$$

where $p'_{\mu\mu'}(\mathbf{m})$ are factors attached to the δ functions:

$$\begin{aligned}
p'_{11}(\mathbf{m}) &= p_{11}(\mathbf{m}) - \tfrac{1}{2} = p'_{22}(\mathbf{m}),\\
p'_{12}(\mathbf{m}) &= p'_{21}(\mathbf{m}) = -p'_{11}(\mathbf{m}).
\end{aligned}$$

The positive sign of $\mathbf{m}$ in the δ functions results from the convolution with the inverted lattice (*cf.* Patterson, 1959). Fourier transformation of the four terms given above yields the four corresponding expressions with $\mu, \mu' = 1, 2$:

$$\tfrac{1}{2}\left[T(\mathbf{H}) * \sum_{\mathbf{m}} p'_{\mu\mu'}(\mathbf{m})\exp\{-2\pi i\mathbf{H}\cdot\mathbf{m}\}\right]F_\mu(\mathbf{H})F^+_{\mu'}(\mathbf{H}). \qquad (4.2.3.49a)$$

Now the summation over $\mathbf{m}$ may be replaced by an integral if the factor $l(\mathbf{m})$ is added to $p'_{\mu\mu'}(\mathbf{m})$, which may then be considered as the smoothest continuous curve passing through the relevant integer values of $\mathbf{m}$:

$$\sum \rightarrow \int l(\mathbf{m})p'_{\mu\mu'}(\mathbf{m})\exp\{-2\pi i\mathbf{H}\cdot\mathbf{m}\}\,\mathrm{d}\mathbf{m}.$$

Since both $l(\mathbf{m})$ and $p'_{\mu\mu'}(\mathbf{m})$ are symmetric in our special case, we obtain

$$\sum = L(\mathbf{H}) * P'_{\mu\mu'}(\mathbf{H}).$$

Insertion of the sum in equation (4.2.3.49*a*) results in

$$\tfrac{1}{2}[L(\mathbf{H}) * T(\mathbf{H}) * P'_{\mu\mu'}(\mathbf{H})]F_\mu(\mathbf{H})F^+_{\mu'}(\mathbf{H}). \qquad (4.2.3.49b)$$

Using all symmetry relations for $p'_{\mu\mu'}(\mathbf{m})$ and $P'_{\mu\mu'}(\mathbf{H})$, respectively, we obtain for the diffuse scattering after summing over μ, μ'

$$I_{\mathrm{D}} \simeq [L(\mathbf{H}) * T(\mathbf{H}) * P'_{11}(\mathbf{H})]|\Delta F(\mathbf{H})|^2 \qquad (4.2.3.50)$$

with $\Delta F(\mathbf{H}) = \frac{1}{2}[F_1(\mathbf{H}) - F_2(\mathbf{H})]$.

It should be borne in mind that $P'_{11}(\mathbf{H})$ decreases rapidly if $p'_{11}(\mathbf{r})$ decreases slowly and *vice versa.* It is interesting to compare the different results from equations (4.2.3.43*b*) and (4.2.3.50). Equation (4.2.3.50) indicates diffuse maxima at the positions of the sharp Bragg peaks, while the multiplication by $D(\mathbf{H})$ causes satellite reflections in the neighbourhood of Bragg maxima. Both equations contain the factor $|\Delta F(\mathbf{H})|^2$, indicating the same influence of the two structures. More complicated formulae may be derived for several cell occupations. In principle, a result similar to equation (4.2.3.50) will be obtained, but more interdependent correlation functions $p_{\mu\mu'}(\mathbf{r})$ have to be introduced. Consequently, the behaviour of diffuse intensities becomes more differentiated in so far as all $p'_{\mu\mu'}(\mathbf{r})$ are now correlated with the corresponding $\Delta F_\mu(\mathbf{r})$, $\Delta F_{\mu'}(-\mathbf{r})$. Hence the method of correlation functions becomes increasingly ineffective with an increasing number of correlation functions. Here the cluster method seems to be more convenient and is discussed below.

(5) *Lamellar domains with long-range order: tendency to exsolution*

The Patterson function of a disordered crystal exhibiting long-range order is shown in Fig. 4.2.3.5(*b*). Now $p_{11}(\infty)$ converges against $\frac{1}{2}+s$ and the *a priori* probability changes correspondingly. Since $p_{12}(\infty)$ becomes $\frac{1}{2}-s$, the symmetry relation given in equation (4.2.3.47) is violated: $p_{11}(\mathbf{r}) \neq p_{22}(\mathbf{r})$ for a finite crystal; it is evident that another crystal shows long-range order with the inverted correlation function, $p_{22}(\infty) = \frac{1}{2}+s$, $p_{21}(\infty) = \frac{1}{2}-s$, such that the symmetry $p_{11}(\mathbf{r}) = p_{22}(\mathbf{r})$ is now valid for an assembly of finite crystals only. According to Fig. 4.2.3.5(*b*), there is a change in the intensities of the Bragg peaks.

$$\begin{aligned}
I_1 &\simeq |(\tfrac{1}{2}+s)F_1(\mathbf{H}) + (\tfrac{1}{2}-s)F_2(\mathbf{H})|^2,\\
I_2 &\simeq |(\tfrac{1}{2}+s)F_2(\mathbf{H}) + (\tfrac{1}{2}-s)F_1(\mathbf{H})|^2,
\end{aligned} \qquad (4.2.3.51)$$

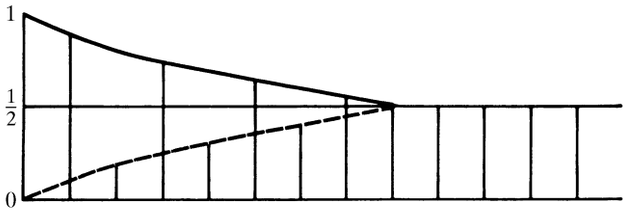

Fig. 4.2.3.7. The same distribution (*cf.* Fig. 4.2.3.5) in the case of superstructure formation.

where I_1, I_2 represent the two solutions discussed for the assembly of crystals and have to be added with the probability $\frac{1}{2}$; the intensities of sharp reflections become

$$I = (I_1 + I_2)/2. \tag{4.2.3.52}$$

Introducing equation (4.2.3.51) into (4.2.3.52), we obtain

$$I \simeq |\tfrac{1}{2}[F_1(\mathbf{H}) + F_2(\mathbf{H})]|^2 + s^2|F_1(\mathbf{H}) - F_2(\mathbf{H})^2|^2. \tag{4.2.3.53a}$$

$s = 0$ corresponds to the well known behaviour of sharp reflections, $s = \frac{1}{2}$ (maximum long-range order) gives

$$I \simeq \tfrac{1}{2}[|F_1(\mathbf{H})|^2 + |F_2(\mathbf{H})|^2]. \tag{4.2.3.53b}$$

This result reveals some difficulties for the determination of the averaged structure as long as s is different from zero or $\frac{1}{2}$, since in the former case the use of integrated sharp Bragg intensities yields a correct average structure. If $s = \frac{1}{2}$, a correct structure determination can only be performed with a refinement allowing for an incoherent superposition of two different structures. Having subtracted all periodic contributions to $p_{\mu\mu'}(\mathbf{r})$, new functions that describe the remaining nonperiodic parts have to be introduced (Fig. 4.2.3.6*b*). In order to obtain a clear overview of intensities, $p'_{\mu\mu'}(\mathbf{r})$ is again defined:

$$p'_{\mu\mu'}(\mathbf{r}) = cp_{\mu\mu'}(\mathbf{r}) - p_{\mu\mu'}(\infty),$$

where c should be chosen such that $p_{\mu\mu'}(\mathbf{0}) = 1$. By this definition a very simple behaviour of the diffuse scattering is obtained:

$$p'_{11}(\mathbf{r}) : \tfrac{1}{2} - s; \quad p'_{12}(\mathbf{r}) : -(\tfrac{1}{2} - s);$$
$$p'_{22}(\mathbf{r}) : \tfrac{1}{2} + s; \quad p'_{21}(\mathbf{r}) : -(\tfrac{1}{2} + s).$$

With the definitions introduced above it is found that

$$p'_{11}(\mathbf{r}) = p'_{22}(\mathbf{r}).$$

The diffuse scattering is given by

$$I_{1\mathrm{D}}(\mathbf{H}) = (\tfrac{1}{4} - s^2)|F_1(\mathbf{H}) - F_2(\mathbf{H})|^2[P'_{11}(\mathbf{H}) * L(\mathbf{H})]. \tag{4.2.3.54}$$

Since equation (4.2.3.54) is symmetrical with respect to an interchange of F_1 and F_2, the same result is obtained for $I_{2\mathrm{D}}$. Diffuse reflections occur in the positions of the sharp ones; the integrated intensities of sharp and diffuse reflections are independent of the special shape of $P'_{11}(\mathbf{H})$, hence

$$1 = \int P'_{11}(\mathbf{H}) \exp\{2\pi i \mathbf{0} \cdot \mathbf{H}\}\, \mathrm{d}\mathbf{H} = \int P'_{11}(\mathbf{H})\, \mathrm{d}\mathbf{H}$$

since $p_{11}(\mathbf{0}) = 1$.

(6) *Lamellar domains with long-range order: tendency to superorder*

So far it has been tacitly assumed that the crystal shows a preference for equal neighbours. If there is a reversed tendency (*i.e.* pairs of unequal neighbours are more probable), the whole procedure outlined above may be repeated as shown in Fig. 4.2.3.7 for the one-dimensional example. With the same probability of an unlike pair as used for the equal pair in the preceding example, the order process approaches an alternating structure such that the even-order neighbours have the same pair probabilities, while the odd ones are complementary for equal pairs (Fig. 4.2.3.7). In order to calculate intensities, it is necessary to introduce a new lattice with the doubled lattice constant and the corresponding reciprocal lattice with $b^{*\prime} = b^*/2$. In order to describe the probability $p_{\mu\mu'}(\mathbf{r})$, one has to introduce two lattices in real space – the normal lattice with the undisplaced origin and the displaced one. Fourier transformation of the new functions yields the following very similar results:

Sharp Bragg reflections

(*a*) $k' =$ even

$$I_{\mathrm{S}} = |\tfrac{1}{2}[F_1(\mathbf{H}) + F_2(\mathbf{H})]|^2. \tag{4.2.3.55a}$$

(*b*) $k' =$ odd

$$I_{\mathrm{S}} = s^2|\tfrac{1}{2}[F_1(\mathbf{H}) - F_2(\mathbf{H})]|^2. \tag{4.2.3.55b}$$

Diffuse reflections

(*c*) $k' =$ odd

$$I_{\mathrm{D}} = (\tfrac{1}{4} - s^2)|\tfrac{1}{2}[F_1(\mathbf{H}) - F_2(\mathbf{H})]|^2. \tag{4.2.3.55c}$$

In contrast to (5), this is the better situation for the determination of the averaged structure, which may be performed without any difficulty regardless of whether s is different from zero or not. For this purpose, even reflections (or reflections in the old setting) may be used. The inclusion of odd reflections in the structure determination of the superstructure is also possible if convenient **H**-independent scaling factors are introduced in order to compensate for the loss in intensity which is unavoidable for the integration of the diffuse scattering.

A few comments should be made on the physical meaning of the formulae derived above. All formulae may be applied to the general three-dimensional case, where long-range and short-range order is a function of the relevant thermodynamical parameters. In practice, long-range order will never be realized in a real crystal consisting of mosaic blocks which may behave as small subunits in order–disorder transitions. Another reason to assume partly incoherent areas in single crystals is the possible presence of strains or other distortions at the interfaces between domains, which should cause a decrease of the averaged areas of coherent scattering. All these effects may lead to diffuse scattering in the neighbourhood of Bragg peaks, similar to the diffuse scattering caused by domain structures. For this reason, an incoherent treatment of domains is probably more efficient, although considerable errors in intensity measurements may occur. A very careful study of line profiles is generally useful in order to decide between the various possibilities.

4.2.3.5.5. Two-dimensional disorder

The subject of two-dimensional disorder refers to predominantly one-dimensional structural elements, *e.g.* extended macromolecules and chain- or column-like structural units. A short introduction to this subject and some examples taken from inorganic structures are given in Section 4.2.5.3. Most important in this context, however, would be a treatment of disorder diffuse scattering of polymer/fibre structures. These are subjects in their own right and are treated in Chapter 4.5 of this volume and in Chapter 19.5 of Volume F.

4.2.3.5.6. Three-dimensional disorder

The solution of three-dimensional disorder problems is generally more demanding, although it may start with the formulation given above. Various algorithms have been developed to tackle these problems at least approximately, most of them restricted to particular models. Both real-space (cluster) and reciprocal-space (fluctuation wave) methods are employed and will be briefly addressed in Section 4.2.5.4. The more recently

developed approaches using computer simulations are described in Section 4.2.7.

Here we give only some general remarks on order–disorder problems.

Correlation functions in three dimensions may have very complicated periodicities; hence careful study is necessary to establish whether or not they may be interpreted in terms of a superlattice. If so, extinction rules have to be determined in order to obtain information on the superspace group. In the literature these are often called modulated structures (see Section 4.2.6) because a sublattice, as determined by the basic lattice, and a superlattice may well be defined in reciprocal space: reflections of a sublattice including (000) are formally described by a multiplication by a lattice having larger lattice constants (the superlattice) in reciprocal space; in real space this means a convolution with the Fourier transform of this lattice (the sublattice). In this way, the averaged structure is generated in each of the subcells (the superposition or 'projection' of all subcells into a single one). Obviously, the Patterson function of the averaged structure contains little information in the case of small subcells. Hence it is advisable to include the diffuse scattering of the superlattice reflections at the beginning of any structure determination.

N subcells in real space are assumed, each of them representing a kind of a complicated 'atom' that may be equal by translation or other symmetry operation. Once a superspace group has been determined, the usual extinction rules of space groups may be applied, remembering that the 'atoms' themselves may have systematic extinctions. Major difficulties arise from the existence of different symmetries of the subgroup and the supergroup. Since the symmetry of the supercell is lower in general, all missing symmetry elements may cause domains corresponding to the missing symmetry element: translations cause antiphase domains in their generalized sense; other symmetry elements cause twins generated by rotations, mirror planes or the centre of symmetry. If all these domains are small enough to be detected by a careful study of line profiles, using diffraction methods with a high resolution power, the structural study may be facilitated by introducing scaling factors for groups of reflections affected by the possible domain structures.

4.2.3.6. Symmetry

If disorder problems involving completely different structures (exsolutions *etc.*) are excluded, in general the symmetry of the diffuse-scattering pattern is the same as that of the Bragg peaks, *i.e.* it corresponds to the point group of the space group of the average structure. Only under specific directional growth conditions are deviations from this rule conceivable (although seemingly not very common). On the other hand, the symmetry of the underlying disorder model in direct space may be lower than that of the space group of the average structure (it is usually a subgroup of the space group of the average structure). The overall symmetry in reciprocal space is then restored by employing the missing (point-group) symmetry elements, which have therefore to be used in the calculation of the full diffraction pattern.

From these arguments, some specific disorder models may be classified according to the irreducible representations of the space group of the average structure. While for general wavevectors in the Brillouin zone no further restrictions appear, for high-symmetry directions consideration of the irreducible representations of the little co-group of the wavevector can help to identify the different symmetries of the disorder model. This becomes particularly evident when the modulation-wave approach is used as shown *e.g.* by Welberry & Withers (1990) and Welberry & Butler (1994). Of particular value are observed extinction rules, which may be calculated by group-theoretical methods as developed by Perez-Mato *et al.* (1998) for the extinctions occurring in inelastic neutron-scattering experiments. In favourable cases, the analysis of such extinctions alone can lead to a unique determination of the disorder model (see, *e.g.*, Aroyo *et al.*, 2002).

4.2.4. General guidelines for analysing a disorder problem

In general, the structure determination of a disordered crystal should start in the usual way by solving the average structure. The effectiveness of this procedure strongly depends on the distribution of integrated intensities of sharp and diffuse reflections. In cases where the integrated intensities of Bragg peaks are predominant, the maximum information can be drawn from the averaged structure. The observations of fractional occupations of lattice sites, split positions and anomalous large and anharmonic displacement parameters are indications of the disorder involved. Since these aspects of disorder phenomena in the averaged structure may be interpreted very easily, a detailed discussion of this matter is not given here (see any modern textbook of X-ray crystallography). Therefore, the anomalies of the average structure can give valuable hints on the underlying disorder and, *vice versa*, can be used to check the final disorder model derived from the diffuse scattering.

Difficulties may arise from the intensity integration, which should be carried out very carefully to separate the Bragg peaks from the diffuse contributions, *e.g.* by using a high-resolution diffraction method. The importance of this may be understood from the following argument. The averaged structure is determined by the coherent superposition of different structure factors. This interpretation is true if there is a strictly periodic subcell with long-range order that allows for a clear separation of sharp and diffuse scattering. There are important cases, however, where this procedure cannot be applied without loss of information.

(*a*) The diffuse scattering (other than thermal diffuse scattering) is concentrated near the Bragg peaks for a large number of reflections. Because of the limited resolution power of conventional single-crystal methods, the separation of sharp and diffuse scattering is impossible. Hence, the conventional study of integrated intensities does not really lead to an averaged structure. In this case, a refinement should be tried using an incoherent superposition of different structure factors (from the average structure and the difference structure). Application of this procedure is subject to conditions which have to be checked very carefully before starting the refinement: first, it is necessary to estimate the amount of diffuse scattering not covered by intensity integration of the 'sharp' reflections. Since loss in intensity, hidden in the background scattering, is underestimated very frequently, it should be checked whether nearly coinciding sharp and diffuse maxima are modulated by the same structure factor. It may be difficult to meet this condition in some cases; *e.g.* this condition is fulfilled for antiphase domains but the same is not true for twin domains.

(*b*) The concentration of diffuse maxima near Bragg peaks is normally restricted to domain structures with a strictly periodic sublattice. Cases deviating from this rule are possible. Since they are rare, they are omitted here. Even structures with small deviations from the average structure do not necessarily lead to structure factors for diffuse scattering that are proportional to those of the average structure. This has been shown in the case of a twin structure correlated by a mirror plane, where the reflections of a zone only have equal structure factors (Cowley & Au, 1978). This effect causes even more difficulties for orthogonal lattices, where the two twins have reflections in exactly the same positions, although differing in their structure factors. In this particular case, the incoherent or coherent treatment in refinements may be seriously hampered by strains originating from the boundary. Unsatisfactory refinements may be explained in this way but this does not improve their reliability.

The integrated intensity within a Brillouin zone of any structure is independent of atomic positions if the atomic form factors remain unchanged by structural fluctuations. Small deviations of atomic form factors owing to electron-density changes of valence electrons are neglected. Consequently, the integrated diffuse intensities remain unchanged if the average structure is not altered by the degree of order. The latter condition is obeyed in cases where a geometrical long-range order of the lattice is independent of the degree of order, and no long-range order in the structure exists. This law is extremely useful for the interpretation of diffuse scattering. Unfortunately, intensity integration over coinciding sharp and diffuse maxima does not necessarily lead to a structure determination of the corresponding undistorted structure. This integration may be useful for antiphase domains without major structural changes at the boundaries. In all other cases, the deviations of domains (or clusters) from the averaged structure determine the intensities of maxima, which are no longer correlated with those of the average structure.

If the integrated intensity of diffuse scattering is comparable with, or even larger than, those of the Bragg peaks, it is useful to begin the interpretation with a careful statistical study of the diffuse intensities. Intensity statistics can be applied in a way similar to the intensity statistics in classical structure determination. The following rules are briefly discussed in order to enable a semiquantitative interpretation of the essential features of disorder.

(1) First, it is recommended that the integrated intensities are studied in certain areas of reciprocal space.

(2) Since low-angle scattering is very sensitive to fluctuations of densities, the most important information can be drawn from its intensity behaviour. If there is at least a one-dimensional sublattice in reciprocal space without diffuse scattering, it may often be concluded that there is no important low-angle scattering either. This law is subject to the condition of a sufficient number of reflections obeying this extinction rule without any exception.

(3) If the diffuse scattering shows maxima and minima, it should be checked whether the maxima observed may be approximately assigned to a lattice in reciprocal space. Obviously, this condition can hardly be met exactly if these maxima are modulated by a kind of structure factor, which causes displacements of maxima proportional to the gradient of this structure factor. Hence this influence may well be estimated from a careful study of the complete diffuse diffraction pattern.

It should then be checked whether the corresponding lattice represents a sub- or a superlattice of the structure. An increase of the width of reflections as a function of increasing $|\mathbf{H}|$ indicates strained clusters of this sub- or superlattice.

(4) The next step is to search for extinction rules for the diffuse scattering. The simplest is the lack of low-angle scattering, which has already been mentioned above. Since diffuse scattering is generally given by equation (4.2.3.23*b*),

$$I_{\rm D}(\mathbf{H}) = \langle |F(\mathbf{H})|^2 \rangle - |\langle F(\mathbf{H}) \rangle|^2 = \sum_\mu p_\mu |F_\mu(\mathbf{H})|^2 - \Big| \sum_\mu p_\mu F_\mu(\mathbf{H}) \Big|^2,$$

it may be concluded that this condition is fulfilled in cases where all structural elements participating in disorder differ by translations only (stacking faults, antiphase domains *etc.*). They add phase factors to the various structure factors, which may become $n2\pi$ (n = integer) for specific values of the reciprocal vector $\mathbf{H}$. If all p_μ are equivalent by symmetry

$$p \sum_\mu |F_\mu(\mathbf{H})|^2 - \left[p \sum_\mu F_\mu(\mathbf{H}) \right] \left[p \sum_\mu F_\mu^+(\mathbf{H}) \right] = 0.$$

Other possibilities for vanishing diffuse scattering may be derived in a similar manner for special reflections if glide operations are responsible for disorder. Since we are concerned with disordered structures, these glide operations need not necessarily be a symmetry operation of the lattice. It should be pointed out, however, that all these extinction rules of diffuse scattering are a kind of 'anti'-extinction rule, because they are valid for reflections having maximum intensity for the sharp reflections unless the structure factor itself vanishes.

(5) Furthermore, it is important to plot the integrated intensities of sharp and diffuse scattering as a function of the reciprocal coordinates, at least in a semiquantitative way. If the ratio of integrated intensities remains constant in the statistical sense, we are predominantly concerned with a density phenomenon. It should be pointed out, however, that a particle-size effect of domains behaves like a density phenomenon (the density changes at the boundary!).

If the ratio of 'diffuse' to 'sharp' intensities increases with diffraction angle, we have to take into account atomic displacements. A careful study of this ratio yields very important information on the number of displaced atoms. The result has to be discussed separately for domain structures if the displacements are equal in the subcells of a single domain but different for the various domains. In the case of two domains with displacements of all atoms, the integrated intensities of sharp and diffuse reflections become statistically equal for large $|\mathbf{H}|$. Other rules may be derived from statistical considerations.

(6) The next step of a semiquantitative interpretation is to check the intensity distribution of diffuse reflections in reciprocal space. In general this modulation is simpler than that of the sharp reflections. Hence it is frequently possible to start a structure determination with diffuse scattering. This method is extremely helpful for one- and two-dimensional disorder where partial structure determinations yield valuable information, even for the evaluation of the average structure.

(7) In cases where no sub- or superlattice belonging to the diffuse scattering can be determined, a careful check of integrated intensities in the neighbourhood of Bragg peaks should again be performed. If systematic absences are found, the disorder is most probably restricted to specific lattice sites which may also be found in the average structure. The accuracy, however, is much lower here. If no such effects correlated with the average structure are observed, the disorder problem is related to a distribution of molecules or clusters with a structure differing from the average structure. As pointed out in Section 4.2.3.1, the problem of the representative structure(s) of the molecule(s) or the cluster(s) should be solved. Furthermore, their distribution function(s) is (are) needed. In this particular case, it is very useful to start with a study of diffuse intensity at low diffraction angles in order to acquire information about density effects. Despite the contribution to sharp reflections, one should remember that the level of information derived from the average structure may be very low (*e.g.* small displacements, low concentrations *etc.*).

(8) A Patterson picture – or strictly speaking a difference Patterson ($|\Delta F|^2$ Fourier synthesis) – may be very useful in this case. This method is promising in the case of disorder in molecular structures where the molecules concerned are at least partly known. Hence the interpretation of the difference Patterson may start with some internal molecular distances. Nonmolecular structures show some distances of the average structure. Consequently, a study of the important distances will yield information on displacements or replacements in the average structure. For a detailed study of this matter the reader is referred to the literature (Schwartz & Cohen, 1977).

Although it is highly improbable that exactly the same diffraction picture will be found, the use of an atlas of optical transforms (Wooster, 1962; Harburn *et al.*, 1975; Welberry & Withers, 1987) may be helpful at the beginning of any study of

diffuse scattering. Alternatively, computer simulations may be helpful, as discussed in Section 4.2.7. The most important step is the separation of the distribution function from the molecular scattering. Since this information may be derived from a careful comparison of low-angle diffraction with the remaining sharp reflections, this task is not too difficult. If the influence of the distribution function is unknown, the reader is strongly advised to disregard the immediate neighbourhood of Bragg peaks in the first step of the interpretation. Obviously information may be lost in this way but, as has been shown in the past, much confusion caused by an attempt to interpret the scattering near the Bragg peaks with specific structural properties of a cluster or molecular model is avoided. The inclusion of this part of diffuse scattering can be made after a complete interpretation of the change of the influence of the distribution function on diffraction in the wide-angle region.

4.2.5. Quantitative interpretation

4.2.5.1. Introduction

In these sections, quantitative interpretations of the elastic part of X-ray and neutron diffuse scattering are outlined. Although similar relations are valid for the magnetic scattering of neutrons, this particular topic is excluded. Obviously, all disorder phenomena are strongly temperature-dependent if thermal equilibrium is reached. Consequently, the interpretation of diffuse scattering should include a statistical thermodynamical treatment. Unfortunately, no quantitative theory for the interpretation of structural phenomena is so far available: all quantitative solutions introduce formal order parameters such as correlation functions or distributions of defects. At low temperatures (*i.e.* with a low concentration of defects) the distribution function plays the dominant role in diffuse scattering. With increasing temperature the number of defects increases with corresponding strong interactions between them. Therefore, correlations become increasingly important, and phase transformations of first or higher order may occur which need a separate theoretical treatment. In many cases, large fluctuations of structural properties occur that are closely related to the dynamical properties of the crystal. Theoretical approximations are possible, but their presentation is far beyond the scope of this article. Hence we restrict ourselves to formal parameters in the following.

Point defects or limited structural units, such as molecules, clusters of finite size *etc.*, may only be observed in diffraction if there is a sufficiently large number of defects. This statement is no longer true in high-resolution electron diffraction, where single defects may be observed either by diffraction or by optical imaging if their contrast is high enough. Hence electron microscopy and diffraction are valuable methods in the interpretation of disorder phenomena.

The arrangement of a finite assembly of structural defects is described by its structure and its three-dimensional (3D) distribution function. Structures with a strict 1D periodicity (chain-like structures) need a 2D distribution function, while for structures with a 2D periodicity (layers) a 1D distribution function is sufficient. Since the distribution function is the dominant factor in statistics with correlations between defects, we define the dimensionality of disorder as that of the corresponding distribution function. This definition is more effective in diffraction problems because the dimension of the disorder problem determines the dimension of the diffuse scattering: 1D diffuse streaks, 2D diffuse layers or a general 3D diffuse scattering.

Strictly speaking, completely random distributions cannot be realized, as shown in Section 4.2.3. They occur approximately if the following conditions are satisfied:

(1) The average volume of all defects including their surrounding strain fields NcV_d (where N is the number of unit cells, c is the concentration of defects and V_d is the volume of the defect with $V_d > V_c$, V_c being the volume of the unit cell) is small in comparison with the total volume NV_c of the crystal, or $V_c \gg cV_d$.

(2) Interactions between the defects are negligible. These conditions, however, are valid in very rare cases only, *i.e.* where small concentrations and vanishing strain fields are present. Remarkable exceptions from this rule are real point defects without interactions, such as isotope distribution (which can be studied by neutron diffraction) or the system AuAg at high temperature.

As already mentioned, disorder phenomena may be observed in thermal equilibrium. Two completely different cases have to be considered:

(1) The concentration of defects is given by the chemical composition, *i.e.* impurities in a closed system.

(2) The number of defects increases with temperature and also depends on pressure or other parameters, *i.e.* interstitials, voids, static displacements of atoms, stacking faults, dislocations *etc.*

In many cases, the defects do not occur in thermal equilibrium. Nevertheless, their diffuse scattering is temperature-dependent because of the anomalous thermal movements at the boundary of the defect. Hence the observation of a temperature-dependent behaviour of diffuse scattering cannot be taken as a definite criterion of thermal equilibrium without further careful interpretation.

Ordering of defects may take place in a very anisotropic manner. This is demonstrated by the huge number of examples of 1D disorder. As shown by Jagodzinski (1963), this type of disorder cannot occur in thermal equilibrium for the infinite crystal. This type of disorder is generally formed during crystal growth or mechanical deformation. Similar arguments may be applied to 2D disorder. This is a further reason why the Ising model can hardly ever be used to obtain interaction energies of structural defects. From these remarks it becomes clear that order parameters are formal parameters without strict thermodynamical meaning.

The following section is organized as follows: first we discuss the simple case of 1D disorder where reliable solutions of the diffraction problem are available. Intensity calculations for diffuse scattering from 2D disorder by chain-like structures follow. Finally, the 3D case is treated, where formal solutions of the diffraction problem have been tried and applied successfully to metallic systems to some extent. A short concluding section concerns the special phenomenon of orientational disorder.

4.2.5.2. Layered structures: one-dimensional disorder

As has been pointed out above, it is often useful to start the interpretation of diffuse scattering by checking the diffraction pattern with respect to the dimensionality of the disorder concerned. Since each disordered direction in the crystal demands a violation of the corresponding Laue condition, this question may easily be answered by looking at the diffuse scattering. Diffuse streaks in reciprocal space are due to a one-dimensional violation of the Laue conditions, and will be called one-dimensional disorder. This kind of order is typical for layer structures, but it is frequently observed in cases where several sequences of layers do not differ in the interactions of next-nearest neighbours. Typical examples are structures which may be described in terms of close packing, *e.g.* hexagonal and cubic close packing.

For a quantitative interpretation of diffuse streaks we need one-dimensional correlation functions, which may be determined uniquely if a single independent correlation function is active. According to equation (4.2.3.50), Fourier transformation yields the information required. In all other cases, a specific model has to be suggested for a full interpretation of diffuse streaks. It is worth noting that disorder parameters can be defined uniquely

only if the diffraction pattern allows for a differentiation between long-range and short-range order. This question can be answered at least partly by studying the line width of sharp reflections at very good resolution. Since integrated intensities of sharp reflections have to be separated from the diffuse scattering, this question is of outstanding importance in most cases. Inclusion of diffuse parts in the diffraction pattern during intensity integration of sharp reflections may lead to serious errors in the interpretation of the average structure.

The existence of diffuse streaks in more than one direction of reciprocal space means that the diffraction problem is no longer one-dimensional. Sometimes the problem may be treated independently if the streaks are sharp and no interference effects are observed in the diffraction pattern in areas where the diffuse streaks do overlap. In all other cases, there are correlations between the various directions of one-dimensional disorder which can be determined with the aid of a model covering more than one of the pertinent directions of disorder.

Before starting the discussion of the quantitative solution of the one-dimensional problem, some remarks should be made about the usefulness of quantitative disorder parameters. It is well known from statistical thermodynamics that a one-dimensional system cannot show long-range order above $T = 0$ K. Obviously, this statement is in contradiction with many experimental observations of long-range order even in layer structures. The reason for this behaviour is given by the following arguments, which are valid for any structure. Let us assume a structure with strong interactions at least in two directions. From the theoretical treatment of the two-dimensional Ising model it is known that such a system shows long-range order below a critical temperature T_c. This statement is true even if the layer is finite, although the strict thermodynamic behaviour is not really critical in the thermodynamical sense. A three-dimensional crystal can be constructed by adding layer after layer. Since each layer has a typical two-dimensional free energy, the full statistics of the three-dimensional crystal may be calculated by introducing a specific free energy for the various stackings of layers. Obviously, this additional energy also has to include terms describing potential and entropic energies. They may be formally developed into contributions of next, next-but-one *etc.* nearest neighbours. The contribution to entropy must include configurational and vibrational parts, which are strongly coupled. As long as the layers are finite, there is a finite probability of a fault in the stacking sequence of layers which approaches zero with increasing extension of the layers. Consequently, the free energy of a change in the favourite stacking sequence becomes infinite quadratically with the size of the layer. Therefore, the crystal should be either completely ordered or disordered; the latter case can only be realized if the free energies of one or more stacking sequences are exactly equal (this is very rare but is possible over a small temperature range during phase transformations). An additional positive entropy associated with a deviation from the periodic stacking sequence may lead to a kind of competition between entropy and potential energy, in such a way that periodic sequences of faults result. This situation occurs in the transition range of two structures differing only in their stacking sequence. On the other hand, one must assume that defects in the stacking sequence may occur if the size of the layers is small. This situation occurs during crystal growth, but one should remember that the number of stacking defects should decrease with increasing size of the growing crystal. Apparently, this rearrangement of layers may be suppressed as a consequence of relaxation effects. The growth process itself may influence the propagation of stacking defects and, consequently, the determination of stacking-fault probabilities, with the aim of interpreting the chemical bonding, seems to be irrelevant in most cases.

The quantitative solution of the diffraction problem of one-dimensional disorder follows a method similar to the Ising model. As long as next-nearest neighbours alone are considered, the solution is very simple if only two possibilities for the structure factors are to be taken into account. Introducing the probability of equal pairs 1 and 2, α, one arrives at the known solution for the *a priori* probability p_μ and *a posteriori* probabilities $p_{\mu\mu'}(\mathbf{m})$, respectively. In the one-dimensional Ising model with two spins and the interaction energies $(U \mp \Delta U)/k_B T$, defining the pair probability $[\alpha = p_{11}(\mathbf{1})]$ as

$$\alpha = \frac{\exp\{\pm \Delta U/k_B T\}}{[\exp\{+\Delta U/k_B T\} + \exp\{-\Delta U/k_B T\}]},$$

the full symmetry is $p_1 = p_2 = \frac{1}{2}$ and $p_{11}(\mathbf{m}) = p_{22}(\mathbf{m})$.

Consequently

$$p_{12}(\mathbf{m}) = p_{22}(\mathbf{m}) = 1 - p_{11}(\mathbf{m}).$$

The scattered intensity is given by

$$I(\mathbf{H}) = L(h,k) \sum_{\mathbf{m}} \langle FF_m^+ \rangle (N - |m|) \exp\{-2\pi i m l\}, \qquad (4.2.5.1)$$

where $\mathbf{m} = m\mathbf{c}$, N is the number of unit cells in the $\mathbf{c}$ direction and $\langle FF^+ \rangle$ depends on λ_1, λ_2, which are the eigenvalues of the matrix

$$\begin{pmatrix} \alpha & 1-\alpha \\ 1-\alpha & \alpha \end{pmatrix}.$$

From the characteristic equation

$$\lambda^2 - 2\alpha\lambda - 1 + 2\alpha = 0 \qquad (4.2.5.2)$$

one has

$$\lambda_1 = 1; \quad \lambda_2 = 2\alpha - 1. \qquad (4.2.5.2a)$$

λ_1 describes a sharp Bragg reflection (from the average structure) which need not be calculated. Its intensity is simply proportional to $\langle F(\mathbf{H}) \rangle$. The second characteristic value yields a diffuse reflection in the same position if the sign is positive ($\alpha > 0.5$) and in a position displaced by $\frac{1}{2}$ in reciprocal space if the sign is negative ($\alpha < 0.5$). Because of the symmetry conditions only $p_{11}(\mathbf{m})$ is needed; it may be determined with the aid of the boundary conditions

$$p_{11}(\mathbf{0}) = 1, \quad p_{11}(\mathbf{1}) = \alpha,$$

and the general relation

$$p_{\mu\mu'}(\mathbf{m}) = c'_{\mu\mu'} \lambda_1^m + c''_{\mu\mu'} \lambda_2^m.$$

The final solution of our problem yields simply

$$p_{11}(\mathbf{m}) = \tfrac{1}{2} + \tfrac{1}{2}\lambda_2^m = p_{22}(\mathbf{m}),$$
$$p_{12}(\mathbf{m}) = \tfrac{1}{2} - \tfrac{1}{2}\lambda_2^m = p_{21}(\mathbf{m}).$$

The calculation of the scattered intensity is now performed with the general formula

$$I(\mathbf{H}) = L(h,k) \sum_m \sum_{\mu,\mu'} p_\mu p_{\mu\mu'}(\mathbf{m}) F_\mu F_{\mu'}^+ (N - |m|) \exp\{-2\pi i m l\}. \qquad (4.2.5.3)$$

Evaluation of this expression yields

$$I(\mathbf{H}) = L(h,k) \sum_m (N - |m|) \exp\{-2\pi i m l\} \times [|\tfrac{1}{2}(F_1 + F_2)|^2 \lambda_1^m + |\tfrac{1}{2}(F_1 - F_2)|^2 \lambda_2^m]. \qquad (4.2.5.4)$$

Since the characteristic solutions of the problem are real,

$$I(\mathbf{H}) = L(\mathbf{G})|(F_1 + F_2)/2|^2 + L(h,k)|(F_1 - F_2)/2|^2 \times \frac{1 - |\lambda_2|^2}{1 - 2\lambda_2 \cos 2\pi l + |\lambda_2|^2}. \quad (4.2.5.5)$$

The particle-size effect has been neglected in (4.2.5.5). This result confirms the fact mentioned above that the sharp Bragg peaks are determined by the averaged structure factor and the diffuse ones by its mean-square deviation.

For the following reason there are no examples of quantitative applications: two different structures generally have different lattice constants, so the original assumption of an undisturbed lattice geometry is not valid. The only case known to the authors is the typical lamellar structure of plagioclases reported by Jagodzinski & Korekawa (1965). The authors interpret the well known 'Schiller effect' as a consequence of optical diffraction. Hence, the size of the lamellae is of the order of 2000 Å. This long-period superstructure cannot be explained in terms of next-nearest-neighbour interactions. In principle, however, the diffraction effects are similar: instead of the diffuse peak as described by the second term in equation (4.2.5.5), satellites of first and second order *etc.* accompanying the Bragg peaks are observed. The study of this phenomenon (Korekawa & Jagodzinski, 1967) has in the meantime found a quantitative interpretation (Burandt *et al.*, 1992; Kalning *et al.*, 1997).

Obviously, the symmetry relation used in the formulae discussed above is only valid if the structures described by the F_μ are related by symmetries such as translations, rotations or combinations of the two. The type of symmetry has an important influence on the diffraction pattern.

(1) *Translation parallel to the ordered layers*

If the translation vector between the two layers in question is such that $2\Delta\mathbf{r}$ is a translation vector parallel to the layer, there are two relevant structure factors:

$$F_1, F_2 = F_1 \exp\{2\pi i \mathbf{H} \cdot \Delta\mathbf{r}\}.$$

$\mathbf{H} \cdot \Delta\mathbf{r}$ may be either an integer or an integer + $\frac{1}{2}$. Since any integer may be neglected because of the translation symmetry parallel to the layer, we have $F_1 = F_2$ in the former case and $F_1 = -F_2$ in the latter. As a consequence, either the sharp reflections given in equation (4.2.5.4) vanish, or the same is true for the diffuse ones. Hence the reciprocal lattice may be described in terms of two kinds of lattice rows, sharp and diffuse, parallel to the reciprocal coordinate l.

Disorder of this type is observed very frequently. One of the first examples was wollastonite, $CaSiO_3$, studied by Jefferey (1953). Here the reflections with $k = 2n$ are sharp Bragg peaks without any diffuse scattering. Diffuse streaks parallel to (h00), however, are detected for $k = 2n + 1$. In the light of the preceding discussion, the translation vector is $\frac{1}{2}\mathbf{b}$ and the plane of ordered direction (the plane of intergrowth of the two domains) is (100). Hence the displacement is parallel to this plane. Since the intensity of the diffuse lines does not vary according to the structure factor involved, the disorder cannot be random. The maxima observed are approximately in the position of a superstructure generated by large domains without faults in the stacking sequence mutually displaced by $\frac{1}{2}\mathbf{b}$ (antiphase domains). This complicated ordering behaviour is typical for 1D order and may easily be explained by the above-mentioned fact that an infinitely extended interface between two domains causes an infinite unfavourable energy (Jagodzinski, 1964*b*, p. 188). Hence a growing crystal should become increasingly ordered. This consideration explains why the agreement between a 1D disorder theory and experiment is often so poor.

Examples where more than one single displacement vector occur are common. If these are symmetrically equivalent all symmetries have to be considered. The most important cases of displacements differing only by translation are the well known close-packed structures (see below). A very instructive example is the mineral maucherite (approximately Ni_4As_3). According to Jagodzinski & Laves (1947), the structure has the following disorder parameters: interface (001), displacement vectors [000], [$\frac{1}{2}$00], [0$\frac{1}{2}$0], [$\frac{1}{2}\frac{1}{2}$0]. From equation (4.2.5.5) we obtain

$$\langle F(\mathbf{H})\rangle = [1 + \exp\{\pi i h\} + \exp\{\pi i k\} + \exp\{\pi i (h + k)\}]/4.$$

Hence there are sharp reflections for h, k = even and diffuse ones otherwise. Further conclusions may be drawn from the average structure.

(2) *Translation perpendicular to the ordered layers*

If the translation is $\mathbf{c}/2$ the structure factors are

$$F_2 = F_1 \exp\{2\pi i l\},$$
$$F_1 = F_2 \text{ for } l = \text{even},$$
$$F_1 = -F_2 \text{ for } l = \text{odd}.$$

There are sharp ($l = 2n$) *and* diffuse ($l = 2n + 1$) reflections on all reciprocal-lattice rows discussed above.

Since the sharp and diffuse reflections occur on the same reciprocal line, the behaviour is completely different compared with the preceding case. In general, a component of any displacement vector perpendicular to the interface gives rise to a change in chemical composition, as shown in the next example: in a binary system consisting of A and B atoms with a tendency towards an alternating arrangement of A and B layers, any fault in the sequence $BABAB|BABAB|B$ increases the number of B atoms (or A atoms). In general, such kinds of defects will lead to an interface with a different lattice constant, at least in the direction perpendicular to the interface. Consequently, the exact displacement vectors of $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$ are rare. Since ordered structures should be realized in the 1D case, incommensurate superstructures will occur; these are very abundant during ordering processes. An interesting example has been reported and interpreted by Cowley (1976*a*,*b*), where the displacement vector has a translational period of $\frac{1}{4}$ perpendicular to the plane of intergrowth. Reflections 00l and 22l with l = 4n are sharp, all remaining reflections more or less diffuse. Since the maxima ($\bar{1}11$), ($\bar{1}33$) show a systematically different behaviour, there is also a displacement component parallel to the plane of intergrowth in question. A semiquantitative interpretation was given in his papers.

(3) *Rotations*

Layers related by a twofold rotation parallel to **c** may easily be discussed by simply considering their structure factors. Since the layers do not obey the twofold symmetry, their structure factors are generally different; unless they become equal accidentally there are sharp and diffuse reflections according to the values of $\langle F\rangle$ and ΔF, respectively. Obviously, $F_1 = F_2$ is valid only if $h = k = 0$; consequently there is just one reciprocal-lattice row free from diffuse scattering.

(4) *Asymmetric case*

In the asymmetric case, the symmetry conditions used above are no longer valid:

$$p_1 \neq p_2, \quad p_{12} \neq p_{21}, \quad p_{11} \neq p_{22}.$$

However, there is one condition which may be derived from the invariance of the numbers of pairs in the relevant and its opposite direction:

$$p_\mu p_{\mu\mu'}(\mathbf{m}) = p_{\mu'} p_{\mu'\mu}(-\mathbf{m}).$$

This equation does not require that $p_{\mu\mu'}(\mathbf{m})$ should be symmetric in $\mathbf{m}$. The calculation of characteristic values yields

$$\lambda_1 = 1, \qquad \lambda_2 = (\alpha_1 + \alpha_2) - 1. \quad (4.2.5.6)$$

The *a priori* probabilities are now different from $\frac{1}{2}$ and may be calculated by considering $p_{\mu\mu'}(\mathbf{m}) \rightarrow p_{\mu'}(\mathbf{m} \rightarrow \infty)$:

$$p_1 = \alpha_1/(\alpha_1 + \alpha_2); \quad p_2 = \alpha_2/(\alpha_1 + \alpha_2).$$

The intensity is given by an expression very similar to (4.2.5.5):

$$\begin{aligned} I(\mathbf{H}) = {} & L(\mathbf{G})|[\alpha_1/(\alpha_1 + \alpha_2)]F_1 + [\alpha_2/(\alpha_1 + \alpha_2)]F_2|^2 \\ & + L(h,k)|[\alpha_1/(\alpha_1 + \alpha_2)]F_1 - [\alpha_2/(\alpha_1 + \alpha_2)]F_2|^2 \\ & \times (1 - |\lambda_2|^2)/(1 - 2\lambda_2 \cos 2\pi l + |\lambda_2|^2). \end{aligned} \tag{4.2.5.7}$$

Again, there are sharp Bragg reflections and diffuse ones in the same positions or in a displaced position depending on the sign of λ_2.

From a discussion of the next-nearest-neighbour Ising model, one may conclude that a detailed study of the qualitative behaviour of sharp and diffuse reflections may give additional information on the symmetry of the layers involved.

In the case of translations between neighbouring layers not fulfilling the condition $\mathbf{h} \cdot \mathbf{r}$ = integer, where $\mathbf{r}$ is parallel to the layer, more than two structure factors have to be taken into account. If $n\mathbf{h} \cdot \mathbf{r}$ = integer, where n is the smallest integer fulfilling the said condition, n different structure factors have to be considered. The characteristic equation has formally to be derived with the aid of an $n \times n$ matrix containing internal symmetries, which may be avoided by adding the phase factors $\varepsilon = \exp\{2\pi i \mathbf{H} \cdot \mathbf{r}/n\}$, $\varepsilon^+ = \exp\{-2\pi i \mathbf{H} \cdot \mathbf{r}/n\}$ to the probability of pairs. The procedure is allowed if the displacements $\mathbf{r}$ and $-\mathbf{r}$ are admitted only for neighbouring layers. The matrix yielding the characteristic values may then be reduced to

$$\begin{pmatrix} \alpha_1\varepsilon & (1-\alpha_1)\varepsilon^+ \\ (1-\alpha_2)\varepsilon & \alpha_2\varepsilon^+ \end{pmatrix}$$

and yields the characteristic equation

$$\lambda^2 - \lambda(\alpha_1\varepsilon + \alpha_2\varepsilon^+) - 1 + \alpha_1 + \alpha_2 = 0. \tag{4.2.5.8}$$

Equation (4.2.5.8) gives sharp Bragg reflections for $\mathbf{H} \cdot \mathbf{r}/n$ = integer; the remaining diffuse reflections are displaced according to the phase of the complex characteristic value. Equation (4.2.5.8) has been used in many cases. Qualitative examples are the mixed-layer structures published by Hendricks & Teller (1942). An example of a four-layer-type structure is treated by Dubernat & Pezerat (1974). A first quantitative treatment with good agreement between theory and experimental powder diffraction data has been given by Dorner & Jagodzinski (1972) for the binary system TiO_2–SnO_2. In the range of the so-called spinodal decomposition, the chemical compositions of the two domains and the average lengths of the two types of domains could be determined. Another quantitative application was reported by Jagodzinski & Hellner (1956) for the transformation of $RhSn_2$ into a very complicated mixed-layer type. A good agreement of measured and calculated diffuse scattering (with asymmetric line profiles and displacement of maxima) could be found over a wide angular range of single-crystal diffraction.

4.2.5.2.1. Stacking disorder in close-packed structures

From an historical point of view, stacking disorder in close-packed systems is most important. The three relevant positions of ordered layers are represented by the atomic coordinates $|0,0|$, $|\frac{1}{3},\frac{2}{3}|$, $|\frac{2}{3},\frac{1}{3}|$ in the hexagonal setting of the unit cell, or simply by the figures 1, 2, 3 in the same sequence. Structure factors F_1, F_2, F_3 refer to the corresponding positions of the same layer:

$$F_2 = F_1 \exp\{2\pi i(h-k)/3\},$$
$$F_3 = F_1 \exp\{-2\pi i(h-k)/3\},$$

hence

$$F_1 = F_2 = F_3 \quad \text{if } h - k \equiv 0 \pmod 3.$$

According to the above discussion, the indices 1, 2, 3 define the reciprocal-lattice rows exhibiting sharp reflections only, as long as the distances between the layers are exactly equal. The symmetry conditions caused by the translation are normally

$$p_1 = p_2 = p_3, \qquad p_{11} = p_{22} = p_{33},$$
$$p_{12} = p_{23} = p_{31}, \quad p_{13} = p_{21} = p_{32}.$$

For the case of close packing of spheres and some other problems any configuration of $\mathbf{m}$ layers determining the *a posteriori* probability $p_{\mu\mu'}(\mathbf{m})$, $\mu = \mu'$, has a symmetrical counterpart where μ is replaced by $\mu' + 1$ (if $\mu' = 3$, $\mu' + 1 = 1$).

In this particular case, $p_{12}(\mathbf{m}) = p_{13}(\mathbf{m})$ and equivalent relations generated by translation.

Nearest-neighbour interactions do not lead to an ordered structure if the principle of close packing is obeyed (no pairs are in equal positions) (Hendricks & Teller, 1942; Wilson, 1942). Extension of the interactions to next-but-one or more neighbours may be carried out by introducing the method of matrix multiplication developed by Kakinoki & Komura (1954, 1965) or the method of overlapping clusters (Jagodzinski, 1954). The latter procedure is outlined in the case of interactions between four layers. A given set of three layers may occur in the following 12 combinations:

$$123, 231, 312; \quad 132, 213, 321;$$
$$121, 232, 313; \quad 131, 212, 323.$$

Since three of them are equivalent by translation, only four representatives have to be introduced:

$$123; \quad 132; \quad 121; \quad 131.$$

In the following, the new indices 1, 2, 3, 4 are used for these four representatives for the sake of simplicity.

In order to construct the statistics layer by layer, the next layer must belong to a triplet starting with the same two symbols with which the preceding one ended, *e.g.* 123 can only be followed by 231 or 232. In a similar way, 132 can only be followed by 321 or 323. Since both cases are symmetrically equivalent, the probabilities α_1 and $1 - \alpha_1$ are introduced. In a similar way, 121 may be followed by 212 or 213 *etc.* For these two groups the probabilities α_2 and $1 - \alpha_2$ are defined. The different translations of groups are considered by introducing the phase factors as described above. Hence the matrix for the characteristic equation may be set up as follows. As a representative cluster of each group the one having the number 1 at the centre is chosen, *e.g.* 312 is the representative for the group 123, 231, 312; in a similar way 213, 212 and 313 are the remaining representatives. Since this arrangement of three layers is equivalent by translation, it may be assumed that the structure of the central layer is not influenced by the statistics to a first approximation. The same arguments hold for the remaining three groups. On the other hand, the groups 312 and 213 are equivalent by rotation only. Consequently, their structure factors may differ if the influence of the two neighbours has to be taken into account. A different situation exists for the groups 212 and 313, which are correlated by a centre of symmetry, which causes different corresponding structure factors. It should be pointed out, however, that the structure factor is invariant as long as there is no influence of neighbouring layers on the structure of the central layer. The latter is often observed in close-packed metal structures or in compounds like

ZnS, SiC and others. For the calculation of intensities $p_\mu p_{\mu\mu'}$ and $F_\mu F^+_{\mu'}$ are needed.

According to the following scheme of sequences, any sequence of pairs is correlated with the same phase factor for FF^+ due to translation if both members of the pair belong to the same group. Consequently, the phase factor may be attached to the sequence probability such that FF^+ remains unchanged and the group may be treated as a single element in the statistics. In this way, the reduced matrix for the solution of the characteristic equation is given by

F_μ	$F^+_{\mu'}$ (1) 312, 123(ε^+), 231(ε)	(2) 212, 323(ε^+), 131(ε)	(3) 213, 321(ε^+), 132(ε)	(4) 313, 121(ε^+), 232(ε)
(1) 312, 123(ε), 231(ε^+)	$\alpha_1\varepsilon^+$	0	0	$(1-\alpha_1)\varepsilon^+$
(2) 212, 323(ε), 131(ε^+)	$(1-\alpha_2)\varepsilon^+$	0	0	$\alpha_2\varepsilon^+$
(3) 213, 321(ε), 132(ε^+)	0	$(1-\alpha_2)\varepsilon$	$\alpha_1\varepsilon$	0
(4) 313, 121(ε), 232(ε^+)	0	$\alpha_2\varepsilon$	$(1-\alpha_2)\varepsilon$	0

It should be pointed out that clusters 1 and 3 describe a cubic arrangement of three layers in the case of simple close packing, while clusters 2 and 4 represent the hexagonal close packing. There may be a small change in the lattice constant c perpendicular to the layers. Additional phase factors then have to be introduced in the matrix for the characteristic equation and a recalculation of the constants is necessary. As a consequence, the reciprocal-lattice rows $(h-k)\equiv 0\,(\mathrm{mod}\ 3)$ become diffuse if $l\neq 0$ and the diffuseness increases with l. Similar behaviour results for the remaining reciprocal-lattice rows.

There are three solutions of the diffraction problem:

(1) If $h - k = 0$ (mod 3), $\varepsilon = +1$, there are two quadratic equations:

$$\begin{aligned}\lambda^2-(\alpha_1+\alpha_2)\lambda-1+\alpha_1+\alpha_2&=0,\\ \lambda^2-(\alpha_1-\alpha_2)\lambda+1-\alpha_1-\alpha_2&=0,\end{aligned}\qquad(4.2.5.9)$$

with solutions

$$\lambda_1=1,\qquad \lambda_2=\alpha_1+\alpha_2-1,$$
$$\lambda_{3/4}=\frac{\alpha_1-\alpha_2}{2}\pm\left[\frac{(\alpha_1-\alpha_2)^2}{4}-1+\alpha_1-\alpha_2\right]^{1/2}.\qquad(4.2.5.10)$$

λ_1 and λ_2 are identical with the solution of the asymmetric case of two kinds of layers [*cf.* equation (4.2.5.6)]. They yield sharp reflections for l = integer and diffuse ones in a position determined by the sequence probabilities α_1 and α_2 (with a position of either l = integer or $l = \frac{1}{2}$ + integer, respectively). The remaining two characteristic values may be given in the form $\lambda = |\lambda|\exp\{2\pi i\varphi\}$, where φ determines the position of the reflection. If the structure factors of the layers are independent of the cluster, λ_2, λ_3 and λ_4 become irrelevant because of the new identity of the F's and there is no diffuse scattering. Weak diffuse intensities on the lattice rows $h - k = 0$ (mod 3) may be explained in terms of this influence.

(2) The remaining two solutions for $\varepsilon = \exp\{\pm 2\pi i(h-k)/3\}$ are equivalent and result in the same characteristic values. They have been discussed explicitly in the literature; the reader is referred to the papers of Jagodzinski (1949*a*,*b*,*c*, 1954).

In order to calculate the intensities, one has to reconsider the symmetry of the clusters, which is different to the symmetry of the layers. Fortunately, a threefold rotation axis is invariant against the translations, but this is not true for the remaining symmetry operations in the layer if there are any more. Since we have two pairs of inequivalent clusters, namely 312, 213 and 212, 313, there are only two different *a priori* probabilities $p_1 = p_3$ and $p_2 = p_4 = \frac{1}{2}(1 - 2p_1)$.

The symmetry conditions of the new clusters may be determined using 'probability trees' as described by Wilson (1942) and Jagodzinski (1949*b*). For example: $p_{11} = p_{33}$, $p_{22} = p_{44}$, $p_{13} = p_{31}$, $p_{24} = p_{42}$ *etc*.

The final solution of the diffraction problem results in the following general intensity formula:

$$\begin{aligned}I(\mathbf{H}) = L(h,k)N\sum_\nu\{&A_\nu(\mathbf{H})(1-|\lambda_\nu|^2)\\ &\times[1-2|\lambda_\nu|\cos 2\pi(l-\varphi_\nu)+|\lambda_\nu|^2]^{-1}\\ &-2B_\nu(\mathbf{H})|\lambda_\nu|\sin 2\pi(l-\varphi_\nu)\\ &\times[1-2|\lambda_\nu|\cos 2\pi(l-\varphi_\nu)+|\lambda_\nu|^2]^{-1}\}.\end{aligned}\qquad(4.2.5.11)$$

Here A_ν and B_ν represent the real and imaginary part of the constants to be calculated with the aid of the boundary conditions of the problem. The first term in equation (4.2.5.11) determines the symmetrical part of a diffuse reflection with respect to the maximum and is completely responsible for the integrated intensity. The second term causes an antisymmetrical contribution to intensity profiles but does not influence the integrated intensities. These general relations enable a semiquantitative interpretation of the sharp and diffuse scattering in any case, without performing the time-consuming calculations of the constants, which may only be done in more complicated disorder problems with the aid of a computer program evaluating the boundary conditions of the problem.

This can be carried out with the aid of the characteristic values and a linear system of equations (Jagodzinski, 1949*a*,*b*,*c*), or with the aid of matrix formalism (Kakinoki & Komura, 1954; Takaki & Sakurai, 1976). As long as only the line profiles and positions of the reflections are required, these quantities may be determined experimentally and fitted to characteristic values of a matrix. The size of this matrix is given by the number of sharp and diffuse maxima observed, while $|\lambda_\nu|$ and $\exp\{2\pi i\varphi_\nu\}$ may be found by evaluating the line width and the position of diffuse reflections. Once this matrix has been found, a semiquantitative model of the disorder problem can be given. If a system of sharp reflections is available, the averaged structure can be solved as described in Section 4.2.3.2. The determination of the constants of the diffraction problem is greatly facilitated by considering the intensity modulation of diffuse scattering, which enables a phase determination of structure factors to be made under certain conditions.

The theory of close-packed structures with three equivalent translation vectors has been applied very frequently, even to

systems that do not obey the principle of close-packing. The first quantitative explanation was published by Halla *et al.* (1953). It was shown there that single crystals of $C_{18}H_{24}$ from the same synthesis may have a completely different degree of order. This was true even within the same crystal. Similar results were found for C, Si, CdI_2, CdS_2, mica and many other compounds. Quantitative treatments are less abundant [*e.g.* CdI_2 (Martorana *et al.*, 1986); MX_3 structures (Conradi & Müller, 1986)]. Special attention has been paid to the quantitative study of polytypic phase transformations in order to gain information about the thermodynamical stability or the mechanism of layer displacements, *e.g.* Co (Edwards & Lipson, 1942; Frey & Boysen, 1981), SiC (Jagodzinski, 1972; Pandey *et al.*, 1980*a*,*b*,*c*), ZnS (Müller, 1952; Mardix & Steinberger, 1970; Frey *et al.*, 1986) and others.

Certain laws may be derived for the reduced integrated intensities of diffuse reflections. 'Reduction' in this context means a division of the diffuse scattering along l by the structure factor, or the difference structure factor if $\langle F\rangle \neq 0$. This procedure is valuable if the number of stacking faults rather than a complete solution of the diffraction problem is required.

The discussion given above has been made under the assumption that the full symmetry of the layers is maintained in the statistics. Obviously, this is not necessarily true if external lower symmetries influence the disorder. An important example is the generation of stacking faults during plastic deformation. Problems of this kind need a complete reconsideration of symmetries. Furthermore, it should be pointed out that a treatment with the aid of an extended Ising model as described above is irrelevant in most cases. Simplified procedures describing the diffuse scattering of intrinsic, extrinsic, twin stacking faults and others have been described in the literature. Since their influence on *structure determination* can generally be neglected, the reader is referred to the literature for additional information.

A different approach to the analysis of planar disorder in close-packed structures is given by Varn *et al.* (2002). With simplifying assumptions, *e.g.* that spacings between identical defect-free layers are independent of local stacking arrangements, average correlations between them are extracted from experimental diffractograms *via* Fourier analysis. Spatial patterns of the layers are then constructed by a so-called epsilon machine, which reproduces the correlations with minimal states of the stacking process. The basic statistical description of the ensemble of spatial patterns produces the stacking distribution. With this technique, stacking sequences are generated which are compared with the correlation factors and the diffractograms. The authors report an improved matching of calculated and experimental data for ZnS.

4.2.5.3. Chain-like structures: two-dimensional disorder

In this section, disorder phenomena that are related to chain-like structural elements in crystals are considered. This topic includes the so-called '1D crystals', where translational symmetry (in direct space) exists in one direction only – crystals in which highly anisotropic binding forces are responsible for chain-like atomic groups, *e.g.* compounds that exhibit a well ordered 3D framework structure with tunnels in a unique direction in which atoms, ions or molecules are embedded. Examples are compounds with platinum, iodine or mercury chains, urea inclusion compounds with columnar structures (organic or inorganic), 1D ionic conductors, polymers *etc.* Diffuse-scattering studies of 1D conductors have been carried out in connection with investigations of stability/instability problems, incommensurate structures, phase transitions, dynamic precursor effects *etc.* These areas are not treated here. For general reading about diffuse scattering in connection with these topics see, *e.g.*, Comes & Shirane (1979) and references therein. Also excluded are specific problems related to polymers or liquid crystals (mesophases) (see Chapter 4.4) and magnetic structures with chain-like spin arrangements.

Trivial diffuse scattering occurs as 1D Bragg scattering (diffuse layers) by internally ordered chains. Diffuse phenomena in reciprocal space are due to 'longitudinal' disordering within the chains (along the unique direction) as well as to 'transverse' correlations between different chains over a restricted volume. Only static aspects are considered; diffuse scattering resulting from collective excitations or diffusion-like phenomena which are of inelastic or quasielastic origin are not treated here.

4.2.5.3.1. Randomly distributed collinear chains

As found in any elementary textbook of diffraction, the simplest result of scattering by a chain with period c,

$$l(\mathbf{r}) = l(z) = \sum_{n_3} \delta(z - n_3 c), \tag{4.2.5.12}$$

is described by one of the Laue equations:

$$G(L) = |L(L)|^2 = \sin^2 \pi NL / \sin^2 \pi L, \tag{4.2.5.13}$$

which gives broadened profiles for small N. In the context of phase transitions the Ornstein–Zernike correlation function is frequently used, *i.e.* (4.2.5.13) is replaced by a Lorentzian:

$$1/[\xi^2 + 4\pi^2 (L - l)^2], \tag{4.2.5.14}$$

where ξ denotes the correlation length.

In the limiting case $N \rightarrow \infty$, (4.2.5.13) becomes

$$\sum_l \delta(L - l). \tag{4.2.5.15}$$

The scattering by a real chain $a(\mathbf{r})$ consisting of molecules with structure factor F_M is therefore determined by

$$F_M(\mathbf{H}) = \sum_j f_j \exp\{2\pi i(Hx_j + Ky_j + Lz_j)\}. \tag{4.2.5.16}$$

The Patterson function is

$$\begin{aligned} P(\mathbf{r}) = {} & (1/c) \int\int |F_0(H, K)|^2 \cos 2\pi(Hx + Ky)\, \mathrm{d}H\, \mathrm{d}K \\ & + (2/c) \sum_l \int\int |F_l|^2 \exp\{2\pi i(Hx + Ky)\} \\ & \times \exp\{-2\pi i l z\}\, \mathrm{d}H\, \mathrm{d}K, \end{aligned} \tag{4.2.5.17}$$

where the index l denotes the only relevant position $L = l$ (the subscript M is omitted).

The intensity is concentrated in diffuse layers perpendicular to $\mathbf{c}^*$ from which the structural information may be extracted. Projections are:

$$\int a(\mathbf{r})\, \mathrm{d}z = \int\int F_0(H, K) \exp\{2\pi i(Hx + Ky)\}\, \mathrm{d}H\, \mathrm{d}K, \tag{4.2.5.18}$$

$$\int\int a(\mathbf{r})\, \mathrm{d}x\, \mathrm{d}y = (2/c) \sum_l F_l(00l) \exp\{-2\pi i l z\}. \tag{4.2.5.19}$$

Obviously the z parameters can be determined by scanning along a meridian $(00L)$ through the diffuse sheets (*e.g.* by a diffractometer recording). Owing to intersection of the Ewald sphere with the set of planes, the meridian cannot be recorded on *one* photograph; successive equi-inclination photographs are necessary. Only in the case of large c spacings is the meridian well approximated in one photograph.

There are many examples where a tendency to cylindrical symmetry exists: chains with p-fold rotational or screw symmetry around the preferred direction or assemblies of chains (or domains) with a statistical orientational distribution around the texture axis. In this context, it should be mentioned that symmetry operations with rotational parts belonging to the 1D rod groups actually occur, *i.e.* not only $p = 2, 3, 4, 6$.

In all these cases a treatment in the frame of cylindrical coordinates is advantageous (see, *e.g.*, Vainshtein, 1966):

Direct space	Reciprocal space
$x = r\cos\psi$	$H = H_r\cos\Psi$
$y = r\sin\psi$	$K = H_r\sin\Psi$
$z = z$	$L = L$

$$a(r,\psi,z) = \int\int\int F(\mathbf{H})\exp\{-2\pi i[H_r r\cos(\psi-\Psi)+Lz]\} \times H_r\,\mathrm{d}H_r\,\mathrm{d}\Psi\,\mathrm{d}L, \quad (4.2.5.20)$$

$$F(\mathbf{H}) = \int\int\int a(r,\psi,z)\exp\{2\pi i[H_r r\cos(\psi-\Psi)+Lz]\} \times r\,\mathrm{d}r\,\mathrm{d}\psi\,\mathrm{d}z. \quad (4.2.5.21)$$

The integrals may be evaluated by the use of Bessel functions:

$$J_n(u) = \tfrac{1}{2}\pi i^n\int\exp\{i(u\cos\varphi + n\varphi)\}\,\mathrm{d}\varphi$$

($u = 2\pi r H_r$; $\varphi = \psi - \Psi$).

The 2D problem $a = a(r,\psi)$ is treated first; an extension to the general case $a(r,\psi,z)$ is easily made afterwards.

Along the theory of Fourier series one has

$$a(r,\psi) = \sum_n a_n(r)\exp\{in\psi\},$$
$$a_n(r) = \frac{1}{2\pi}\int a(r,\psi)\exp\{-in\psi\}\,\mathrm{d}\psi, \quad (4.2.5.22)$$

or with

$$\alpha_n = \frac{1}{2\pi}\int a(r,\psi)\cos(n\psi)\,\mathrm{d}\psi,$$
$$\beta_n = \frac{1}{2\pi}\int a(r,\psi)\sin(n\psi)\,\mathrm{d}\psi,$$
$$a_n(r) = |a_n(r)|\exp\{-i\psi_n(r)\},$$
$$|a_n(r)| = \sqrt{a_n^2+\beta_n^2},$$
$$\psi_n(r) = \arctan\,\beta_n/\alpha_n.$$

If contributions to anomalous scattering are neglected $a(r,\psi)$ is a real function:

$$a(r,\psi) = \sum_n |a_n(r)|\cos[n\psi - \psi_n(r)]. \quad (4.2.5.23)$$

Analogously, one has

$$F(H_r,\Psi) = \sum_n |F_n(H_r)|\exp\{in\Psi\}. \quad (4.2.5.24)$$

$F(H_r,\Psi)$ is a complex function; $F_n(H_r)$ are the Fourier coefficients that are to be evaluated from the $a_n(r)$:

$$F_n(H_r) = \frac{1}{2\pi}\int F(H_r,\Psi)\exp\{-in\Psi\}\,\mathrm{d}\Psi$$
$$= \exp\{in\pi/2\}\int a_n(r)J_n(2\pi r H_r)2\pi r\,\mathrm{d}r,$$
$$F(H_r,\Psi) = \sum_n \exp\{in[\Psi+(\pi/2)]\} \times \int a_n(r)J_n(2\pi r H_r)2\pi r\,\mathrm{d}r, \quad (4.2.5.25)$$

$$a(r,\psi) = \sum_n \exp\{in[\Psi-(\pi/2)]\} \times \int F_n(H_r)J_n(2\pi r H_r)\,2\pi H_r\,\mathrm{d}H_r. \quad (4.2.5.26)$$

The formulae may be used for calculation of the diffuse intensity distribution within a diffuse sheet, in particular when the chain molecule is projected along the unique axis [*cf.* equation (4.2.5.18)].

Special cases are:

(1) *Complete cylinder symmetry*

$$F(H_r) = 2\pi\int a(r)J_0(2\pi r H_r)r\,\mathrm{d}r \quad (4.2.5.27),$$
$$a(r) = 2\pi\int F(H_r)J_n(2\pi r H_r)H_r\,\mathrm{d}H_r. \quad (4.2.5.28)$$

(2) *p-fold symmetry of the projected molecule*, where $a(r,\psi) = a[r,\psi+(2\pi/p)]$

$$F_p(H_r,\Psi) = \sum_n \exp\{inp[\Psi+(\pi/2)]\} \times \int a_{np}(r)J_{np}(2\pi r H_r)2\pi r\,\mathrm{d}r, \quad (4.2.5.29)$$

$$a_p(r,\psi) = \sum_n |a_{np}(r)|\cos[np\psi - \psi_{np}(r)]. \quad (4.2.5.30)$$

Only Bessel functions $J_0, J_p, J_{2p}, \ldots$ occur. In most cases J_{2p} and higher orders may be neglected.

(3) *Vertical mirror planes*

Only cosine terms occur, *i.e.* all $\beta_n = 0$ or $\psi_n(r) = 0$.

The *general 3D expressions* valid for extended chains with period c [equation (4.2.5.12)] are found in an analogous way,

$$a(r,\psi,z) = a_{\mathrm{M}}(r,\psi,z) * l(z),$$

$$F(\mathbf{H}) = F_l(H_r,\Psi,L) = F_{\mathrm{M}}(\mathbf{H})L(L) = \int\int\int a_{\mathrm{M}}(r,\psi,z)\exp\{2\pi i\,[H_r r\cos(\psi-\Psi)+Lz]\} \times 2\pi r\,\mathrm{d}r\,\mathrm{d}\psi\,\mathrm{d}z. \quad (4.2.5.31)$$

Using a series expansion analogous to (4.2.5.23) and (4.2.5.24),

$$a_{nl}(r) = \frac{1}{2\pi}\int\int a_{\mathrm{M}}\exp\{-i(n\psi - 2\pi lz)\}\,\mathrm{d}\psi\,\mathrm{d}z, \quad (4.2.5.32)$$

$$F_{nl}(H_r) = \exp\{in\pi/2\}\int a_{nl}(r)J_n(2\pi H_r r)2\pi r\,\mathrm{d}r, \quad (4.2.5.33)$$

one has

$$F_l(\mathbf{H}) = \sum_n \exp\{in[\Psi+(\pi/2)]\}\int a_{nl}(r)J_n(2\pi H_r r)2\pi r\,\mathrm{d}r. \quad (4.2.5.34)$$

In practice the integrals are often replaced by discrete summation of j atoms at positions $r = r_j$, $\psi = \psi_j$, $z = z_j$ ($0 \le z_j < c$):

$$F_l(\mathbf{H}) = \sum_j\sum_n f_j J_n(2\pi H_r r_j)\exp\{-in\psi_j\} \times \exp\{2\pi ilz_j\}\exp\{in[\Psi+(\pi/2)]\} \quad (4.2.5.35)$$

or

$$F_l(\mathbf{H}) = \sum_n(\alpha_n + i\beta_n)\exp\{in\Psi\},$$

$$\alpha_n = \sum_j f_j J_n(2\pi H_r r_j)\cos\{n[(\pi/2)-\psi_j] + 2\pi lz_j\},$$
$$\beta_n = \sum_j f_j J_n(2\pi H_r r_j)\sin\{n[(\pi/2)-\psi_j] + 2\pi lz_j\}.$$

Intensity in the lth diffuse layer is given by

$$I_l = \sum_n\sum_{n'}[(\alpha_n\alpha_{n'} + \beta_n\beta_{n'}) + i(\alpha_{n'}\beta_n - \alpha_n\beta_{n'})] \times \exp\{i(n-n')\Psi\}. \quad (4.2.5.36)$$

(*a*) *Cylinder symmetry* (free rotating molecules around the chain axis or statistical averaging with respect to ψ over an assembly of chains). Only component F_{0l} occurs:

$$F_{0l}(H_r, L) = 2\pi\int\int\langle a_{\mathrm{M}}\rangle J_0(2\pi H_r r)\exp\{2\pi ilz\}r\,\mathrm{d}r\,\mathrm{d}z$$

or

$$F_{0l}(H_r, L) = \sum_j f_j J_0(2\pi H_r r_j) \exp\{2\pi i l z_j\}.$$

In particular, $F_{00}(H_r)$ determines the radial component of the molecule projected along z:

$$F_{00}(H_r) = \sum_j f_j J_0(2\pi H_r r_j).$$

(*b*) *p-fold symmetry* of a plane molecule (or projected molecule) as outlined previously: only components *np* instead of *n* occur. Bessel functions J_0 and J_p are sufficient in most cases.

(*c*) *Vertical mirror plane*: see above.

(*d*) *Horizontal mirror plane* (perpendicular to the chain): Exponentials $\exp\{2\pi i l z\}$ in equation (4.2.5.32) may be replaced by $\cos 2\pi l z$.

(*e*) *Twofold symmetry axis* perpendicular to the chain axis (at positions $\psi = 0,\ 2\pi/p, \ldots$). Exponentials $\exp\{-i(np\psi - 2\pi l z)\}$ in equation (4.2.5.32) are replaced by the corresponding cosine term $\cos(np\psi + 2\pi l z)$.

Formulae concerning the reverse method (Fourier synthesis) are not given here (see, *e.g.*, Vainshtein, 1966). There is usually no practical use for this in diffuse-scattering work because it is very difficult to separate out a single component F_{nl}. *Every* diffuse layer is affected by *all* components F_{nl}. There is a chance of doing so only if *one* diffuse layer corresponds predominantly to *one* Bessel function.

4.2.5.3.2. Disorder within randomly distributed collinear chains

Deviations from strict periodicities in the z direction within one chain may be due to loss of translational symmetry of the centres of the molecules along z and/or due to varying orientations of the molecules with respect to different axes, such as azimuthal misorientation, tilting with respect to the z axis or combinations of both types. As in 3D crystals, there may or may not exist 1D structures in an averaged sense.

(1) *General treatment*

All formulae given in this section are only special cases of a 3D treatment (see, *e.g.*, Guinier, 1963). The 1D lattice (4.2.5.12) is replaced by a distribution:

$$\begin{aligned} d(z) &= \sum_\nu \delta(z - z_\nu), \\ D(L) &= \sum_\nu \exp\{2\pi i L z_\nu\}, \\ F(\mathbf{H}) &= F_{\rm M}(\mathbf{H}) D(L). \end{aligned} \tag{4.2.5.37}$$

The Patterson function is given by

$$P(\mathbf{r}) = [a_{\rm M}(\mathbf{r}) * a_{\rm M}(-\mathbf{r})] * [d(z) * d(-z)]. \tag{4.2.5.38}$$

Because the autocorrelation function $w = d * d$ is centrosymmetric,

$$w(z) = N\delta(z) + \sum_\nu \sum_\mu \delta[z - (z_\nu - z_\mu)] + \sum_\nu \sum_\mu \delta[z + (z_\nu - z_\mu)], \tag{4.2.5.39}$$

the interference function $W(L)$ $(= |D(L)|^2)$ is given by

$$W(L) = N + 2 \sum_\nu \sum_\mu \cos 2\pi [L(z_\nu - z_\mu)], \tag{4.2.5.40}$$

$$I(\mathbf{H}) = |F_{\rm M}(\mathbf{H})|^2 W(L). \tag{4.2.5.41}$$

Sometimes, *e.g.* in the following example of orientational disorder, there is an order only within domains. As shown in Section 4.2.3, this may be treated by a box or shape function $b(z) = 1$ for $z \le z_N$ and 0 elsewhere.

$$\begin{aligned} d(z) &= d_\infty b(z), \\ a(\mathbf{r}) &= a_{\rm M}(\mathbf{r}) * [d_\infty b(z)], \\ F(\mathbf{H}) &= F_{\rm M}(\mathbf{H})[D_\infty * B(L)], \end{aligned} \tag{4.2.5.42}$$

with

$$\begin{aligned} b(z) * b(-z) &\leftrightarrow |B(L)|^2, \\ I &= |F_{\rm M}(\mathbf{H})|^2 |D_\infty * B(L)|^2. \end{aligned} \tag{4.2.5.43}$$

If the order is perfect within one domain one has $D_\infty(L) \simeq \sum \delta(L - l)$; $(D_\infty * B) = \sum D(L - l)$; *i.e.* each reflection is affected by the shape function.

(2) *Orientational disorder*

A misorientation of the chain molecules with respect to one another is taken into account by different structure factors $F_{\rm M}$.

$$I(\mathbf{H}) = \sum_\nu \sum_\mu F_\nu(\mathbf{H}) F_\mu(\mathbf{H})^+ \exp\{2\pi i L(z_\nu - z_\mu)\}. \tag{4.2.5.44}$$

A further discussion follows the same arguments outlined in Section 4.2.3. For example, a very simple result is found in the case of uncorrelated orientations. Averaging over all pairs $F_\nu F_\mu^+$ yields

$$I(\mathbf{H}) = N(\langle |F|^2 \rangle - \langle |F| \rangle^2) + \langle |F| \rangle^2 L(L), \tag{4.2.5.44a}$$

where

$$\begin{aligned} \langle |F| \rangle^2 &= 1/N^2 \langle F_\nu F_\mu^+ \rangle \\ &= \sum_\nu \alpha_\nu F_\nu(\mathbf{H}) \sum_\mu \alpha_\mu F_\mu^+(\mathbf{H}), \quad (\nu \ne \mu) \\ \langle |F|^2 \rangle &= 1/N \langle F_\nu F_\nu^+ \rangle = \sum_\nu \alpha_\nu |F_\nu(\mathbf{H})|^2. \end{aligned}$$

Besides the diffuse layer system, there is a diffuse background modulated by the $\mathbf{H}$ dependence of $[\langle |F(\mathbf{H})|^2 \rangle - \langle |F(\mathbf{H})| \rangle^2]$.

(3) *Longitudinal disorder*

In this context, the structure factor of a chain molecule is neglected. Irregular distances between the molecules within a chain occur owing to the shape of the molecules, intrachain interactions and/or interaction forces *via* a surrounding matrix. A general discussion is given by Guinier (1963). It is convenient to reformulate the discrete Patterson function, *i.e.* the correlation function (4.2.5.39),

$$\begin{aligned} w(z) = N\delta(z) &+ \sum_\nu \delta[z \pm (z_\nu - z_{\nu+1})] \\ &+ \sum_\nu \delta[z \pm (z_\nu - z_{\nu+2})] + \ldots \end{aligned} \tag{4.2.5.39a}$$

in terms of continuous functions $a_\mu(z)$ that describe the probability of finding the μth neighbour within an arbitrary distance,

$$\begin{aligned} w'(z) = w(z)/N = \delta(z) &+ a_1(z) + a_{-1}(z) + \ldots \\ &+ a_\mu(z) + a_{-\mu}(z) + \ldots \end{aligned} \tag{4.2.5.45}$$

$[\int a_\mu(z)\,{\rm d}z = 1,\ a_\mu(z) = a_{-\mu}(-z)]$.

There are two principal ways to define $a_\mu(z)$. The first is the case of a well defined one-dimensional lattice with positional fluctuations of the molecules around the lattice points, *i.e.* long-range order is retained: $a_\mu(z) = \mu c_0 + z_\mu$, where z_μ denotes the displacement of the μth molecule in the chain. Gaussian distributions are frequently used:

$$c' \exp\{-(z - \mu c_0)^2 / 2\Delta^2\},$$

where c' is a normalizing constant and Δ is the standard deviation. Fourier transformation of equation (4.2.5.45) gives the well known result

$$I_D \simeq (1 - \exp\{-L^2\Delta^2\}),$$

i.e. a monotonically increasing intensity with L (any modulation due to a molecular structure factor is neglected). This result is quite analogous to the treatment of the scattering of independently vibrating atoms. If (short-range) correlations exist between the molecules, the Gaussian distribution is replaced by a multivariate normal distribution where correlation coefficients κ^μ $(0 < \kappa < 1)$ between a molecule and its μth neighbour are incorporated. κ^μ is defined by the second moment: $\langle z_0 z_\mu \rangle / \Delta^2$.

$$a_\mu(z) = c'' \exp\{-(z - \mu c_0)^2 / 2\Delta^2(1 - \kappa^\mu)\}.$$

Obviously, the variance increases if the correlation diminishes and reaches an upper bound of twice the single-site variance. Fourier transformation gives an expression for the diffuse intensity (Welberry, 1985):

$$I_D(L) \simeq \exp\{-L^2\Delta^2\} \sum_j (-L^2\Delta^2)^j / j! \times (1 - \kappa^{2j})/(1 + \kappa^{2j} - 2\kappa^j \cos 2\pi L c_0). \quad (4.2.5.46)$$

For small Δ, terms with $j > 1$ are mostly neglected. The terms become increasingly important with higher values of L. On the other hand, κ^j becomes smaller with increasing j, each additional term in equation (4.2.5.46) becomes broader and, as a consequence, the diffuse planes in reciprocal space become broader with higher L.

In a different way – in the paracrystal method – the position of the second and subsequent molecules with respect to some reference zero point depends on the *actual* position of the predecessor. The variance of the position of the μth molecule relative to the first becomes unlimited. There is a continuous transition to a fluid-like behaviour of the chain molecules. This 1D paracrystal (these are sometimes called distortions of the second kind) is only a special case of the 3D paracrystal concept (see Hosemann & Bagchi, 1962; Wilke, 1983). Despite some difficulties with this concept (Brämer, 1975; Brämer & Ruland, 1976), it is widely used as a theoretical model for describing diffraction by highly distorted lattices. One essential development is to limit the size of a paracrystalline grain so that fluctuations never become too large (Hosemann, 1975).

If this concept is used for the 1D case, $a_\mu(z)$ is defined by convolution products of $a_1(z)$. For example, the probability of finding the next-nearest molecule is given by

$$a_2(z) = \int a_1(z')\, a_1(z - z')\, \mathrm{d}z' = a_1(z) * a_1(z)$$

and, generally,

$$a_\mu(z) = a_1(z) * a_1(z) * a_1(z) * \ldots * a_1(z)$$

(μ-fold convolution).

The mean distance between next-nearest neighbours is

$$\langle c \rangle = \int z' a_1(z')\, \mathrm{d}z'$$

and between neighbours of the μth order it is $\mu\langle c \rangle$. The average value of $a_\mu = 1/\langle c \rangle$, which is also the value of $w(z)$ for $z > z_k$, where the distribution function is completely smeared out. The general expression for the interference function $G(L)$ is

$$G(L) = 1 + \sum_\mu \{F^\mu + F^{+\mu}\} = \mathrm{Re}\{(1 + F)/(1 - F)\} \quad (4.2.5.47)$$

with $F(L) \leftrightarrow a_1(z)$, $F^\mu(L) \leftrightarrow a_\mu(z)$.

With $F = |F| \exp\{i\chi\}$ $(\chi = L\langle c \rangle)$, equation (4.2.5.47) is written

$$G(L) = [1 - |F(L)|^2]/[1 - 2|F(L)| \cos\chi + |F(L)|^2]. \quad (4.2.5.47a)$$

[Note the close similarity to the diffuse part of equation (4.2.5.5), which is valid for 1D disorder problems.]

This function has maxima of height $(1 + |F|)/(1 - |F|)$ and minima of height $(1 - |F|)/(1 + |F|)$ at positions lc^* and $(l + \frac{1}{2})c^*$, respectively. With decreasing $|F|$ the oscillations vanish; a critical L value (corresponding to z_k) may be defined by $G_{max}/G_{min} \lesssim 1.2$. Actual values depend strongly on $F(\mathbf{H})$.

The paracrystal method is substantiated by the choice $a_1(z)$, *i.e.* the disorder model. Again, a Gaussian distribution is frequently used:

$$a_1(z) = (1/\sqrt{2\pi}\Delta) \exp\{-(z - \langle c \rangle)^2 / 2\Delta^2\}$$
$$a_\mu(z) = (1/\sqrt{\mu})(1/\sqrt{2\pi}\Delta) \exp\{-(z - \mu\langle c \rangle)^2 / 2\mu\Delta^2\} \quad (4.2.5.48)$$

with the two parameters $\langle c \rangle$, Δ.

There are peaks of height $1/[\pi^2 L^2 (\Delta/\langle c \rangle)^2]$ which obviously decrease with L^2 and $(\Delta/\langle c \rangle)^2$. The oscillations vanish for $|F| \simeq 0.1$, *i.e.* $1/\langle c \rangle \simeq 0.25/\Delta$. The width of the mth peak is $\Delta_m = \sqrt{m}\Delta$. The integral reflectivity is approximately $1/\langle c \rangle [1 - \pi^2 L^2 (\Delta/\langle c \rangle)^2]$ and the integral width (defined by integral reflectivity divided by peak reflectivity) (background subtracted!) is $1/\langle c \rangle \pi^2 L^2 (\Delta/\langle c \rangle)^2$ which, therefore, increases with L^2. In principle, the same results are given by Zernike & Prins (1927). In practice, a single Gaussian distribution is not fully adequate and modified functions must be used (Rosshirt *et al.*, 1985).

Our final remark concerns the normalization [equation (4.2.5.39)]. Going from (4.2.5.39) to (4.2.5.45) it is assumed that N is a large number so that the correct normalization factors $(N - |\mu|)$ for each $a_\mu(z)$ may be approximated by a uniform N. If this is not true then

$$G(L) = N + \sum_\mu (N - |\mu|)(F^\mu + F^{+\mu}) = N\,\mathrm{Re}\{(1 + |F|)/(1 - |F|)\} - 2\,\mathrm{Re}\{|F|(1 - |F|^N)/(1 - |F|^2)\}. \quad (4.2.5.49)$$

The correction term may be important in the case of relatively small (1D) domains. As mentioned above, the structure factor of a chain molecule was neglected. The $\mathbf{H}$ dependence of F_M, of course, obscures the intensity variation of the diffuse layers as described by (4.2.5.47*a*).

The matrix method developed for the case of planar disorder was adapted to 2D disorder by Scaringe & Ibers (1979). Other models and corresponding expressions for diffuse scattering are developed from specific microscopic models (potentials), *e.g.* in the case of $Hg_{3-\delta}AsF_6$ (Emery & Axe, 1978; Radons *et al.*, 1983), hollandites (Beyeler *et al.*, 1980; Ishii, 1983), iodine chain compounds (Endres *et al.*, 1982) or urea inclusion compounds (Forst *et al.*, 1987; Weber *et al.*, 2000).

4.2.5.3.3. Correlations between almost collinear chains

In real cases there are quite strong correlations between different chains, at least within small domains. Deviations from a strict (3D) order of chain-like structural elements are due to several reasons: the shape and structure of the chains, varying binding forces, and thermodynamical or kinetic considerations.

Many types of disorder occur. (1) Relative shifts parallel to the common axis while projections along this axis give a perfect 2D ordered net ('axial disorder'). (2) Relative fluctuations of the distances between the chains (perpendicular to the unique axis) with short-range order along the transverse **a** and/or **b** directions. The net of projected chains down to the *ab* plane is distorted ('net distortions'). Disorder of types (1) and (2) is sometimes correlated owing to nonuniform cross sections of the chains. (3) Turns, twists and torsions of chains or parts of chains. This azimuthal type of disorder may be treated in a similar way to the case of

azimuthal disorder of single-chain molecules. Correlations between axial shifts and torsions produce 'screw shifts' (helical structures). Torsion of chain parts may be of dynamic origin (such as rotational vibrations). (4) Tilting or bending of the chains in a uniform or nonuniform way ('conforming/nonconforming' disorder). Many of these types and a variety of combinations between them are found in polymer and liquid crystals, and are therefore treated separately. Only some simple basic ideas are discussed here in brief.

For the sake of simplicity, the paracrystal concept in combination with Gaussians is used again. Distribution functions are given by convolution products of next-nearest-neighbour distribution functions. As long as averaged lattice directions and lattice constants in a plane perpendicular to the chain axis exist, only two functions, $a_{100} = a_1(xyz)$ and $a_{010} = a_2(xyz)$, are needed to describe the arrangement of next-nearest chains. Longitudinal disorder is treated as before by a third distribution function $a_{001} = a_3(xyz)$. The phenomena of chain bending or tilting may be incorporated by an x and y dependence of a_3. Any general fluctuation in the spatial arrangement of chains is given by

$$a_{mpq} = a_1 * \ldots * a_1 * a_2 * \ldots * a_2 * a_3 * \ldots * a_3. \qquad (4.2.5.50)$$

(m-fold, p-fold, q-fold self-convolution of a_1, a_2, a_3, respectively.)

$$w(\mathbf{r}) = \delta(\mathbf{r}) \sum_m \sum_p \sum_q [a_{mpq}(\mathbf{r}) + a_{-mpq}(\mathbf{r})]. \qquad (4.2.5.51)$$

a_ν ($\nu = 1, 2, 3$) are called fundamental functions. If an averaged lattice cannot be defined, more fundamental functions a_ν are needed to account for correlations between them.

By Fourier transformations, the interference function is given by

$$G(\mathbf{H})\, G_\nu = \mathrm{Re}\{(1 + |F_\nu|)/(1 - |F_\nu|)\}. \qquad (4.2.5.52)$$

If Gaussian functions are assumed, simple pictures are derived. For example

$$a_1(\mathbf{r} + \langle \mathbf{a} \rangle) = [1/(2\pi)^{3/2}][1/(\Delta_{11}\Delta_{12}\Delta_{13})] \times \exp\left\{-\tfrac{1}{2}[(x^2/\Delta_{11}^2) + (y^2/\Delta_{12}^2) + (z^2/\Delta_{13}^2)]\right\} \qquad (4.2.5.53)$$

describes the distribution of neighbours in the x direction (with a mean distance $\langle a \rangle$). Parameters Δ_{13}, Δ_{11} and Δ_{12} concern axial, radial and tangential fluctuations, respectively. Pure axial distribution along **c** is given by projection of a_1 on the z axis; pure net distortions are given by projection on the xy plane. If the chain-like structure is neglected, the interference function

$$G_1(\mathbf{H}) = \exp\{-2\pi^2(\Delta_{11}^2 H^2 + \Delta_{12}^2 K^2 + \Delta_{13}^2 L^2)\} \qquad (4.2.5.54)$$

describes a set of diffuse planes perpendicular to $\mathbf{a}^*$ with a mean distance of $1/\langle a \rangle$. These diffuse layers broaden along H with $m\Delta_{11}$ and decrease in intensity along K and L monotonically. There is an ellipsoid-shaped region in reciprocal space defined by main axes of length $1/\Delta_{11}, 1/\Delta_{12}, 1/\Delta_{13}$ with a limiting surface given by $|F| \simeq 0.1$, beyond which the diffuse intensity is completely smeared out. The influence of a_2 may be discussed in an analogous way.

If the chain-like arrangement parallel to **c** [equation (4.2.5.12)] is taken into consideration,

$$l(z) = \sum_{n_3} \delta(z - n_3 c),$$

the set of planes perpendicular to $\mathbf{a}^*$ (and/or $\mathbf{b}^*$) is subdivided in the L direction by a set of planes located at $l(1/c)$ [equation (4.2.5.15)].

Longitudinal disorder is given by $a_3(z)$ [equation (4.2.5.48), $\Delta_{33} = \Delta$] and leads to two intersecting sets of broadened diffuse layer systems.

Particular cases like pure axial distributions ($\Delta_{11}, \Delta_{12} \simeq 0$), pure tangential distributions (net distortions: $\Delta_{11}, \Delta_{13} \simeq 0$), uniform bending of chains or combinations of these effects are discussed in the monograph by Vainshtein (1966).

4.2.5.4. Defects, short-range ordering, clustering: three-dimensional disorder

4.2.5.4.1. General formulation (elastic diffuse scattering)

In this section general formulae for diffuse scattering will be derived that may best be applied to crystals with a well ordered average structure, characterized by (almost) sharp Bragg peaks. Textbooks and review articles concerning defects and local ordering are by Krivoglaz (1969, 1996*a*,*b*), Dederichs (1973), Peisl (1975), Schwartz & Cohen (1977), Schmatz (1973, 1983), Bauer (1979), Kitaigorodsky (1984) and Schweika (1998). A series of interesting papers on local order is given by Young (1975) and also by Cowley *et al.* (1979). Expressions for polycrystalline samples are given by Warren (1969) and Fender (1973).

Two general methods may be applied: (*a*) the average difference cluster method, where a representative cluster of scattering differences between the average structure and the cluster is used; and (*b*) the method of short-range-order correlation functions, where formal parameters are introduced.

The two methods are equivalent in principle. The cluster method is generally more convenient in cases where a single average cluster is a good approximation. This holds for small concentrations of clusters. In the literature this problem is treated in terms of fluctuations of the distribution functions as will be discussed below (Section 4.2.5.4.6). The most convenient way to derive the distribution function correctly from experimental data is the use of low-angle scattering, which generally shows one or more clear maxima caused by partly periodic properties of the distribution function. For the deconvolution of the distribution function, achieved by Fourier transformation of the corrected diffuse low-angle scattering, the reader is referred to the relevant literature. However, deconvolutions are not unique and some reasonable assumptions are necessary for a final solution.

The method of short-range-order parameters is optimal in cases where isolated clusters are not realized and the correlations do not extend to long distances. Otherwise periodic solutions are more convenient in most cases.

In any case, the first step towards the solution of the diffraction problem is the accurate determination of the average structure. As described in Section 4.2.4, important information on fractional occupations, interstitials and displacements of atoms (shown by unusual thermal parameters) may be derived. Unfortunately, all defects contribute to diffuse scattering; hence one has to start with the assumption that the disorder to be interpreted is predominant. Fractional occupancy of certain lattice sites by two or more kinds of atoms plays an important role in the literature, especially in metallic or ionic structures. Since vacancies may be treated as atoms with zero scattering amplitude, structures containing vacancies may be formally treated as multicomponent systems.

Since the solution of the diffraction problem should not be restricted to metallic systems with a simple (primitive) structure, we have to consider the structure of the unit cell – as given by the average structure – and the propagation of order according to the translation group separately. In simple metallic systems this difference is immaterial. It is well known that the thermodynamic problem of propagation of order in a three-dimensional crystal can hardly ever be solved analytically in a general way. Some solutions have been published with the aid of the Ising model using next-nearest-neighbour interactions. They are excellent for

an understanding of the principles of order–disorder phenomena, but they can rarely be applied quantitatively in practical problems. Hence, methods have been developed to derive the propagation of order from the diffraction pattern by means of Fourier transformation. This method has been described qualitatively in Section 4.2.3.1 and will be used here for a quantitative application. In a first approximation, the assumption of a small number of different configurations of the unit cell is made, represented by the corresponding number of structure factors. Displacements of atoms caused by the configurations of the neighbouring cells are excluded. This problem will be treated subsequently.

The finite number of structures of the unit cell in the disordered crystal is given by

$$F_\nu(\mathbf{r}) = \sum_j \sum_\mu \pi^\nu_{j\mu} f_\mu(\mathbf{r} - \mathbf{r}_j). \tag{4.2.5.55}$$

Note that $F_\nu(\mathbf{r})$ is defined in real space and $\mathbf{r}_j$ gives the position vector of site j; $\pi^\nu_{j\mu} = 1$ if in the νth structure factor the site j is occupied by an atom of kind μ, and 0 elsewhere.

In order to apply the laws of Fourier transformation adequately, it is useful to introduce the distribution function of F_ν,

$$\pi_\nu(\mathbf{r}) = \sum_{\mathbf{n}} \pi_{\mathbf{n}\nu} \delta(\mathbf{r} - \mathbf{n}), \tag{4.2.5.56}$$

with $\pi_{\mathbf{n}\nu} = 1$ if the cell $\mathbf{n} = n_1\mathbf{a} + n_2\mathbf{b} + n_3\mathbf{c}$ has the F_ν structure and $\pi_{\mathbf{n}\nu} = 0$ elsewhere.

In the definitions given above $\pi_{\mathbf{n}\nu}$ are numbers (scalars) assigned to the cell. Since all these are occupied we have

$$\sum_\nu \pi_\nu(\mathbf{r}) = l(\mathbf{r})$$

where $l(\mathbf{r})$ is the lattice in real space.

The structure of the disordered crystal is given by

$$\sum_\nu \pi_\nu(\mathbf{r}) * F_\nu(\mathbf{r}). \tag{4.2.5.57}$$

$\pi_\nu(\mathbf{r})$ consists of $\alpha_\nu N$ points, where $N = N_1N_2N_3$ is the total (large) number of unit cells and α_ν denotes the *a priori* probability (concentration) of the νth cell occupation.

It is now useful to introduce

$$\Delta\pi_\nu(\mathbf{r}) = \pi_\nu(\mathbf{r}) - \alpha_\nu l(\mathbf{r}) \tag{4.2.5.58}$$

with

$$\sum_\nu \Delta\pi_\nu(\mathbf{r}) = \sum_\nu \pi_\nu(\mathbf{r}) - l(\mathbf{r}) \sum_\nu \alpha_\nu = l(\mathbf{r}) - l(\mathbf{r}) = 0.$$

Introducing (4.2.5.58) into (4.2.5.57) gives

$$\begin{aligned}\sum_\nu \pi_\nu(\mathbf{r}) * F_\nu(\mathbf{r}) &= \sum_\nu \Delta\pi_\nu(\mathbf{r}) * F_\nu(\mathbf{r}) + l(\mathbf{r}) \sum_\nu \alpha_\nu F_\nu(\mathbf{r}) \\ &= \sum_\nu \Delta\pi_\nu(\mathbf{r}) * F_\nu(\mathbf{r}) + l(\mathbf{r})\langle F(\mathbf{r})\rangle.\end{aligned} \tag{4.2.5.59}$$

Similarly

$$\begin{aligned}\Delta F_\nu(\mathbf{r}) &= F_\nu(\mathbf{r}) - \langle F(\mathbf{r})\rangle, \\ \sum_\nu \alpha_\nu \Delta F_\nu(\mathbf{r}) &= \sum_\nu \alpha_\nu F_\nu(\mathbf{r}) - \sum_\nu \alpha_\nu \langle F(\mathbf{r})\rangle = 0.\end{aligned} \tag{4.2.5.60}$$

Using (4.2.5.60) it follows from (4.2.5.58) that

$$\begin{aligned}\sum_\nu \pi_\nu(\mathbf{r}) * F_\nu(\mathbf{r}) &= \sum_\nu \Delta\pi_\nu(\mathbf{r}) * \Delta F_\nu(\mathbf{r}) \\ &\quad + \sum_\nu \Delta\pi_\nu(\mathbf{r}) * \langle F(\mathbf{r})\rangle + l(\mathbf{r}) * \langle F(\mathbf{r})\rangle \\ &= \sum_\nu \Delta\pi_\nu(\mathbf{r}) * \Delta F_\nu(\mathbf{r}) + l(\mathbf{r}) * \langle F(\mathbf{r})\rangle.\end{aligned} \tag{4.2.5.61}$$

Comparison with (4.2.5.59) yields

$$\sum_\nu \Delta\pi_\nu(\mathbf{r}) * F_\nu(\mathbf{r}) = \sum_\nu \Delta\pi_\nu(\mathbf{r}) * \Delta F_\nu(\mathbf{r}).$$

Fourier transformation of (4.2.5.61) gives

$$\sum_\nu \Pi_\nu(\mathbf{H}) F_\nu(\mathbf{H}) = \sum_\nu \Delta\Pi_\nu(\mathbf{H}) \Delta F_\nu(\mathbf{H}) + L(\mathbf{H})\langle F(\mathbf{H})\rangle$$

with

$$\sum_\nu \Delta\Pi_\nu(\mathbf{H}) = 0, \quad \sum_\nu \Delta F_\nu(\mathbf{H}) = 0.$$

The expression for the scattered intensity is therefore

$$\begin{aligned}I(\mathbf{H}) &= \left|\sum_\nu \Delta\Pi_\nu(\mathbf{H}) \Delta F_\nu(\mathbf{H})\right|^2 + |L(\mathbf{H})\langle F(\mathbf{H})\rangle|^2 \\ &\quad + L(\mathbf{H})\Bigg\{\langle F^+(\mathbf{H})\rangle \sum_\nu \Delta\Pi_\nu(\mathbf{H}) F_\nu(\mathbf{H}) \\ &\quad + \langle F^+(\mathbf{H})\rangle \sum_\nu \Delta\Pi^+_\nu(\mathbf{H}) F^+_\nu(\mathbf{H})\Bigg\}.\end{aligned} \tag{4.2.5.62}$$

Because of the multiplication by $L(\mathbf{H})$, the third term in (4.2.5.62) contributes to sharp reflections only. Since they are correctly given by the second term in (4.2.5.62), the third term vanishes. Hence the diffuse part is given by

$$I_{\rm D}(\mathbf{H}) = \left|\sum_\nu \Delta\Pi_\nu(\mathbf{H}) \Delta F_\nu(\mathbf{H})\right|^2. \tag{4.2.5.63}$$

For a better understanding of the behaviour of diffuse scattering it is useful to return to real space:

$$\begin{aligned}i_{\rm D}(\mathbf{r}) &= \sum_\nu \Delta\pi_\nu(\mathbf{r}) * \Delta F_\nu(\mathbf{r}) * \sum_{\nu'} \Delta\pi_{\nu'}(-\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r}) \\ &= \sum_\nu \sum_{\nu'} \Delta\pi_\nu(\mathbf{r}) * \Delta\pi_{\nu'}(-\mathbf{r}) * \Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r})\end{aligned} \tag{4.2.5.64}$$

and with (4.2.5.58):

$$\begin{aligned}i_{\rm D}(\mathbf{r}) &= \sum_\nu \sum_{\nu'} [\pi_\nu(\mathbf{r}) - \alpha_\nu l(\mathbf{r})] * [\pi_{\nu'}(-\mathbf{r}) - \alpha_{\nu'} l(\mathbf{r})] \\ &\quad * \Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r}).\end{aligned} \tag{4.2.5.65}$$

Evaluation of this equation for a single term yields

$$\begin{aligned}&[\pi_\nu(\mathbf{r}) * \pi_{\nu'}(-\mathbf{r}) - \alpha_\nu l(\mathbf{r}) * \pi_{\nu'}(-\mathbf{r}) \\ &\quad - \alpha_{\nu'} l(\mathbf{r}) * \pi_\nu(\mathbf{r}) + \alpha_\nu \alpha_{\nu'} l(\mathbf{r}) * l(\mathbf{r})] \\ &\quad * \Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(\mathbf{r}).\end{aligned} \tag{4.2.5.66}$$

Since $l(\mathbf{r})$ is a periodic function of points, all convolution products with $l(\mathbf{r})$ are also periodic. For the final evaluation the decrease of the number of overlapping points (maximum N) in the convolution products with increasing displacements of the functions is neglected (it is assumed that there is no particle-size effect). Then (4.2.5.66) becomes

$$[\pi_\nu(\mathbf{r}) * \pi_{\nu'}(-\mathbf{r}) - N\alpha_\nu\alpha_{\nu'}l(\mathbf{r}) - N\alpha_\nu\alpha_{\nu'}l(\mathbf{r}) + N\alpha_\nu\alpha_{\nu'}l(\mathbf{r})]$$
$$* \Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r})$$
$$= [\pi_\nu(\mathbf{r}) * \pi_{\nu'}(-\mathbf{r}) - N\alpha_\nu\alpha_{\nu'}l(\mathbf{r})]$$
$$* \Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r}). \quad (4.2.5.67)$$

If the first term in (4.2.5.67) is considered, the convolution of the two functions for a given distance $\mathbf{n}$ counts the number of coincidences of the function $\pi_\nu(\mathbf{r})$ with $\pi_{\nu'}(-\mathbf{r})$. This quantity is given by $Nl(\mathbf{r})\alpha_\nu p_{\nu\nu'}(-\mathbf{r})$, where $\alpha_\nu p_{\nu\nu'}(\mathbf{r})$ is the probability of a pair occupation in the $\mathbf{r}$ direction.

Equation (4.2.5.67) then reads

$$[Nl(\mathbf{r})\alpha_\nu p_{\nu\nu'}(-\mathbf{r}) - N\alpha_\nu\alpha_{\nu'}l(\mathbf{r})]$$
$$* \Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r})$$
$$= N\alpha_\nu[p'_{\nu\nu'}(-\mathbf{r})l(\mathbf{r})]$$
$$* [\Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r})] \quad (4.2.5.68)$$

with $p'_{\nu\nu'}(\mathbf{r}) = p_{\nu\nu'}(\mathbf{r}) - \alpha_{\nu'}$. The function $\alpha_\nu p'_{\nu\nu'}(\mathbf{r})$ is usually called the pair-correlation function $g \leftrightarrow \alpha_{\nu\nu'|\mathbf{nn}'}$ in physics.

The following relations hold:

$$\sum_\nu \alpha_\nu = 1; \quad (4.2.5.69a)$$
$$\sum_{\nu'} \alpha_\nu p_{\nu\nu'}(\mathbf{r}) = \alpha_{\nu'}; \quad \sum_{\nu'} \alpha_\nu p'_{\nu\nu'}(\mathbf{r}) = 0 \quad (4.2.5.69b)$$
$$\sum_\nu \alpha_\nu p_{\nu\nu'}(\mathbf{r}) = \alpha_{\nu'}; \quad \sum_\nu \alpha_\nu p'_{\nu\nu'}(\mathbf{r}) = 0 \quad (4.2.5.69c)$$
$$\alpha_\nu p_{\nu\nu'}(\mathbf{r}) = \alpha_{\nu'} p_{\nu'\nu}(-\mathbf{r}). \quad (4.2.5.69d)$$

Functions normalized to unity are also in use. Obviously the following relation is valid: $p'_{\nu\nu'}(0) = \delta_{\nu\nu'} - \alpha_{\nu'}$.

Hence

$$\alpha_{\nu\nu'|\mathbf{nn}'} = \alpha_{\nu'} p'_{\nu\nu'}(\mathbf{r})/(\delta_{\nu\nu'} - \alpha_{\nu'})$$

is unity for $\mathbf{r} = 0\,(\mathbf{n} = \mathbf{n}')$. This property is especially convenient in binary systems.

With (4.2.5.68), equation (4.2.5.64) becomes

$$i_{\mathrm{D}}(\mathbf{r}) = N \sum_\nu \sum_{\nu'} [\alpha_\nu p'_{\nu\nu'}(-\mathbf{r})l(\mathbf{r})] * [\Delta F_\nu(\mathbf{r}) * \Delta F_{\nu'}(-\mathbf{r})] \quad (4.2.5.70)$$

and Fourier transformation yields

$$I_{\mathrm{D}}(\mathbf{H}) = N \sum_\nu \sum_{\nu'} [\alpha_\nu P'_{\nu\nu'}(-\mathbf{H}) * L(\mathbf{H})] \Delta F_\nu(\mathbf{H}) \Delta F^+_{\nu'}(\mathbf{H}). \quad (4.2.5.71)$$

It may be concluded from equations (4.2.5.69) that all functions $p'_{\nu\nu'}(\mathbf{r})$ may be expressed by $p'_{11}(\mathbf{r})$ in the case of two structure factors F_1, F_2. Then all $p'_{\nu\nu'}(\mathbf{r})$ are symmetric in $\mathbf{r}$; the same is true for the $P'_{\nu\nu'}(\mathbf{H})$. Consequently, the diffuse reflections described by (4.2.5.71) are all symmetric. The position of the diffuse peak depends strongly on the behaviour of $p'_{\nu\nu'}(\mathbf{r})$; in the case of cluster formation Bragg peaks and diffuse peaks coincide. Diffuse superstructure reflections are observed if the $p'_{\nu\nu'}(\mathbf{r})$ show some damped periodicities.

It should be emphasized that the condition $p'_{\nu\nu'}(\mathbf{r}) = p'_{\nu\nu'}(-\mathbf{r})$ may be violated for $\nu \neq \nu'$ if more than two cell occupations are involved. As shown below, the possibly asymmetric functions may be split into symmetric and antisymmetric parts. From equation (4.2.3.8) it follows that the Fourier transform of the antisymmetric part of $p'_{\nu\nu'}(\mathbf{r})$ is also antisymmetric. Hence, the convolution in the two terms in square brackets in (4.2.5.71) yields an antisymmetric contribution to each diffuse peak, generated by the convolution with the reciprocal lattice $L(\mathbf{h})$.

Obviously, equation (4.2.5.71) may also be applied to primitive lattices occupied by two or more kinds of atoms. Then the structure factors F_ν are merely replaced by the atomic scattering factors f_ν and the α_ν are equivalent to the concentrations of atoms c_ν. In terms of the $\alpha_{\nu\nu'|\mathbf{nn}'}$ (Warren short-range-order parameters) equation (4.2.5.71) reads

$$I_{\mathrm{D}}(\mathbf{H}) = N(\overline{f^2} - \bar{f}^2) \sum_{\mathbf{n}} \sum_{\mathbf{n}'} \alpha_{\nu\nu'|\mathbf{nn}'} \exp\{2\pi i \mathbf{H} \cdot (\mathbf{n} - \mathbf{n}')\}. \quad (4.2.5.71a)$$

In the simplest case of a binary system A, B,

$$\alpha_{\mathbf{nn}'} = (1 - p_{AB|\mathbf{nn}'})/c_B = (1 - p_{BA|\mathbf{nn}'})/c_A;$$
$$c_A p_{AB} = c_B p_{BA}; \quad p_{AA} = 1 - p_{AB};$$

$$I_{\mathrm{D}}(\mathbf{H}) = N c_A c_B (f_A - f_B)^2 \sum_{\mathbf{n}} \sum_{\mathbf{n}'} \alpha_{\mathbf{nn}'} \exp\{2\pi i \mathbf{H} \cdot (\mathbf{n} - \mathbf{n}')\}. \quad (4.2.5.71b)$$

[The exponential in (4.2.5.71*b*) may even be replaced by a cosine term owing to the centrosymmetry of this particular case.]

It should be mentioned that the formulations of the problem in terms of pair probabilities, pair-correlation functions, short-range-order parameters or concentration waves (Krivoglaz, 1969, 1996*a*,*b*) are equivalent. The Patterson function may also be used when using continuous electron (or nuclear) density functions where site occupancies are implied (Cowley, 1981).

4.2.5.4.2. Random distribution of defects

As shown above in the case of random distributions, all $p'_{\nu\nu'}(\mathbf{r})$ are zero except for $\mathbf{r} = 0$. Consequently, $p'_{\nu\nu'}(\mathbf{r})l(\mathbf{r})$ may be replaced by

$$\alpha_\nu p'_{\nu\nu'}(\mathbf{r}) = \alpha_\nu \delta_{\nu\nu'} - \alpha_\nu\alpha_{\nu'}. \quad (4.2.5.72)$$

According to (4.2.5.59) and (4.2.5.61), the diffuse scattering can be given by the Fourier transformation of

$$\sum_\nu \sum_{\nu'} \Delta\pi_\nu(\mathbf{r}) * \Delta\pi_{\nu'}(-\mathbf{r}) * F_\nu(\mathbf{r}) * F_\nu(-\mathbf{r})$$
$$= \sum_\nu \sum_{\nu'} p'_{\nu\nu'}(\mathbf{r}) * F_\nu(\mathbf{r}) * F_{\nu'}(-\mathbf{r})$$

or with (4.2.5.72)

$$i_{\mathrm{D}}(\mathbf{r}) = N \sum_\nu \sum_{\nu'} [\alpha_\nu \delta_{\nu\nu'} - \alpha_\nu\alpha_{\nu'}] * F_\nu(\mathbf{r}) * F_{\nu'}(-\mathbf{r}).$$

Fourier transformation gives

$$I_{\mathrm{D}}(\mathbf{H}) = N\left\{\sum_\nu \alpha_\nu |F_\nu(\mathbf{H})|^2 - \sum_\nu \alpha_\nu F_\nu(\mathbf{H}) \sum_{\nu'} \alpha_{\nu'} F^+_{\nu'}(\mathbf{H})\right\}$$
$$= N\{\langle |F(\mathbf{H})|^2 \rangle - |\langle F(\mathbf{H}) \rangle|^2\}. \quad (4.2.5.73)$$

This is the most general form of any diffuse scattering by systems ordered randomly ('Laue scattering'). Occasionally it is called 'incoherent scattering' (see Section 4.2.2).

4.2.5.4.3. Short-range order in multicomponent systems

The diffuse scattering of a disordered binary system without displacements of the atoms has already been discussed in Section 4.2.5.4.1. It could be shown that all distribution functions $p'_{\nu\nu'}(\mathbf{r})$ are mutually dependent and may be replaced by a single function [*cf.* (4.2.5.69)]. In that case $p'_{\nu\nu'}(\mathbf{r}) = p'_{\nu\nu'}(-\mathbf{r})$ was valid for all. This condition, however, may be violated in multicomponent systems. If a tendency towards an $F_1F_2F_3$ order in a ternary system is assumed, for example, $p_{12}(\mathbf{r})$ is apparently different from $p_{12}(-\mathbf{r})$. In this particular case it is useful to introduce

$$\langle p'_{\nu\nu'}(\mathbf{r})\rangle = \tfrac{1}{2}[p'_{\nu\nu'}(\mathbf{r}) + p'_{\nu\nu'}(-\mathbf{r})],$$
$$\Delta p'_{\nu\nu'}(\mathbf{r}) = \tfrac{1}{2}[p'_{\nu\nu'}(\mathbf{r}) - p'_{\nu\nu'}(-\mathbf{r})]$$

and their Fourier transforms $\langle P'_{\nu\nu'}(\mathbf{H})\rangle$, $\Delta P'_{\nu\nu'}(\mathbf{H})$, respectively.

The asymmetric correlation functions are therefore expressed by

$$p'_{\nu\nu'}(\mathbf{r}) = \langle p'_{\nu\nu'}(\mathbf{r})\rangle + \Delta p'_{\nu\nu'}(\mathbf{r});$$
$$p'_{\nu\nu'}(-\mathbf{r}) = \langle p'_{\nu\nu'}(\mathbf{r})\rangle - \Delta p'_{\nu\nu'}(\mathbf{r});$$
$$\Delta p'_{\nu\nu}(\mathbf{r}) = 0.$$

Consequently, $i_{\mathrm{D}}(\mathbf{r})$ (4.2.5.70) and $I_{\mathrm{D}}(\mathbf{H})$ (4.2.5.71) may be separated according to the symmetric and antisymmetric contributions. The final result is

$$\begin{aligned} I_{\mathrm{D}}(\mathbf{H}) = N\Big\{ & \sum_{\nu} \alpha_\nu [P'_{\nu\nu}(\mathbf{H}) * L(\mathbf{H})] |F_\nu(\mathbf{H})|^2 \\ & + \sum_{\nu>\nu'} \alpha_\nu [\langle P'_{\nu\nu'}(\mathbf{H})\rangle * L(\mathbf{H})] \\ & \times [\Delta F_\nu(\mathbf{H}) \Delta F^+_{\nu'}(\mathbf{H}) + \Delta F^+_\nu(\mathbf{H}) \Delta F_{\nu'}(\mathbf{H})] \\ & + \sum_{\nu>\nu'} \alpha_\nu [\Delta P'_{\nu\nu'}(-\mathbf{H}) * L(\mathbf{H})] \\ & \times [\Delta F_\nu(\mathbf{H}) \Delta F^+_{\nu'}(\mathbf{H}) - \Delta F^+_\nu(\mathbf{H}) \Delta F_{\nu'}(\mathbf{H})] \Big\}. \end{aligned} \tag{4.2.5.74}$$

Obviously, antisymmetric contributions to line profiles will only occur if structure factors of acentric cell occupations are involved. This important property may be used to draw conclusions with respect to the structure factors involved in the statistics. It should be mentioned here that the Fourier transform of the antisymmetric function $\Delta p'_{\nu\nu'}(\mathbf{r})$ is imaginary and antisymmetric. Since the last term in (4.2.5.74) is also imaginary, the product of the two factors in brackets is real, as it should be.

4.2.5.4.4. Displacements: general remarks

Even small displacements may have an important influence on the problem of propagation of order. Therefore, no structural treatments other than the introduction of formal parameters (*e.g.* Landau's theory) have been published in the literature. Most of the examples with really reliable results refer to binary systems and even these represent very crude approximations, as will be shown below. For this reason we shall restrict ourselves here to binary systems, although general formulae where displacements are included may be developed in a formal way.

Two kinds of atoms, $f_1(\mathbf{r})$ and $f_2(\mathbf{r})$, are considered. Obviously, the position of any given atom is determined by its surroundings. Their extension depends on the forces acting on the atom under consideration. These may be very weak in the case of metals (repulsive forces, the 'size effect'), but long-range effects have to be expected in ionic crystals. For the development of formulae authors have assumed that small displacements $\Delta\mathbf{r}_{\nu\nu'}$ may be assigned to the pair-correlation functions $p'_{\nu\nu'}(\mathbf{r})$ by adding a phase factor $\exp\{2\pi i\mathbf{H}\cdot\Delta\mathbf{r}_{\nu\nu'}\}$, which is then expanded in the usual way:

$$\exp\{2\pi i\mathbf{H}\cdot\Delta\mathbf{r}_{\nu\nu'}\} \simeq 1 + 2\pi i\mathbf{H}\cdot\Delta\mathbf{r}_{\nu\nu'} - 2[\pi\mathbf{H}\cdot\Delta\mathbf{r}_{\nu\nu'}]^2. \tag{4.2.5.75}$$

The displacements and correlation probabilities are separable if the change of atomic scattering factors in the angular range considered may be neglected. The formulae in use are given in the next section. As shown below, this method represents nothing other than a kind of average over certain sets of displacements. For this purpose, the correct solution of the problem has to be discussed. In the simplest model the displacements are due to next-nearest neighbours only. It is further assumed that the configurations rather than the displacements determine the position of the central atom and a general displacement of the centre of the first shell does not occur (there is no influence of a strain field). Obviously, the formal correlation function of pairs is not independent of displacements. This difficulty may be avoided either by assuming that the pair-correlation function has already been separated from the diffraction data, or by theoretical calculations of the correlation function (the mean-field method) (Moss, 1966; de Fontaine, 1972, 1973). The validity of this procedure is subject to the condition that the displacements have no influence on the correlation functions themselves.

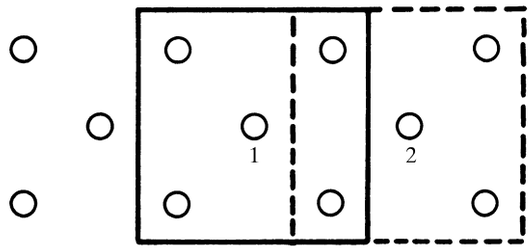

Fig. 4.2.5.1. Construction of the correlation function in the method of overlapping clusters.

The observation of a periodic average structure justifies the definition of a periodic array of origins, which normally depends on the degree of order. Local deviations of origins may be due to fluctuations in the degree of order and due to the surrounding atoms of a given site. For example, a b.c.c. lattice with eight nearest neighbours is considered. It is assumed that only these have an influence on the position of the central atom owing to different forces of the various configurations. With two kinds of atoms, there are $2^9 = 512$ possible configurations of the cluster (the central atom plus 8 neighbours). Symmetry considerations reduce this number to 28. Each is characterized by a displacement vector. Hence their *a priori* probabilities and the propagation of 28 different configurations have to be determined. Since each atom has to be considered as the centre once, this problem may be treated by introducing 28 different atomic scattering factors as determined from the displacements: $f_\nu(\mathbf{r})\exp\{2\pi i\mathbf{H}\cdot\Delta\mathbf{r}_{\nu\nu'}\}$. The diffraction problem has to be solved with the aid of the propagation of order of overlapping clusters. This is demonstrated by a two-dimensional model with four nearest neighbours (Fig. 4.2.5.1). Here the central and the neighbouring cluster (full and broken lines) overlap with two sites in, for example, the x direction. Hence only neighbouring clusters with the same overlapping pairs are admitted. These restrictions introduce severe difficulties into the problem of propagation of cluster ordering which determines the displacement field. Since it was assumed that the problem of pair correlation had been solved, the cluster probabilities may be derived by calculating

$$\alpha_\nu l(\mathbf{r}) \prod_{\mathbf{n}\neq 0} p'_{\nu\nu'}(\mathbf{r}-\mathbf{n}). \tag{4.2.5.76}$$

Only next-nearest neighbours have to be included in the product. This must be performed for the central cluster ($\mathbf{r} = 0$) *and* for the reference cluster at $\mathbf{r} = n_1\mathbf{a} + n_2\mathbf{b} + n_3\mathbf{c}$, because all are characterized by different displacements. So far, possible displacement of the centre has not been considered; this may also be influenced by the problem of propagation of cluster ordering. These displacement factors should best be attached to the function describing the propagation of order which determines, in principle, the local fluctuations of the lattice constants (the strain field *etc.*). This may be understood by considering a binary system with a high degree of order but with atoms of different size. Large fluctuations of lattice constants are involved in the case of

exsolution of the two components because of their different lattice parameters, but they become small in the case of superstructure formation where a description in terms of antiphase domains is reasonable (with equal lattice constants). This example demonstrates the mutual dependence of ordering and displacements, which is mostly neglected in the literature.

The method of assigning phase factors to the pair-correlation function is now discussed. Pair-correlation functions average over all pairs of clusters having the same central atom. An analogous argument holds for displacements: using pair correlations for the determination of displacements means nothing other than averaging over all displacements caused by various clusters around the same central atom. There remains the general strain field due to the propagation of order, whereas actual displacements of atoms are realized by fluctuations of configurations. Since large fluctuations of this type occur in highly disordered crystals, the displacements become increasingly irrelevant. Hence the formal addition of displacement factors to the pair-correlation function does not yield much information about the structural basis of the displacements. This situation corresponds exactly to the relationship between a Patterson function and a real structure: the structure has to be found which explains the quite complicated function completely, and its unique solution is rather difficult. We state these points here because in most publications related to this subject these considerations are not taken into account adequately. Displacements usually give rise to antisymmetric contributions to diffuse reflections. As pointed out above, the influence of displacements has to be considered as phase factors which may be attached either to the structure factors or to the Fourier transforms $P'_{\nu\nu'}(\mathbf{H})$ of the correlation functions in equation (4.2.5.71). As has been mentioned in the context of equation (4.2.5.74), antisymmetric contributions will occur if acentric structure factors are involved. Apparently, this condition is met by the phase factors of displacements. In consequence, antisymmetric contributions to diffuse reflections may also originate from the displacements. This fact can also be demonstrated if the assignment of phase factors to the Fourier transforms of the correlation functions is advantageous. In this case, equations (4.2.5.69*a*,*b*) are no longer valid because the functions $p'_{\nu\nu'}(\mathbf{r})$ become complex. The most important change is the relation corresponding to (4.2.5.69):

$$\alpha_\nu p'_{\nu\nu'}(\mathbf{r}) = \alpha_{\nu'} p'^{+}_{\nu\nu'}(-\mathbf{r}) \leftrightarrow \alpha_\nu P'_{\nu\nu'}(\mathbf{H}) = \alpha_{\nu'} P'^{+}_{\nu'}(\mathbf{H}). \quad (4.2.5.77)$$

Strictly speaking, we have to replace the *a priori* probabilities α_ν by complex numbers $\alpha_\nu \exp\{2\pi i \Delta\mathbf{r}_\nu \cdot \mathbf{H}\}$, which are determined by the position of the central atom. In this way, all correlations between displacements may be included with the aid of the clusters mentioned above. To a rough approximation it may be assumed that no correlations of this kind exist. In this case, the complex factors may be assigned to the structure factors involved. Averaging over all displacements results in diffraction effects that are very similar to a static Debye–Waller factor for all structure factors. On the other hand, the thermal motion of atoms is treated similarly. Obviously, both factors affect the sharp Bragg peaks. Hence this factor can easily be determined by the average structure, which contains a Debye–Waller factor including static and thermal displacements. It should be pointed out, however, that these static displacements cause elastic diffuse scattering, which cannot be separated by inelastic neutron-scattering techniques.

A careful study of the real and imaginary parts of

$$\langle p'_{\nu\nu'}(\mathbf{r})\rangle = \langle p'_{\nu\nu'}(\mathbf{r})\rangle_{\mathrm{R}} + \langle p'_{\nu\nu'}(\mathbf{r})\rangle_{\mathrm{I}}$$

and

$$\Delta p'_{\nu\nu'}(\mathbf{r}) = \Delta p'_{\nu\nu'}(\mathbf{r})_{\mathrm{R}} + \Delta p'_{\nu\nu'}(\mathbf{r})_{\mathrm{I}}$$

and their Fourier transforms results, after some calculations, in the following relation for diffuse scattering:

$$\begin{aligned} I_{\mathrm{D}} \simeq\ & N \sum_\nu \alpha_\nu |\Delta F_\nu(\mathbf{H})|^2 \{[\langle P'_{\nu\nu}(\mathbf{H})\rangle - \Delta P'_{\nu\nu}(\mathbf{H})] * L(\mathbf{H})\} \\ & + 2N \sum_{\nu>\nu'} \alpha_\nu (\Delta F_\nu \Delta F^{+}_{\nu'})_{\mathrm{R}} \\ & \times \{[\langle P'_{\nu\nu'}(\mathbf{H})\rangle_{\mathrm{R}} - \Delta P'_{\nu\nu'}(\mathbf{H})_{\mathrm{I}}] * L(\mathbf{H})\} \\ & + 2N \sum_{\nu>\nu'} \alpha_\nu (\Delta F_\nu \Delta F^{+}_{\nu'})_{\mathrm{I}} \\ & \times \{[\langle P'_{\nu\nu'}(\mathbf{H})\rangle_{\mathrm{I}} - \Delta P'_{\nu\nu'}(\mathbf{H})_{\mathrm{R}}] * L(\mathbf{H})\}. \end{aligned} \quad (4.2.5.78)$$

It should be noted that all contributions are real. This follows from the properties of Fourier transforms of symmetric and antisymmetric functions. All $\Delta P_{\nu\nu'}(\mathbf{H})$ are antisymmetric; hence they generate antisymmetric contributions to the line profiles. In contrast to equation (4.2.5.75), the real *and* the imaginary parts of the structure factors contribute to the asymmetry of the line profiles.

4.2.5.4.5. Distortions in binary systems

In substitutional binary systems (with a primitive cell with only one sublattice) the Borie–Sparks method is widely used (Sparks & Borie, 1966; Borie & Sparks, 1971). The method is formulated in the short-range-order-parameter formalism. The diffuse scattering may be separated into two parts (*a*) owing to short-range order and (*b*) owing to static displacements.

Corresponding to the expansion (4.2.5.75), $I_{\mathrm{D}} = I_{\mathrm{sro}} + I_2 + I_3$, where I_{sro} is given by equation (4.2.5.71*b*) and the correction terms I_2 and I_3 relate to the linear and the quadratic term in (4.2.5.75). The intensity expression will be split into terms of A–A, A–B, ... pairs. More explicitly $\Delta\mathbf{r}_{\nu\nu'} = \mathbf{u}_{\mathbf{n}\nu} - \mathbf{u}_{\mathbf{n}'\nu'}$ and with the following abbreviations

$$\begin{aligned} \delta_{\mathbf{nn}'|AA} &= \mathbf{u}_{\mathbf{n}|A} - \mathbf{u}_{\mathbf{n}'|A} = x_{\mathbf{nn}'|AA}\mathbf{a} + y_{\mathbf{nn}'|AA}\mathbf{b} + z_{\mathbf{nn}'|AA}\mathbf{c} \\ \delta_{\mathbf{nn}'|AB} &= \mathbf{u}_{\mathbf{n}|A} - \mathbf{u}_{\mathbf{n}'|B} = \ldots \\ F_{\mathbf{nn}'|AA} &= [f_A^2/(f_A - f_B)^2][(c_A/c_B) + \alpha_{\mathbf{nn}'}] \\ F_{\mathbf{nn}'|BB} &= [f_B^2/(f_A - f_B)^2][(c_B/c_A) + \alpha_{\mathbf{nn}'}] \\ F_{\mathbf{nn}'|AB} &= [2f_A f_B/(f_A - f_B)^2](1 - \alpha_{\mathbf{nn}'}) = F_{\mathbf{nn}'|BA} \end{aligned}$$

one finds (where the short-hand notation is self-explanatory):

$$\begin{aligned} I_2 = 2\pi i c_A c_B (f_A - f_B)^2 \sum_{\mathbf{n}} \sum_{\mathbf{n}'} \{ & H[F_{\mathbf{nn}'|AA}\langle x_{\mathbf{nn}'|AA}\rangle \\ & + F_{\mathbf{nn}'|BB}\langle x_{\mathbf{nn}'|BB}\rangle + F_{\mathbf{nn}'|AB}\langle x_{\mathbf{nn}'|AB}\rangle] + K[\text{`}y\text{'}] \\ & + L[\text{`}z\text{'}]\} \exp\{2\pi i \mathbf{H}\cdot(\mathbf{n} - \mathbf{n}')\}, \end{aligned} \quad (4.2.5.79)$$

$$\begin{aligned} I_3 = c_A c_B (f_A - f_B)^2 (-2\pi)^2 \sum_{\mathbf{n}} \sum_{\mathbf{n}'} \{ & H^2[F_{\mathbf{nn}'}\langle x^2_{\mathbf{nn}'|AA}\rangle \\ & + F_{\mathbf{nn}'|BB}\langle x^2_{\mathbf{nn}'|BB}\rangle + F_{\mathbf{nn}'|AB}\langle x^2_{\mathbf{nn}'|AB}\rangle] \\ & + K^2[\text{`}y^2\text{'}] + L^2[\text{`}z^2\text{'}] \\ & + HK[F_{\mathbf{nn}'|AA}\langle (xy)_{\mathbf{nn}'|AA}\rangle + F_{\mathbf{nn}'|BB}\langle (xy)_{\mathbf{nn}'|BB}\rangle \\ & + F_{\mathbf{nn}'|AB}\langle (xy)_{\mathbf{nn}'|AB}\rangle] \\ & + KL[\text{`}(yz)\text{'}] + LH[\text{`}(zx)\text{'}]\} \\ & \times \exp\{2\pi i \mathbf{H}\cdot(\mathbf{n} - \mathbf{n}')\}. \end{aligned} \quad (4.2.5.80)$$

With further abbreviations

$$\gamma_{\mathbf{nn}'|x} = 2\pi(F_{\mathbf{nn}'|AA}\langle x_{\mathbf{nn}'|AA}\rangle + F_{\mathbf{nn}'|BB}\langle x_{\mathbf{nn}'|BB}\rangle + F_{\mathbf{nn}'|AB}\langle x_{\mathbf{nn}'|AB}\rangle)$$
$$\gamma_{\mathbf{nn}'|y} = \ldots$$
$$\gamma_{\mathbf{nn}'|z} = \ldots$$
$$\delta_{\mathbf{nn}'|x} = (-2\pi^2)(F_{\mathbf{nn}'|AA}\langle x^2_{\mathbf{nn}'|AA}\rangle + F_{\mathbf{nn}'|BB}\langle x^2_{\mathbf{nn}'|BB}\rangle + F_{\mathbf{nn}'|AB}\langle x^2_{\mathbf{nn}'|AB}\rangle)$$
$$\delta_{\mathbf{nn}'|y} = \ldots$$
$$\delta_{\mathbf{nn}'|z} = \ldots$$
$$\varepsilon_{\mathbf{nn}'|xy} = (-4\pi^2)(F_{\mathbf{nn}'|AA}\langle (xy)_{\mathbf{nn}'|AA}\rangle + F_{\mathbf{nn}'|BB}\langle (xy)_{\mathbf{nn}'|BB}\rangle + F_{\mathbf{nn}'|AB}\langle (xy)_{\mathbf{nn}'|AB}\rangle)$$
$$\varepsilon_{\mathbf{nn}'|yz} = \ldots$$
$$\varepsilon_{\mathbf{nn}'|zx} = \ldots$$
$$I_2 = c_A c_B (f_A - f_B)^2 \sum_{\mathbf{n}} \sum_{\mathbf{n}'} i(\gamma_{\mathbf{nn}'|x} + \gamma_{\mathbf{nn}'|y} + \gamma_{\mathbf{nn}'|z}) \times \exp\{2\pi i \mathbf{H}\cdot(\mathbf{n}-\mathbf{n}')\}$$
$$I_3 = c_A c_B (f_A - f_B)^2 \sum_{\mathbf{n}} \sum_{\mathbf{n}'} (\delta_{\mathbf{nn}'|x}H^2 + \delta_{\mathbf{nn}'|y}K^2 + \delta_{\mathbf{nn}'|z}L^2 + \varepsilon_{\mathbf{nn}'|xy}HK + \varepsilon_{\mathbf{nn}'|yz}KL + \varepsilon_{\mathbf{nn}'|zx}LH)\exp\{2\pi i \mathbf{H}\cdot(\mathbf{n}-\mathbf{n}')\}.$$

If the $F_{\mathbf{nn}'|AA}, \ldots$ are independent of $|\mathbf{H}|$ in a range of measurement which is better fulfilled with neutrons than with X-rays (see below), γ, δ, ε are the coefficients of the Fourier series:

$$Q_x = \sum_{\mathbf{n}} \sum_{\mathbf{n}'} i\gamma_{\mathbf{nn}'|x} \exp\{2\pi i \mathbf{H}\cdot(\mathbf{n}-\mathbf{n}')\};$$
$$Q_y = \ldots; \qquad Q_z = \ldots;$$
$$R_x = \sum_{\mathbf{n}} \sum_{\mathbf{n}'} \delta_{\mathbf{nn}'|x} \exp\{2\pi i \mathbf{H}\cdot(\mathbf{n}-\mathbf{n}')\};$$
$$R_y = \ldots; \qquad R_z = \ldots;$$
$$S_{xy} = \sum_{\mathbf{n}} \sum_{\mathbf{n}'} \varepsilon_{\mathbf{nn}'|xy} \exp\{2\pi i \mathbf{H}\cdot(\mathbf{n}-\mathbf{n}')\};$$
$$S_{yz} = \ldots; \qquad S_{zx} = \ldots.$$

The functions Q, R, S are then periodic in reciprocal space.

The double sums over $\mathbf{n}$, $\mathbf{n}'$ may be replaced by $N\sum_{m,n,p}$ where m, n, p are the coordinates of the interatomic vectors $(\mathbf{n}-\mathbf{n}')$ and I_2 becomes

$$I_2 = -Nc_A c_B (f_A - f_B)^2 \sum_m \sum_n \sum_p (H\gamma_{lmn|x} + \ldots + \ldots) \times \sin 2\pi(Hm + Kn + Lp). \qquad (4.2.5.81)$$

The intensity is therefore modulated sinusoidally and increases with scattering angle. The modulation gives rise to an asymmetry in the intensity around a Bragg peak. Similar considerations for I_3 reveal an intensity contribution h_i^2 times a sum over cosine terms which is symmetric around the Bragg peaks ($i = 1, 2, 3$ with $h_1 = h$, $h_2 = k$, $h_3 = l$). This term shows a quite analogous influence of local static displacements and thermal movements: an increase of diffuse intensity around the Bragg peaks and a reduction of Bragg intensities, which is not discussed here. The second contribution I_2 has no analogue owing to the nonvanishing average displacement. The various diffuse intensity contributions may be separated by symmetry considerations. Once they are separated, the single coefficients may be determined by Fourier inversion. Owing to the symmetry constraints, there are relations between the displacements $\langle x \ldots \rangle$ and, in turn, between the γ and Q components. The same is true for the δ, ε and R, S components. Consequently, there are symmetry conditions for the individual contributions of the diffuse intensity which may be used to distinguish them. In general, the total diffuse intensity may be split into only a few independent terms. The single components of Q, R, S may be expressed separately by combinations of diffuse intensities that are measured in definite selected volumes in reciprocal space. Only a minimum volume must be explored in order to reveal the behaviour over the whole reciprocal space. This minimum repeat volume is different for the single components: I_{sro}, Q, R, S or combinations of them.

The Borie–Sparks method has been applied very frequently to binary and even ternary systems; some improvements have been communicated by Bardhan & Cohen (1976). The diffuse scattering of the historically important metallic compound Cu_3Au was been studied by Cowley (1950*a*,*b*) and the pair-correlation parameters could be determined. The typical fourfold splitting was found by Moss (1966) and explained in terms of atomic displacements. The same splitting has been found for many similar compounds such as Cu_3Pd (Ohshima *et al.*, 1976), Au_3Cu (Bessière *et al.*, 1983) and $Ag_{1-x}Mg_x$ (x = 0.15–0.20) (Ohshima & Harada, 1986). Similar pair-correlation functions have been determined. In order to demonstrate the disorder parameters in terms of structural models, computer programs were used (*e.g.* Gehlen & Cohen, 1965). A similar microdomain model was proposed by Hashimoto (1974, 1981, 1983, 1987). According to approximations made in the theoretical derivation, the evaluation of diffuse scattering is generally restricted to an area in reciprocal space where the influence of displacements is of the same order of magnitude as that of the pair-correlation function. The agreement between calculation and measurement is fairly good, but it should be remembered that the amount and quality of the experimental information used is low. No residual factors are so far available; these would give an idea of the reliability of the results.

The more general case of a multicomponent system with several atoms per lattice point was treated similarly by Hayakawa & Cohen (1975). Sources of error in the determination of the short-range-order coefficients are discussed by Gragg *et al.* (1973). In general, the assumption of constant $F_{\mathbf{nn}'|AA}, \ldots$ produces an incomplete separation of the order- and displacement-dependent components of diffuse scattering. By an alternative method, by separation of the form factors from the Q, R, S functions and solving a large array of linear relationships by least-squares methods, the accuracy of the separation of the various contributions is improved (Tibbals, 1975; Georgopoulos & Cohen, 1977; Wu *et al.*, 1983). The method does not work for neutron diffraction. The case of planar short-range order with corresponding diffuse intensity along rods in reciprocal space may also be treated along the Borie & Sparks method (Ohshima & Moss, 1983).

Multiwavelength methods taking advantage of the variation of the structure factor near an absorption edge (anomalous dispersion) are discussed by Cenedese *et al.* (1984). The same authors show that in some cases the neutron method allows contrast variation by using samples with different isotope substitution.

In general, X-ray and neutron methods are complementary. The neutron method is helpful in the cases of hydrides, oxides, carbides, Al–Mg distributions *etc.* In favourable cases it is possible to suppress (nuclear) Bragg scattering of neutrons when isotopes are used so that $\sum_\nu c_\nu f_\nu = 0$ for all equivalent positions. Another way to separate Bragg peaks is to record the diffuse intensity, if possible, at low $|\mathbf{H}|$ values. This can be achieved either by measurement at low angles or by using long wavelengths. For reasons of absorption the latter are the domain of neutron scattering. Bragg scattering is ruled out by exceeding the Bragg cut-off. In this way, 'diffuse' background owing to multiple Bragg scattering is avoided. Other diffuse-scattering contributions that increase with the $|\mathbf{H}|$ value [thermal diffuse scattering (TDS) and scattering due to long-range static displacements] are thus also minimized. Neutrons are preferable in cases where X-rays show only a small scattering contrast: (heavy) metal lattice distortions,

Huang scattering and so on should be measured at large values of $|\mathbf{H}|$. TDS can be separated by purely elastic neutron methods within the limits given by the energy resolution of an instrument. This technique is of particular importance at higher temperatures where TDS becomes remarkably strong. Neutron scattering is a good tool only in cases where (isotope/spin-) incoherent scattering is not too strong. In the case of magnetic materials, confusion with paramagnetic diffuse scattering could occur. This is also important when electrons are trapped by defects which themselves act as paramagnetic centres.

4.2.5.4.6. Comparison with the cluster method

In the general formula for diffuse scattering from random distributions equation (4.2.3.23*a*,*b*) may be used. Here $|\langle F(\mathbf{H})\rangle|^2$ describes the sharp Bragg maxima, while $|\Delta F(\mathbf{H})|^2 = \langle|F(\mathbf{H})|^2\rangle - |\langle F(\mathbf{H})\rangle|^2$ represents the contribution to diffuse scattering. Correlation effects can also be taken into account by using clusters of sufficient size if their distribution may be considered as random to a good approximation. The diffuse intensity is then given by

$$I_{\rm D}(\mathbf{H}) = \sum_\nu p_\nu |F_\nu(\mathbf{H})|^2 - \Big|\sum_\nu p_\nu F_\nu(\mathbf{H})\Big|^2, \qquad (4.2.5.82)$$

where $F_\nu(\mathbf{H})$ represents the difference structure factor of the νth cluster and p_ν is its *a priori* probability. Obviously equation (4.2.5.82) is of some use in only two cases. (1) The number of clusters is sufficiently small and meets the condition of a nearly random distribution. In principle, the structure may then be determined with the aid of refinement methods according to equation (4.2.5.82). Since the second term is assumed to be known from the average structure, the first term may be evaluated by introducing as many parameters as there are clusters involved. A special computer program for incoherent refinement has to be used if more than one representative cluster has to be introduced. In the case of more clusters constraints are necessary. (2) The number of clusters with similar structures is not limited. It may be assumed that their size distribution may be expressed by fluctuations using well known analytical expressions, *e.g.* Gaussians or Lorentzians. The distribution is still assumed to be random.

An early application of the cluster method was the calculation of the diffuse intensity of Guinier–Preston zones, where a single cluster is sufficient (see, *e.g.*, Gerold, 1954; Bubeck & Gerold, 1984). Unfortunately, no refinements of cluster structures have so far been published. The full theory of the cluster method was outlined by Jagodzinski & Haefner (1967).

A different approach to analysing extended defects in crystals is simply to construct analytically disorder models that include chemical substitution and atomic displacements around an atomic defect as consequence of the surrounding local distortions. This method works if the number of 'shells' of the first, second, ... neighbours is limited and if short- or long-range correlations between different clusters are neglected. After subtracting the underlying average structure and the calculation of the Fourier transform of the difference structure ΔF, the intensities can be fitted to the observed diffuse diffraction pattern and the parameters of the disorder model (occupancies and displacements) can be determined. For examples of this method see Neder *et al.* (1990) or Kaiser-Bischoff *et al.* (2005). Short-range correlations may simply be included by approximating the distribution function by summing over a finite number of defects (clusters) (Goff *et al.*, 1999).

4.2.5.5. Molecular crystals: orientational disorder

Molecular crystals show in principle disorder phenomena similar to those discussed in previous sections (*i.e.* substitutional or displacement disorder). Here we have to replace the structure factors $F_\nu(\mathbf{H})$ used in the previous sections by the molecular structure factors in their various orientations. These are usually rapidly varying functions in reciprocal space which may obscure the disorder diffuse scattering. Disorder in molecular crystals is treated by Guinier (1963), Amorós & Amorós (1968), Flack (1970), Epstein *et al.* (1982), Welberry & Siripitayananon (1986, 1987) and others.

A particular type of disorder is very common in molecular and also in ionic crystals: the centres of masses of molecules or ionic complexes form a perfect 3D lattice but their orientations are disordered. Sometimes these solids are called plastic crystals. In comparison, the liquid-crystalline state is characterized by an orientational order in the absence of long-range positional order of the centres of the molecules. A clear-cut separation is not possible in cases where translational symmetry occurs in a low dimension, *e.g.* in sheets or parallel to a few directions in crystal space. For discussion of these mesophases see Chapter 4.4.

An orientationally disordered crystal may be pictured by freezing molecules in different sites in one of several orientations. Local correlations between neighbouring molecules and correlations between position and orientation may be responsible for orientational short-range order. Thermal reorientations of the molecules are often related to an orientationally disordered crystal. Thermal vibrations of the centres of masses of the molecules, librational or rotational excitations around one or more axes of the molecules, jumps between different equilibrium positions or diffusion-like phenomena are responsible for diffuse scattering of dynamic origin. As mentioned above, the complexity of molecular structures and the associated large number of thermal modes complicate a separation from static disorder effects.

In general, high Debye–Waller factors are typical for scattering by orientationally disordered crystals. Consequently only a few Bragg reflections are observable. A large amount of structural information is stored in the diffuse background. It has to be analysed with respect to an incoherent and coherent part, elastic, quasielastic or inelastic nature, short-range correlations within one and the same molecule and between orientations of different molecules, and cross correlations between positional and orientational disorder scattering. Combined X-ray and neutron methods are therefore highly recommended.

(1) *General expressions*

On the assumption of a well ordered 3D lattice, a general expression for the scattering by an orientationally disordered crystal with one molecule per unit cell may be given. This is a very common situation. Moreover, orientational disorder is frequently related to molecules with an overall 'globular' shape and consequently to crystals of high (in particular, averaged) spherical symmetry. In the following, the relevant equations are given for this situation; these are discussed in some detail in a review article by Fouret (1979). The orientation of a molecule is characterized by a parameter ω_l, *e.g.* the set of Eulerian angles of three molecular axes with respect to the crystal axes: $l = 1, \ldots, D$ (for D possible different orientations). The equilibrium position of the centre of mass of a molecule in orientation ω_l is given by $\mathbf{r}_l$, the equilibrium position of atom k within a molecule l in orientation ω_l by $\mathbf{r}_{lk}$ and a displacement from this equilibrium position by $\mathbf{u}_{lk}$. Averaging over a long time, *i.e.* supposing that the lifetime of a discrete configuration is long compared with the period of atomic vibrations, the observed intensity may be deduced from the intensity expression corresponding to a given configuration at time t:

$$I(\mathbf{H}, t) = \sum_l \sum_{l'} F_l(\mathbf{H}, t) F_{l'}^+(\mathbf{H}, t) \times \exp\{2\pi i \mathbf{H}\cdot(\mathbf{r}_l - \mathbf{r}_{l'})\}, \qquad (4.2.5.83)$$

$$F_l(\mathbf{H}, t) = \sum_k f_k \exp\{2\pi i \mathbf{H}\cdot(\mathbf{r}_{lk} + \mathbf{u}_{lk})\}. \qquad (4.2.5.84)$$

Averaging procedures must be carried out with respect to the thermal vibrations (denoted by an overbar) and over all configurations (symbol $\langle\,\rangle$). The centre-of-mass translational vibrations and librations of the molecules are most important in this context. (Internal vibrations of the molecules are assumed to be decoupled and remain unconsidered.)

$$I(\mathbf{H},t)=\sum_l\sum_{l'}\langle\overline{F_l(\mathbf{H},t)F_{l'}^{+}(\mathbf{H},t)}\rangle \times\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_l-\mathbf{r}_{l'})\}. \quad (4.2.5.83a)$$

Thermal averaging gives (*cf.* Chapter 4.1)

$$I=\sum_l\sum_{l'}\overline{F_lF_{l'}^{+}}\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_l-\mathbf{r}_{l'})\},$$
$$\overline{F_lF_{l'}^{+}}=\sum_k\sum_{k'}f_kf_{k'}\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_{lk}-\mathbf{r}_{l'k'})\} \times\overline{\exp\{2\pi i\mathbf{H}\cdot(\mathbf{u}_{lk}-\mathbf{u}_{l'k'})\}}. \quad (4.2.5.85)$$

In the harmonic approximation $\exp\{\overline{2\pi i\mathbf{H}\cdot\Delta\mathbf{u}}\}$ is replaced by $\exp\{\frac{1}{2}|2\pi\mathbf{H}\cdot\Delta\mathbf{u}|^2\}$. This is, however, a rather crude approximation because strongly anharmonic vibrations are quite common in an orientationally disordered crystal. In this approximation $\overline{F_lF_{l'}^{+}}$ becomes

$$\overline{F_lF_{l'}^{+}}=\sum_k\sum_{k'}f_kf_{k'}\exp\{-B_k(\omega_l)\} \times\exp\{-B_{k'}(\omega_{l'})\}\exp\{D_{lk;\,l'k'}\}. \quad (4.2.5.86)$$

B_k is equal to $\frac{1}{2}\overline{(2\pi\mathbf{H}\cdot\mathbf{u}_{lk})^2}$ (the Debye–Waller factor) and depends on the specific configuration ω_l. $D_{lk;\,l'k'}=\overline{(2\pi\mathbf{H}\cdot\mathbf{u}_{lk})(2\pi\mathbf{H}\cdot\mathbf{u}_{l'k'})}$ includes all the correlations between positions, orientations and vibrations of the molecules.

Averaging over different configurations demands a knowledge of the orientational probabilities. The probability of finding molecule l in orientation ω_l is given by $p(\omega_l)$. The double probability $p(\omega_l,\omega_{l'})$ gives the probability of finding two molecules l, l' in different orientations ω_l and $\omega_{l'}$, respectively. In the absence of correlations between the orientations we have $p(\omega_l,\omega_{l'})=p(\omega_l)p(\omega_{l'})$. If correlations exist, $p(\omega_l,\omega_{l'})=p(\omega_l)p'(\omega_l|\omega_{l'})$, where $p'(\omega_l|\omega_{l'})$ defines the conditional probability that molecule l' has the orientation ω_l *if* molecule l has the orientation $\omega_{l'}$. For long distances between l and l' $p'(\omega_l|\omega_{l'})$ tends to $p(\omega_{l'})$.

The difference $\Delta(\omega_l|\omega_{l'})=p'(\omega_l|\omega_{l'})-p(\omega_{l'})$ characterizes, therefore, the degree of short-range orientational correlation. Note that this formalism corresponds fully to the $p_\mu, p_{\mu\mu'}$ used in the context of translational disorder.

The average structure factor, sometimes called averaged form factor, of the molecule is given by

$$\langle F_l\rangle=\sum_{\omega_l}p(\omega_l)F_l(\omega_l). \quad (4.2.5.87)$$

(*a*) Negligible correlations between vibrations of different molecules (Einstein model):

$$D_{lk;\,l'k'}=0 \text{ for } l\neq l'.$$

From (4.2.5.86) it follows that (the prime symbol takes the Debye–Waller factor into account)

$$\overline{\langle I\rangle}=N^2|\langle F'\rangle|^2L(\mathbf{G}) + N\Big\{\sum_k\sum_{k'}\sum_{\omega_l}p(\omega_l)f_kf_{k'}\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_{lk}-\mathbf{r}_{lk'})\} \times\exp\{D_{lk;\,lk'}\}-|\langle F'\rangle|^2\Big\} + N\sum_{\Delta l\neq0}\sum_{\omega_l}\sum_{\omega_{l'}}p(\omega_l)\Delta(\omega_l|\omega_{l'}) \times F_l'(\omega_l)F_{l'}^{+}(\omega_{l'}) \times\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_l-\mathbf{r}_{l'})\}. \quad (4.2.5.88)$$

$L(\mathbf{G})$ is the reciprocal lattice of the well defined ordered lattice. The first term describes Bragg scattering from an averaged structure. The second term governs the diffuse scattering in the absence of short-range orientational correlations. The last term takes the correlation between the orientations into account.

If rigid molecules with centre-of-mass translational displacements and negligible librations are assumed, which is a first approximation only, $|\langle F\rangle|^2$ is no longer affected by a Debye–Waller factor.

In this approximation the diffuse scattering may therefore be separated into two parts:

$$N(\langle F^2\rangle-|\langle F'\rangle|^2)=N(F^2-|\langle F\rangle|^2)+N(|\langle F\rangle|^2-|\langle F'\rangle|^2) \quad (4.2.5.89)$$

with

$$\langle F^2\rangle=\sum_{\omega_l}\sum_{\omega_{l'}}\sum_k\sum_{k'}f_k(\omega_l)f_{k'}(\omega_{l'})p(\omega_l) \times\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_{lk}-\mathbf{r}_{l'k'})\}. \quad (4.2.5.90)$$

The first term in (4.2.5.89) gives the scattering from equilibrium fluctuations in the scattering from individual molecules (diffuse scattering without correlations), the second gives the contribution from the centre-of-mass thermal vibrations of the molecules.

(*b*) If intermolecular correlations between the molecules cannot be neglected, the final intensity expression for diffuse scattering is very complicated. In many cases these correlations are caused by dynamical processes (see Chapter 4.1). A simplified treatment assumes the molecule to be a rigid body with a centre-of-mass displacement $\mathbf{u}_l$ and neglects vibrational–librational and librational–librational correlations: $D_{l;\,l'}=\overline{(2\pi\mathbf{H}\cdot\mathbf{u}_l)(2\pi\mathbf{H}\cdot\mathbf{u}_{l'})}$ $(l\neq l')$. The following expression approximately holds:

$$\overline{\langle I\rangle}=N^2|\langle F'\rangle|^2L(\mathbf{G}) + \Big\langle\sum_l\sum_{l'}F_l'(\omega_l)F_{l'}^{'+}(\omega_{l'})\exp\{D_{l;\,l'}\}\Big\rangle\{2\pi i\mathbf{H}\cdot(\mathbf{r}_l-\mathbf{r}_{l'})\} + N\Big[\sum_{\omega_l}\sum_{k,\,k'}p(\omega_l)f_kf_{k'}\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_{lk}-\mathbf{r}_{l'k'})\} \times\exp\{D_{lk;\,l'k'}\}-\sum_{\omega_l}\sum_{\omega_{l'}}\sum_k\sum_{k'}p(\omega_l)p(\omega_{l'})f_kf_{k'} \times\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_{lk}-\mathbf{r}_{l'k'})\} \times\exp\{D_{lk;\,l'k'}\}\Big]+\sum_{l\neq l'}\sum_{\omega_l}\sum_{\omega_l}p(\omega_l)\Delta(\omega_l|\omega_{l'}) \times F_l'(\omega_l)F_{l'}^{'+}(\omega_{l'}) \times\exp\{2\pi i\mathbf{H}\cdot(\mathbf{r}_l-\mathbf{r}_{l'})\}\exp\{D_{l;\,l'}\}. \quad (4.2.5.91)$$

Again, the first term describes Bragg scattering and the second corresponds to the average thermal diffuse scattering in the disordered crystal. Because just one molecule belongs to one unit cell only acoustic waves contribute to this part. To an approximation, the result for an ordered crystal may be used by replacing F by $\langle F'\rangle$ [Chapter 4.1, equation (4.1.3.4)]. The third term corresponds to random-disorder diffuse scattering. If librations are neglected this term may be replaced by $N(\langle F^2\rangle-\langle F\rangle^2)$. The

last term in (4.2.5.91) describes space correlations. Omission of $\exp\{D_{l;\,l'}\}$ or expansion to $\sim(1 + D_{l;\,l'})$ are further simplifying approximations.

In either (4.2.5.88) or (4.2.5.91) the diffuse-scattering part depends on a knowledge of the conditional probability $\Delta(\omega_l|\omega_{l'})$ and the orientational probability $p(\omega_l)$. The latter may be found, at least in principle, from the average structure factor.

(2) *Rotational structure (form) factor*

In certain cases and with simplifying assumptions, $\langle F\rangle$ [equation (4.2.5.87)] and $\langle \Delta F^2\rangle$ [equation (4.2.5.90)] may be calculated. Assuming only one molecule per unit cell and treating the molecule as a rigid body, one derives from the structure factor of an ordered crystal F_l

$$\langle F\rangle = \sum_k f_k \langle \exp\{2\pi i \mathbf{H}\cdot\mathbf{r}_{lk}\}\rangle \tag{4.2.5.92}$$

and

$$\langle \Delta F^2\rangle = \sum_k \sum_{k'} f_k f_{k'} [\langle \exp\{2\pi i \mathbf{H}\cdot(\mathbf{r}_{lk} - \mathbf{r}_{l'k'})\}\rangle - \langle \exp\{2\pi i \mathbf{H}\cdot\mathbf{r}_{lk}\}\rangle\langle \exp\{2\pi i \mathbf{H}\cdot\mathbf{r}_{l'k'}\}\rangle]. \tag{4.2.5.93}$$

If the molecules have random orientation in space the following expressions hold [see, *e.g.*, Dolling *et al.* (1979)]:

$$\langle F\rangle = \sum_k f_k j_0(\mathbf{H}\cdot\mathbf{r}_k) \tag{4.2.5.94}$$

$$\langle |\Delta F|^2\rangle = \sum_k \sum_{k'} f_k f_{k'} \{ j_0[\mathbf{H}\cdot(\mathbf{r}_k - \mathbf{r}_{k'})] - j_0(\mathbf{H}\cdot\mathbf{r}_k) j_0(\mathbf{H}\cdot\mathbf{r}_{k'})\}. \tag{4.2.5.95}$$

$j_0(z)$ is the zeroth order of the spherical Bessel functions and describes an atom k uniformly distributed over a shell of radius r_k.

In practice the molecules perform finite librations about the main orientation. The structure factor may then be found by the method of symmetry-adapted functions [see, *e.g.*, Press (1973), Press & Hüller (1973), Dolling *et al.* (1979), Prandl (1981, and references therein)].

$$\langle F\rangle = \sum_k f_k 4\pi \sum_\nu \sum_{\mu=-\nu}^{+\nu} i^\nu j_\nu(\mathbf{H}\cdot\mathbf{r}_k) C_{\nu\mu}^{(k)} Y_{\nu\mu}(\theta,\varphi). \tag{4.2.5.96}$$

$j_\nu(z)$ is the νth order of spherical Bessel functions, the coefficients $C_{\nu\mu}^{(k)}$ characterize the angular distribution of $\mathbf{r}_k$ and $Y(\theta,\varphi)$ are the spherical harmonics where $|\mathbf{H}|, \theta, \varphi$ denote polar coordinates of $\mathbf{H}$.

The general case of an arbitrary crystal, site and molecular symmetry and the case of several symmetrically equivalent orientationally disordered molecules per unit cell are treated by Prandl (1981); an example is given by Hohlwein *et al.* (1986). As mentioned above, cubic plastic crystals are common and therefore mostly studied up to now. The expression for $\langle F\rangle$ may then be formulated as an expansion in cubic harmonics $K_{\nu\mu}(\theta,\varphi)$:

$$\langle F\rangle = \sum_k f_k 4\pi \sum_\nu \sum_\mu i^\nu j_\nu(\mathbf{H}\cdot\mathbf{r}_k) C_{\nu\mu}^{\prime(k)} K_{\nu\mu}(\theta,\varphi), \tag{4.2.5.97}$$

where $C'_{\nu\mu}$ are modified expansion coefficients.

Taking into account isotropic centre-of-mass translational displacements, which are not correlated with the librations, we obtain

$$\langle F'\rangle = \langle F\rangle \exp\{-\tfrac{1}{6}H^2\langle U^2\rangle\}. \tag{4.2.5.98}$$

U is the mean-square translational displacement of the molecule. Correlations between translational and vibrational displacements are treated by Press *et al.* (1979).

Equivalent expressions for crystals with symmetry other than cubic may be found from the same concept of symmetry-adapted functions [tables are given by Bradley & Cracknell (1972)].

(3) *Short-range correlations*

The final terms in equations (4.2.5.88) and (4.2.5.91) concern correlations between the orientations of different molecules. Detailed evaluations need knowledge of a particular model. Examples are compounds with nitrate groups (Wong *et al.*, 1984; Lefebvre *et al.*, 1984), CBr_4 (More *et al.*, 1980, 1984) and many others (see Sherwood, 1979). The situation is even more complicated when a modulation wave with respect to the occupation of different molecular orientations is superimposed. A limiting case would be a box-like function describing a pattern of domains. Within one domain all molecules have the same orientation. This situation is common in ferroelectrics where molecules exhibit a permanent dipole moment. The modulation may occur in one or more directions in space. The observed intensity in this type of orientationally disordered crystal is characterized by a system of more or less diffuse satellite reflections. The general scattering theory of a crystal with occupational modulation waves follows the same lines as outlined in Section 4.2.3.5.1.

4.2.6. Disorder diffuse scattering from aperiodic crystals

The preceding sections of this chapter have either been related to disorder phenomena in conventional crystals defined by the presence of 3D translational symmetry, *i.e.* by a 3D lattice function, at least in the averaged sense, or to solids with crystalline order in only lower (2 or 1) dimensions where the ordering principle along 'nonperiodic' directions shows a gradual transition from long- to short-range order, in particular to a liquid-like behaviour and, finally, to an (almost) random ordering behaviour of structural units. So-called aperiodic crystals do not fit this treatment because aperiodicity denotes a different type of order, which is nonperiodic in 3D space but where translational order may be restored in higher-dimensional ($n > 3$) direct space. Three types of solids are commonly included in the class of aperiodic structures: (i) incommensurately modulated structures (IMSs), where structural parameters of any kind (coordinates, occupancies, orientations of extended molecules or subunits in a structure, atomic displacement parameters) deviate periodically from the average ('basic') structure and where the modulation period is incommensurate compared to that of the basic structure; (ii) composite structures (CSs), which consist of two (or more) intergrown incommensurate substructures with mutual interactions giving rise to mutual (incommensurate) modulations; and (iii) quasicrystals (QCs), which might simply be viewed as made up by n (≥ 2) different tiles – analogous to the elementary cell in crystals – which are arranged according to specific matching rules and which are decorated by atoms or atomic clusters. Most common are icosahedral (i-type) quasicrystals with 3D aperiodic order (3D 'tiles') and decagonal quasicrystals (d-phases) with 2D aperiodicity and one unique axis along which the QC is periodically ordered. The basic 'crystallography' of aperiodic crystals is given in Chapter 4.6 of this volume; see also the review articles by Janssen & Janner (1987) and van Smaalen (2004) (and further references therein). We only point out some of the aspects here to provide the background for a short discussion about disorder diffuse scattering in aperiodic crystals.

As outlined in Section 4.6.1, a d-dimensional (dD) ideal aperiodic crystal can be defined as a dD irrational section of an nD ('hyper'-)crystal with nD crystal symmetry. Corresponding to the section of the nD hypercrystal with the dD ($d = 1, 2, 3$) direct physical (= 'external' or 'parallel') space we have a projection of the (weighted) nD reciprocal hyperlattice onto the dD reciprocal physical space. The occurrence of Bragg reflections as a signature

of an ordered (in at least an averaged sense) aperiodic crystal form a countable dense pattern of the projected reciprocal (hyper-)lattice vectors. Disorder phenomena, *i.e.* deviations from the periodicity in higher-dimensional direct (hyper-)space, are thus related to diffuse phenomena in reciprocal (hyper-)space projected down to the reciprocal physical space. Therefore only fluctuations from the aperiodic order infer diffuse scattering in its true sense, which might be hard to discern in a dense pattern of discrete (Bragg) reflections. As a consequence, in the higher-dimensional description of aperiodic crystals the atoms must be replaced by 'hyperatoms' or 'atomic surfaces', which are extended along $(n - d)$ dimensions. If, for example, an IMS exhibits a modulation in only one direction (1D IMS), we have $n = 2$ and a 1D atomic surface (which is a continuous modulation function extended along the 1D 'internal' or 'perpendicular' subspace). The physical subspace is spanned by 1 (and +2 'unaffected') dimensions. In a second example, a decagonal QC with aperiodic order in two dimensions is described by $n = 4$ (plus the remaining coordinate along the unaffected periodic direction) and $d = 2$, *i.e.* by 2D atomic surfaces. The atomic surfaces are, as shown in Chapter 4.6, continuous n-dimensional objects for IMSs and CSs, and discrete ones in the case of QCs. In addition to the 'hyperlattice' fluctuations within the physical (parallel) subspace we have therefore an additional quality of disorder phenomena related to positions and shape and size fluctuations of the atomic surfaces within the perpendicular subspace. Therefore, one has to consider disordering effects in aperiodic crystals related to fluctuations in the (external) physical subspace as well as in the internal subspace, but one should bear in mind that the two types are often coupled. Disordering due to displacements along directions within the physical subspace are – in the context of aperiodic crystals – commonly termed 'phonon-like', in contrast to 'phason-like' disorder related to displacements parallel to directions within the internal subspace. The term phason originates from a particular type of (dynamical) fluctuations of an IMS (see below).

4.2.6.1. Incommensurately modulated structures

Quite generally, small domains with periodic or aperiodic structures give rise to broadening of reflections. Diffuse satellite scattering is due to the limited coherence length of a modulation wave within a crystal or due to short-range order of twin or nanodomains (with an 'internal' modulated structure) embedded in a periodic matrix structure. This type of diffuse scattering can be treated by the rules outlined in Section 4.2.3.5. Structural fluctuations with limited correlation lengths are, for example, responsible for diffuse scattering in 1D organic conductors (Pouget, 2004). In some cases, modulated structures are intermediate phases within a limited temperature range between a high- and low-temperature phase (*e.g.* quartz) where the structural change is driven by a dynamical instability (a soft mode). In addition to (inelastic) soft-mode diffuse scattering, dynamic fluctuations of phase and amplitude of the modulation wave give rise to diffuse intensity. In particular, the phase fluctuations, *phasons*, give rise to low-frequency scattering which might be observable as an additional diffuse contribution around condensing reflections.

4.2.6.2. Composite structures

In the case of CSs, diffuse scattering relates to interactions between the component substructures which are responsible for mutual modulations: each substructure becomes modulated with the period of the other. If one of the substructures is low-dimensional, for example chain-like structural elements embedded in tubes of a host structure, one observes diffuse planes if direct interchain correlations are mostly absent. The diffuse planes are, however, not only due to the included subsystem, but also due to corresponding modulations of the matrix structure. On the other hand, maxima superimposed on the diffuse planes reflect the influence of the matrix structure on the chain system. The thickness of the diffuse planes depends on the degree of short- or long-range order along the unique direction (*cf.* Section 4.2.5.3). This might be either a consequence of faults in the surrounding matrix which interrupt the (longitudinal) coherence of the chains (Rosshirt *et al.*, 1991) or, intrinsically, due to the degree of misfit between the periods of the mutually incommensurate structures of the host and guest structures. If this misfit becomes large, *e.g.* as a consequence of different thermal expansion coefficients of the two substructures, the modulation is only preserved within small domains and one observes a series of diffuse satellite planes (Weber *et al.*, 2000). Equivalent considerations relate to composite systems made up from stacks of planar molecules (*e.g.* van Smaalen *et al.*, 1998) or an intergrowth of layer-like substructures where the modulation is mainly due to a one-dimensional stacking along the normal to the layers. Correspondingly, quite extended diffuse streaks occur at positions of the satellites in reciprocal space.

A further discussion of the more complicated disorder diffuse scattering of higher- (than one-) dimensionally modulated IMSs and CSs and the corresponding diffuse patterns in reciprocal space is beyond the scope of this chapter. We refer to Section 4.6.3 and the references cited therein. For examples, see also Petricek *et al.* (1991).

4.2.6.3. Quasicrystals

As in the case of conventional crystals, there is no unique theory of diffuse scattering by quasicrystals. Chemical disorder, phonon- and phason-like displacive disorder, topological glass-like disorder and domain disorder exist. The term domain covers those with an aperiodic structure as well as periodic approximant domains, which are also known as approximant phases (*cf.* Section 4.6.3). Approximant phases exhibit local atomic clusters which do not differ significantly from those of related aperiodic QCs. In d-phases, disorder diffuse scattering occurs which is related to the periodic direction. Reviews of disorder diffuse scattering from quasicrystals are given, *e.g.*, by Steurer & Frey (1998) and Estermann & Steurer (1998).

Chemical disorder. Many of the quasicrystals are ternary intermetallic phases consisting of atomic clusters where two components are transition metals (TMs) with only a small difference in Z (the number of electrons). Most of them exhibit a certain amount of substitutional (chemical) disorder, in particular with respect to the distribution of the TMs. This behaviour is equally true in the approximant phases. Chemical short-range order between the TMs, if any, is largely uninvestigated because conventional X-ray diffraction and electron-microscopy methods are not sensitive enough to provide significant contrast between the TMs. If the X-ray form-factor difference Δf is small, X-ray patterns do not show diffuse scattering, whereas an analogous neutron pattern could reveal a diffuse component due to the different scattering contrast Δb of the TMs (where the b's are the neutron scattering lengths). In practice, the chemical disorder phenomena might be more complex as the compositional stability of the QCs is often rather extended and the atomic distribution in a sample is not always structurally homogeneous. Depending on the crystal-growth process, microstructures may occur with locally coexisting small QC domains with fluctuating chemical content and, moreover, coexisting QC and approximant domains. Chemical disorder might also be caused by phasonic disorder.

Phonon-type (static or dynamic) displacements, fluctuations or straining relate to the physical subspace coordinates giving rise to continuous local distortions of the atomic structure. Phason-type disorder describes, as indicated above, discontinuous atomic jumps between different sites in an aperiodic structure. Qualitatively, dominant phonon- or phason-related scattering may be separated by analysing the dependence of the diffracted inten-

sities on the components of the scattering vector in the external and the internal subspace, H_e (Q_e) and H_i (Q_i), respectively (*cf.* above and also Section 4.6.3). There are different kinds of phason-like disorder, including random phason fluctuations, phason-type modulations and phason straining, and also shape and size fluctuations of the hyperatomic surfaces. If displacing an atomic surface (hyperatom) parallel to an internal space component by any kind of phason fluctuation which is equivalent to an infinitesimal rotation of the external (physical) space, it might happen that the hyperatom no longer intersects the physical space. Then an empty site is created, which is compensated by a (real) atom 'appearing' at a different position in physical space. In addition, there might even be a change of atomic species as a hyperatom may be chemically different at different sites of the atomic surface. Randomly distributed phason strains are responsible for Bragg-peak broadening and Huang-type diffuse scattering close to Bragg peaks. There are well developed theories based on the elastic theory of icosahedral (*e.g.* Jaric & Nelson, 1988) or decagonal (Lei *et al.*, 1999) quasicrystals that also include phonon–phason coupling. An example of the quantitative analysis of diffuse scattering by an i-phase (Al–Pd–Mn) is given by de Boissieu *et al.* (1995) and by a d-phase (Al–Ni–Fe) by Weidner *et al.* (2004). Dislocations in quasicrystals have partly phonon- and partly phason-like character; a discussion of the specific dislocation-related diffuse scattering will not be given here (*cf.* Section 4.6.3). Arcs and rings of localized diffuse scattering are observed in various i-phases and could be modelled in terms of some short-range 'glass-like' ordering of icosahedral clusters (Goldman *et al.*, 1988; Gibbons & Kelton, 1993). Phason-related diffuse scattering phenomena are discussed in more detail in Section 4.6.3. Depending on the exact stoichiometry and the growth conditions, d-phases very often show intergrown domain structures where the internal atomic structure of an individual domain varies between a (periodic) approximant structure, more or less strained aperiodic domains, or transient aperiodic variants (Frey & Weidner, 2002). Apart from finite size effects of domains of any kind which cause peak broadening, there are complex diffraction patterns of satellite reflections, diffuse maxima and diffuse streaking in d-Al–Ni–Co and other d-phases (Weidner *et al.*, 2001). In various d-phases one also observes, in addition to the Bragg layers, prominent diffuse layers perpendicular to the unique 'periodic' axis. They correspond to n-fold (n = 2, 4, 8) superperiods along this direction. In different d-phases there is a gradual change from almost completely diffuse planes to layers of superstructure reflections (satellites). The picture of a kind of stacking disorder of aperiodic layers does not match such observations. An explanation is rather due to 1D columns of atomic icosahedral clusters along the unique direction (Steurer & Frey, 1998). The temperature behaviour of these diffuse layers was studied by *in situ* neutron diffraction (Frey & Weidner, 2003), which shed some light on the complicated order/disorder phase transitions in d-Al–Ni–Co.

4.2.7. Computer simulations and modelling

4.2.7.1. Introduction

The various analytical expressions given in Section 4.2.5 are mostly rather complex, so their application is often restricted to relatively simple systems. Even in these cases analytical solutions are often not available. For larger displacements the approximations that use an expansion of the exponentials [*e.g.* equation (4.2.3.27)] are no longer valid. Hence there is a need for alternative approaches to tackling more complicated disorder models. In the past, optical transforms (*e.g.* Harburn *et al.*, 1974, 1975) and the videographic method (Rahman, 1993) were developed for this purpose. In the first method, a 2D mask with holes with sizes that represent the scattering power of the atoms is generated, which is then subjected to coherent light (from a laser) to produce a diffraction image. Problems arise for strong scatterers requiring very large holes. These problems were overcome in the second method, where the mask is replaced by a computer image with intensities proportional to the scattering power for each pixel. With the advent of more and more powerful computers these methods are now replaced by complete computer simulations, both to set up the disorder model and to calculate the diffraction pattern.

4.2.7.2. Simulation programs

Having established a disordered crystal with the types and positions of all atoms involved (a configuration), *e.g.* by using one of the methods described below, computer programs employing fast-Fourier-transform techniques can be used to calculate the diffraction pattern, which may be compared with the observation. It has to be borne in mind, however, that there is still a large gap between a real crystal with its ~10^{23} atoms and the one simulated by the computer with only several thousand atoms. This means that very long range correlations can not be included and have to be treated in an average manner. Furthermore, the limited size of the simulated crystal leads to termination effects, giving rise to considerable noise in the calculated diffraction pattern. Butler & Welberry (1992) have introduced a technique to avoid this problem in their program *DIFFUSE* by dividing the simulated crystal into smaller 'lots'. For each lot the intensity is calculated and then the intensities of all lots are summed up incoherently, which finally results in a smooth intensity distribution. Note, however, that in this case long-range correlations are restricted to even smaller values. To overcome this problem Boysen (1997) has proposed a method for suppressing the subsidiary maxima by multiplying the scattering density of the model crystal by a suitably designed weighting function simulating the effect of the instrumental resolution function.

A very versatile computer program, *DISCUS*, which allows not only the calculation of the scattering intensities but also allows the model structures to be built up in various ways, has been designed by Proffen & Neder (1999). It contains modules for reverse Monte Carlo (RMC, see below) simulation, the calculation of powder patterns, RMC-type refinement of pair-distribution functions (PDFs, see below) and many other useful tools for analysing disorder diffuse scattering.

Other computer programs have been developed to calculate diffuse scattering, some for specific tasks, such as *SERENA* (Micu & Smith, 1995), which uses a collection of atomic configurations calculated from a molecular dynamics simulation of molecular crystals.

4.2.7.3. Modelling procedures

Several well established methods can be used to create the simulated crystal on the computer. With such a crystal at hand, it is possible to calculate various thermodynamical properties and study the effect of specific parameters of the underlying model. By Fourier transformation, one obtains the diffraction pattern of the total scattering, *i.e.* the diffuse intensities and the Bragg peaks. The latter may lead to difficulties due to the termination effects mentioned in Section 4.2.7.2. These may be circumvented by excluding regions around the Bragg peaks (note, however, that in this case valuable information about the disorder may be lost), by subtracting the average structure or by using the approximation of Boysen (1997) mentioned above. A major advantage of such modelling procedures is that realistic physical models are introduced at the beginning, providing further insight into the pair interactions of the system, which can only be obtained *a posteriori* from the correlation parameters or fluctuation wave amplitudes derived from one of the methods described in Section 4.2.5.

4.2.7.3.1. Molecular dynamics

Molecular dynamics (MD) techniques have been developed to study the dynamics of a system. They may also be used to study static disorder problems (by taking time averages or snapshots), but they are particularly useful in the case of dynamic disorder, *e.g.* diffusing atoms in superionic conductors. The principle is to set up a certain configuration of atoms with assumed interatomic potentials $\Phi_{ij}(r_{ij})$ and subject them to Newton's equation of motion,

$$F_i(t) = m_i \frac{\mathrm{d}^2 r_i(t)}{\mathrm{d}t^2}, \qquad (4.2.7.1)$$

where the force $F_i(t)$ is calculated from the gradient of Φ. The equations are solved approximately by replacing the differential $\mathrm{d}t$ by a small but finite time step Δt to find new positions $r_i(t + \Delta t)$. This is repeated until an equilibrium configuration is found. MD techniques are quite useful if only short-range interactions are effective, even allowing the transfer of potential parameters between different systems, but are less reliable in the presence of significant long-range interactions.

4.2.7.3.2. Monte Carlo calculations

Monte Carlo (MC) methods appear to be more suited to the study of static disorder and many examples of their application can be found in the literature. Different variants allowing simulations and refinements have been applied:

(1) *Direct MC simulation*. In this method, introduced by Metropolis *et al.* (1953), a starting configuration is again set up in accordance with the known average structure and other crystal, chemical and physical information if available, and an appropriate interaction potential is chosen. The choice of this potential can be a quite delicate task. On the one hand, it should be as simple as possible to allow as large a simulation box size as can reasonably be handled by the computer's capacity. On the other hand, it must be detailed enough to include all the relevant interaction parameters of the system. Frequently used interaction potentials are a pseudo spin Ising Hamiltonian, where the 'spins' can either be binary (*e.g.* atom types or molecular orientations) or continuous (displacements), and harmonic springs for the displacements.

Having set up the starting configuration and defined the Hamiltonian, one proceeds by choosing a specific site at random and changing its parameters (occupancies and positions) by a random amount (a 'move'). The energy of this new configuration is calculated and compared with the old one. If the difference ΔE is negative, the move is accepted. If it is positive it is accepted with a probability

$$P = \exp\{-\Delta E/k_\mathrm{B}T\}/[1 + \exp\{-\Delta E/k_\mathrm{B}T\}], \qquad (4.2.7.2)$$

where T is a temperature and k_B is Boltzmann's constant. Then another site is chosen at random and the process is repeated again and again until an equilibrium configuration is found, *i.e.* until the energies fluctuate around some average value. After this, the corresponding intensity distribution is calculated and compared with the observed one. The parameters of the Hamiltonian may then be modified to improve the agreement between the calculated and observed diffraction patterns. This rather cumbersome trial-and-error method may be used to study the influence of the various parameters of the model. Further details of this method together with some illustrative examples may be found in Welberry & Butler (1994).

In an attempt to automate the adjustment of the model parameters, Welberry *et al.* (1998) have used a least-squares procedure to minimize

$$\chi^2 = \sum w(\Delta I)^2, \qquad (4.2.7.3)$$

where ΔI are the differences between the observed and calculated intensities and w are the appropriate weights. The problem with this approach is that the necessary differentials $\delta\Delta I/\delta p_i$ must be calculated numerically by performing full MC simulations with parameters p_i and $p_i + \delta p_i$ at each iteration step, which presents a formidable task even for the fastest modern computers.

(2) *Reverse MC calculations*. Application of the direct MC method may be very time consuming, as many MC simulations are necessary to arrive at a final configuration. To overcome this problem, the so-called reverse Monte Carlo (RMC) method has been developed, originally for liquids and glasses (McGreevy & Pusztai, 1988) and later for disordered single crystals (Nield *et al.*, 1995).

RMC is a model-free approach, *i.e.* without the need to define a proper interaction Hamiltonian. Otherwise it proceeds in a very similar way to direct MC analysis. A starting configuration is set up and random 'moves' of the atoms are carried out. The only difference is that acceptance or non-acceptance of a move is based on the agreement between observed and calculated diffraction intensities, *i.e.* equation (4.2.7.2) is replaced by

$$P = \exp\{-\Delta\chi^2/2\}, \qquad (4.2.7.4)$$

where χ^2 is defined in equation (4.2.7.3) and $\Delta\chi^2 = \chi^2_\mathrm{new} - \chi^2_\mathrm{old}$. Usually only a single MC run is necessary to arrive at a configuration with a diffraction pattern consistent with the observation. A drawback of the RMC technique is that usually only one configuration is found satisfying the observed diffraction pattern. In fact, it is possible that different configurations may produce the same or very similar intensity distributions (see *e.g.* Welberry & Butler, 1994). In this context, it has to be borne in mind that the diffuse scattering contains information about two-body correlations only, while the physical reason for a particular disordered structure may also be influenced by three- and many-body correlations. Such many-body correlations can easily be incorporated in the direct MC method. Moreover, RMC is susceptible to fitting artefacts (noise) in the diffraction pattern. To avoid unreasonable atomic configurations, restrictions such as a limiting nearest-neighbour approach can be built in. Weak constraints, *e.g.* ranges of interatomic distances or bond angles (*i.e.* three-body correlations) can be introduced by adding further terms in the definition of χ^2 [equation (4.2.7.3)]. In the same way, multiple data sets (*e.g.* neutron and X-ray data, EXAFS measurements *etc.*) may be incorporated. For more details and critical reviews of this method see *e.g.* McGreevy (2001) and Welberry & Proffen (1998). Many applications of this method can be found in the literature, mainly for powder diffraction, but also for single-crystal data.

(3) *Simulated annealing and evolutionary algorithms*. A general problem with MC methods is that they may easily converge to some local minima without having found the global one. One way to reduce such risks is to start with a high probability in (4.2.7.2) by using a large 'temperature' T, *i.e.* initially allowing many 'false' moves before gradually reducing T during the course of the simulation cycles. This is called 'simulated annealing', although it has nothing to do with real annealing. In the RMC method one may introduce a weighting parameter similar to T in (4.2.7.2).

Another effective way to find the global minimum and also to accelerate the optimization of the energy parameters of a given MC model is by using the principles of evolutionary theory: selection, recombination and mutation. Two such evolutionary (or genetic) algorithms have been proposed: the differential evolution (DE) algorithm (Weber & Bürgi, 2002) and the cooperative evolution (CE) algorithm (Weber, 2005). A single parameter of the model is called a gene and a set of genes is called a chromosome, p being the genotype of an individual. First a population consisting of several individuals is built up and the corresponding diffraction patterns are calculated and compared

with the observation. The fitness of each individual is quantified by χ^2. Children are then created by choosing one parent individual and calculating the second one from three randomly chosen individuals according to

$$p'_c = p_c + f_m(p_a - p_b), \qquad (4.2.7.5)$$

where f_m governs the mutations. The chromosome of the child is obtained by combining the genes of the two parents governed by a crossover (or recombination) constant f_r. If its fitness is higher than that of the parent, it replaces it. This procedure is repeated until some convergence criterion is reached. This DE method is still rather time-consuming on the computer. Therefore, the CE technique was introduced, where only one crystal is built up during the refinement. Here a large population is created spanning a large but reasonable parameter space. Individuals are selected at random to decide upon acceptance or rejection of an MC move *via* their own energy criteria. Then χ^2 is calculated and according to its positive or negative change a gratification or penalty weight is given to that individual. It may live as long as this weight is positive, otherwise it is replaced by a new individual calculated from (4.2.7.5). This way, useful individuals live longer to act on the same crystal, while unsuccessful ones are eliminated early. Note that the recombination operation is not used in this technique.

(4) *The PDF method*. The pair-distribution function (PDF) has long been used for the analysis of liquids, glasses and amorphous substances (Warren, 1969), but has recently regained considerable interest for the analysis of crystalline substances as well (Egami, 1990; Billinge & Egami, 1993; Egami, 2004). The PDF is obtained by a Fourier transformation of the total (Bragg plus diffuse) scattering in a powder pattern,

$$\rho_0 G(r) = \rho_0 + \tfrac{1}{2}\int H[S(H) - 1]\sin(2\pi H)\ \mathrm{d}H. \qquad (4.2.7.6)$$

This is nothing other than the van Hove correlation function (4.2.2.2) or the related Patterson function (4.2.2.5) averaged spherically and taken at $t = 0$ (a snapshot) and is given by

$$G^{\mathrm{PDF}}(r) = 4\pi r[\rho(r) - \rho_0] = \left(\sum c_i b_i\right)^{-2} 4\pi r \rho_0 G(r), \qquad (4.2.7.7)$$

where ρ_0 is the average number density and

$$\rho(r) = (1/N)\sum (b_i b_{i'}/\langle b\rangle^2)\delta(r - r_{ii'}). \qquad (4.2.7.8)$$

The δ functions are then convoluted with a normalized Gaussian to account for (harmonic) thermal motion. Parameter refinement proceeds in a similar way to the RMC technique. First a model is built, initially within just one unit cell and with periodic boundary conditions, then its PDF is calculated, compared with the observed one and further improved using, for example, MC simulated annealing. The model is then enlarged to include longer-range correlations. Owing to the small size of the models, this technique is much faster than the RMC method. It is essential, however, that data are measured up to very high H values to minimize truncation errors in (4.2.7.6).

4.2.7.3.3. General remarks

All of the different modelling techniques mentioned in this section have their specific merits and limitations and have contributed much to our understanding of disorder in crystalline materials following the interpretation of the corresponding diffuse scattering. It should be borne in mind, however, that application of these methods is still far from being routine work and it requires a lot of intuition to ensure that the final model is physically and chemically reasonable. In particular, it must always be ensured that the average structure remains consistent with that derived from the Bragg reflections alone. This may be done by keeping the Bragg reflections, *i.e.* by analysing the total scattering, or by designing special algorithms, *e.g.* by swapping two atoms at the same time (Proffen & Welberry, 1997). Moreover, possible traps and corrections like local minima, termination errors, instrumental resolution, statistical noise, inelasticity *etc*. must be carefully considered. All this means that the analytical methods outlined in Section 4.2.5 keep their value and should be preferred wherever possible.

The newly emerging technique of using full quantum-mechanical *ab initio* calculations for structure predictions along with MD simulations may also be applied to disordered systems. The limited currently available computer power, however, restricts this possibility to rather simple systems and small simulation box sizes, but, with the expected further increase of computer capacities, this may open up new perspectives for the future.

4.2.8. Experimental techniques and data evaluation

Single-crystal and powder diffractometry are used in diffuse scattering work. Conventional and more sophisticated special techniques and instruments are now available at synchrotron facilities and modern neutron reactor and spallation sources. The full merit of the dedicated machines may be assessed by inspecting the corresponding handbooks, which are available upon request from the facilities. In the following, some common important aspects that should be considered when planning and performing a diffuse-scattering experiment are summarized and a short overview of the techniques is given. Methodological aspects of diffuse scattering at low angles, *i.e.* small-angle-scattering techniques, and high-resolution single-crystal diffractometers are excluded. Instruments of the latter type are used when diffuse intensities beneath Bragg reflections or reflection profiles and tails must be analysed to study long-range distortion fields around single defects or small defect aggregates. In the case of small defect concentrations, the crystal structure remains almost perfect and the dynamical theory of diffraction is more appropriate. This topic is beyond the scope of this chapter.

4.2.8.1. Single-crystal techniques

In general, diffuse scattering is weak in comparison with Bragg scattering, and is anisotropically and inhomogeneously distributed in reciprocal space. The origin may be a static phenomenon or a dynamic process, giving rise to elastic or inelastic (quasi-elastic) diffuse scattering, respectively. If the disorder problem relates to more than one structural element, different parts of the diffuse scattering may show different behaviour in reciprocal space and/or on an energy scale. Therefore, before starting an experiment, some principal aspects should be considered: Is there need for X-ray and/or neutron methods? What is the optimum wavelength or energy (band), or does a 'white' technique offer advantages? Can focusing techniques be used without too strong a loss of resolution and what are the best scanning procedures? How can the background be minimized? Has the detector a low intrinsic noise and a high dynamic range?

On undertaking an investigation of a disorder problem by an analysis of the diffuse scattering, an overall picture should first be recorded by X-ray diffraction. Several sections through reciprocal space help to define the problem. For this purpose 'old-fashioned' film methods may be used, where the classical film is now commonly replaced by an imaging plate (IP) or a charge-coupled device (CCD) camera (see below). Clearly, short crystal-to-detector distances provide larger sections and avoid long exposure times, but suffer from spatial resolution. Distorted sections through the reciprocal lattice, such as produced by the Weissenberg method, may be transformed into a form suitable for easy interpretation (Welberry, 1983). The transformation of diffuse data measured using an IP or CCD requires suitable

software for the specific type of detector and is not always routinely available (Estermann & Steurer, 1998).

Standing-crystal techniques in combination with monochromatic radiation, usually called monochromatic Laue techniques (see, *e.g.*, Flack, 1970), save exposure time, which is particularly interesting for 'in-house' laboratory diffuse X-ray work. The Noromosic technique (Jagodzinski & Korekawa, 1973) is characterized by a convergent monochromatic beam which simulates an oscillation photograph over a small angular range. Heavily overexposed images, with respect to Bragg scattering, allow for sampling of diffuse intensity if a crystal is oriented in such a way that there is a well defined section between the Ewald sphere and the diffuse phenomenon under consideration. By combining single Noromosic photographs, Weissenberg patterns can be simulated. This relatively tedious method is often unavoidable because the heavily overexposed Bragg peaks obscure weak diffuse phenomena. Furthermore, standing pictures at distinct crystal settings in comparison with conventional continuous recording are frequently sufficient in diffuse scattering work and save time. Long-exposure Weissenberg photographs are therefore not equivalent to a smaller set of standing photographs. In this context it should be mentioned that a layer-line screen has not only the simple function of a selecting diaphragm, but the gap width determines the resolution volume within which diffuse intensity is collected (Welberry, 1983). For further discussion of questions of resolution see below. A comparison of Weissenberg and diffractometer methods for the measurement of diffuse scattering is given by Welberry & Glazer (1985). It should be pointed out, however, that diffractometer methods at synchrotron sources become more widely used if only very small (micrometre-sized) single-crystal specimens have to be used to study a disorder problem.

The basic arguments for using neutron-diffraction methods were given in Section 4.2.2.2: (i) the different interactions of X-rays and neutrons with matter; (ii) the lower absorption of neutrons, in particular when using longer (> 0.15 nm) wavelengths; and (iii) the matching of the energy of thermal neutrons with that of the phonons that contribute to the TDS background, and, in consequence, to separate it by a 'purely' elastic measurement. A comparative consideration of synchrotron- and neutron-related diffuse work on disordered alloys is given by Schweika (1998). Specific aspects of neutron diffraction and instruments are discussed at the end of this section.

Intensities: As mentioned above, diffuse intensities are usually weaker by several orders of magnitude than Bragg data. Therefore intense radiation sources are needed. Even a modern X-ray tube is a stronger source, defined by the flux density from the anode (number of photons $\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$), than modern neutron sources. For this reason most experimental work which can be performed with X-rays should be. In home laboratories the intense characteristic spectrum of an X-ray tube is commonly used. At synchrotron storage rings any wavelength from a certain range can be selected. The extremely high brilliance (number of quanta cm^{-2}, sr^{-1}, s^{-1} and wavelength interval) of modern synchrotron sources is, however, unnecessary in the case of slowly varying diffuse phenomena. In these cases, an experimental setup at a laboratory rotating anode is competitive and often even superior if specimens with sufficient size are available. Various aspects of diffuse X-ray work at a synchrotron facility are discussed by Matsubara & Georgopoulos (1985), Oshima & Harada (1986) and Ohshima *et al.* (1986). Diffuse neutron-diffraction work can only be performed on a high-flux reactor or on a powerful spallation source. Highly efficient monochromator systems are needed when using a crystal diffractometer. Time-of-flight (TOF) neutron diffractometers at pulsed (spallation) neutron sources are equivalent to conventional diffractometers at reactors (Windsor, 1982). The merits of diffuse neutron work at pulsed sources have been discussed by Nield & Keen (2001).

Wavelength: The choice of an optimum wavelength is important with respect to the problem to be solved. For example, point defects cause diffuse scattering to fall off with increasing scattering vector; short-range ordering between clusters causes broad peaks corresponding to large d spacings; lattice-relaxation processes induce a broadening of the interferences; static modulation waves with long periods give rise to satellite scattering close to Bragg peaks. In all these cases, a long wavelength is preferable due to the higher resolution. The use of a long wavelength is also profitable when the main diffuse contributions can be recorded within an Ewald sphere as small as the Bragg cutoff of the sample at $H \simeq 1/(2d_{\max})$. 'Contamination' by Bragg scattering can thus be avoided. This is also advantageous from a different point of view: because the contribution of thermal diffuse scattering increases with increasing scattering vector $\mathbf{H}$, the relative amount of this component becomes negligibly small within the first reciprocal cell. However, one has to take care with the absorption of long-wavelength neutrons.

On the other hand, short wavelengths are needed where atomic displacements play the dominant role. If diffuse peaks in large portions of the reciprocal space, or diffuse streaks or planes, have to be recorded up to high values of the scattering vector in order to decide between different structural disorder models, hard X-rays or hot neutrons are needed. For example, high-energy X-rays (65 keV) provided at a synchrotron source were used by Welberry *et al.* (2003) to study diffuse diffraction from ceramic materials and allowed studies with better d resolution.

The λ^3 dependence of the scattered intensity, in the framework of the kinematical theory, is a crucial point for exposure or data-acquisition times. Moreover, the accuracy with which an experiment can be carried out suffers from a short wavelength: generally, momentum as well as energy resolution are lower. For a quantitative estimate detailed considerations of resolution in reciprocal space (and energy) are needed.

A specific wavelength aspect concerns the method of (X-ray) anomalous dispersion, which may also be used in diffuse-scattering work. It allows the contrast and identification of certain elements in a disordered structure. Even small concentrations of impurity atoms or defects as low as 10^{-6} can be determined by this method if the impurity atoms are located at specific sites, *e.g.* in domain boundaries, or if certain other defect structures exist with characteristic diffuse scattering in reciprocal space. The (weak) diffuse scattering can then be contrasted by tuning the wavelength across an absorption edge of the particular atomic species. To avoid strong fluorescence background scattering such an experiment is usually performed at different wavelengths (energies) at the 'low absorption side' close to an edge. The merit of this method was demonstrated by Berthold & Jagodzinski (1990), who analysed diffuse streaks due to boundaries between lamellar domains in an albite feldspar. Similar element contrast can be achieved in neutron diffuse work if using specimens with different isotopes, *e.g.* H–D exchange.

Monochromacy: In classical crystal diffractometry, monochromatic radiation is used in order to eliminate broadening effects due to the wavelength distribution. Focusing monochromators and other focusing devices (guides, mirrors) help to overcome the lack of luminosity. A focusing technique is very helpful for deciding between geometrical broadening and 'true' diffuseness. In a method that is used with some success, the sample is placed in a monochromatic divergent beam with its selected axis lying in the scattering plane of the monochromator (Jagodzinski, 1968). The specimen is fully embedded in the incident beam, which is focused onto a 2D detector. Using this procedure the influence of the sample size is suppressed in one dimension. In white-beam (neutron) time-of-flight diffractometry the time resolution is the counterpart to the wavelength resolution. This is discussed in some detail in the textbook of Keen & Nield (2004).

Detectors: Valuable developments with a view to diffuse-scattering work are multidetectors (see, *e.g.*, Haubold, 1975) and position-sensitive detectors for X-rays (Arndt, 1986*a*,*b*) and neutrons (Convert & Forsyth, 1983). A classical '2D area detector' is the photographic film – nowadays of less importance – which has to be 'read out' by microdensitometer scanning. Important progress in recording diffuse X-ray data has been made by the availability of multiwire detectors, IPs and CCD cameras (Estermann & Steurer, 1998). For 2D position-sensitive (proportional) counters problems may arise from inhomogeneities of the wire array as well as the limited dynamic range when a Bragg reflection is accidentally recorded. IP systems have the major advantage of a larger dynamic range, 10^5–10^6, compared to 10^2–10^3 for an X-ray film. IPs can also be used in diffuse experiments carried out with hard (65 keV) X-rays (Welberry *et al.*, 2003). IPs are also available for neutron work, where the necessary transformation of the detected neutrons into light signals is provided by special neutron-absorbing converter foils (Niimura *et al.*, 2003). The problem of an intrinsic sensitivity to gamma radiation may be overcome by protection with a thin sheet of lead. IPs allow data collection either in plane geometry or in simple rotation or Weissenberg geometry, both in combination with low- and high-temperature devices. CCD detectors are well suited for X-ray diffuse scattering, and when used in combination with converter foils they can also be used for the detection of neutrons. A basic prerequisite is a low intrinsic noise, which can be achieved by cooling the CCD with liquid nitrogen. With these detectors, extended diffuse data sets can be collected by rotating the sample in distinct narrow steps around a spindle axis over several χ settings and subsequent oscillations over a small angular range. Thus large parts of the reciprocal space can be recorded. An example is given by Campbell *et al.* (2004), who studied subtle defect structures in the microporous framework material mordenite. Linear position-sensitive detectors are mainly used in powder work, but can also be used for recording diffuse scattering by single crystals. By combining a linear position-sensitive detector and the TOF method, a whole area in reciprocal space is accessible simultaneously (Niimura *et al.*, 1982; Niimura, 1986).

Diffuse data recorded with IPs or CCDs are commonly evaluated by commercial software supplied by the manufacturer. These software packages include corrections for extracted Bragg data, but no special software tools for treating extended (diffuse) data are commonly available. One particular problem relates to the background definition for diffuse IP data. Even after subtraction of electronic noise, there remains considerable uncertainty about the amount of true background scattering from the sample as recorded by an IP scanner. The definitions of errors and error maps remain doubtful as long as the true conversion rate between the captured neutron or photon *versus* the recorded optical signal is unknown.

Absorption: Special attention must be paid to absorption phenomena, in particular when (in the X-ray case) an absorption edge of an element of the sample is close to the wavelength. Then strong fluorescence scattering may completely obscure weak diffuse-scattering phenomena. In comparison with X-rays, the generally lower absorption coefficients of neutrons make absolute measurements easier. This also allows the use of larger sample volumes, which is not true in the X-ray case. Moreover, the question of sample environment is less serious in the neutron case than in the X-ray case. However, the availability of hard X-rays at a synchrotron source (Butler *et al.*, 2000; Welberry *et al.*, 2003) makes the X-ray absorption problem less serious: irregularly shaped specimens without special surface treatment could be used. There is also no need for complicated absorption corrections and the separation of fluorescence background is rather simple.

Extinction: An extinction problem does not generally exist in diffuse-scattering work.

Background: An essential prerequisite for a diffuse-scattering experiment is the careful suppression of background scattering. Incoherent X-ray scattering by a sample gives continuous blackening in the case of fluorescence, or scattering at high 2θ angles owing to Compton scattering or 'incoherent' inelastic effects. Protecting the image plate with a thin Al or Ni foil is of some help against fluorescence, but also attenuates the diffuse intensity. Obviously, energy-dispersive counter methods are highly efficient in this case (see below). Air scattering produces a background at low 2θ angles which may easily be avoided by special slit systems and evacuation of the camera.

In X-ray or neutron diffractometer measurements, incoherent and multiple scattering contribute to a background which varies only slowly with 2θ and can be subtracted by linear interpolation or fitting a smooth curve, or can even be calculated quantitatively and then subtracted. In neutron diffraction there are rare cases when monoisotopic and 'zero-nuclear-spin' samples are available and, consequently, the corresponding incoherent scattering part vanishes completely. In some cases, a separation of coherent and incoherent neutron scattering is possible by polarization analysis (Gerlach *et al.*, 1982). An 'empty' scan can take care of instrumental background contributions. Evacuation or controlled-atmosphere studies need a chamber, which may give rise to spurious scattering. This can be avoided if no part of the vacuum chamber is hit by the primary beam. The problem is less serious in neutron work. The mounting of the specimen, *e.g.*, on a silica fibre with cement, poorly aligned collimators and beam catchers are further sources. Sometimes a specimen has to be enclosed in a capillary, which will always be hit by the incident beam. Careful and tedious experimental work is necessary in the case of low- and high-temperature (or -pressure) investigations, which have to be carried out in many disorder problems. While the experimental situation is again less serious in neutron scattering, there are problems with scattering from walls and containers in X-ray work. Because TDS dominates at high temperatures and in the presence of a static disorder problem, a quantitative separation can rarely be carried out in the case of high experimental background. Calculation and subtraction of the TDS is possible in principle, but difficult in practice. If the disorder problem in which one is interested in does not change with temperature, a low-temperature experiment can be carried out. Another way to get rid off TDS, at least partly, is by using a neutron diffractometer with an additional analyser set to zero-energy transfer.

Resolution: A quantitative analysis of diffuse-scattering data is essential for reaching a definite decision about a disorder model, but – in many cases – it is cumbersome. By comparing the calculated and corrected experimental data the magnitudes of the parameters of the structural disorder model may be derived. A careful analysis of the data requires, therefore, after separation of the background (see above), corrections for polarization (in the X-ray case), absorption (in conventional X-ray work) and resolution. Detailed considerations of instrumental resolution are necessary; the resolution depends, in addition to other factors, on the scattering angle and implies intensity corrections analogous to the Lorentz factor used in structure analysis from sharp Bragg reflections.

Resolution is conveniently described by the function $R(\mathbf{H}-\mathbf{H}_0)$, which is defined as the probability of detecting a photon or neutron with momentum transfer $h\mathbf{H} = h(\mathbf{k}-\mathbf{k}_0)$ when the instrument is set to measure $\mathbf{H}_0$. This function R depends on the instrumental parameters (such as the collimations, the mosaic spread of monochromator and the scattering angle) and the spectral width of the source. Fig. 4.2.8.1 shows a schematic sketch of a diffractometer setting. Detailed considerations of resolution volume in X-ray and neutron diffractometry are given by Sparks & Borie (1966) and by Cooper & Nathans (1968*a*,*b*), respectively. If a triple-axis (neutron) instrument is used, for example in a purely elastic configuration, the set of instrumental parameters includes the mosaicity of the analyser

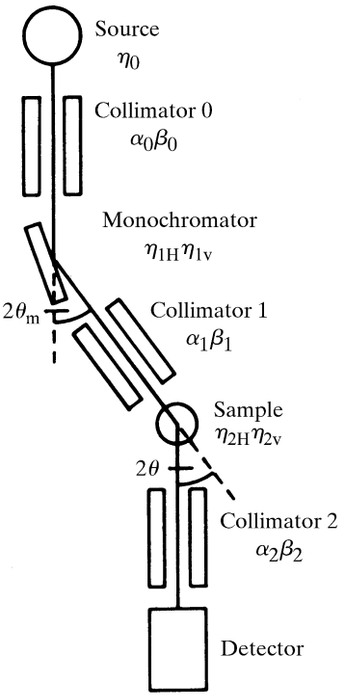

Fig. 4.2.8.1. Schematic sketch of a diffractometer setting.

and the collimations between the analyser and detector. In general, Gaussians are assumed to parameterize the mosaic distributions and transmission functions. Sophisticated resolution-correction programs are usually provided at any standard instrument for carrying out experiments at synchrotron and neutron facilities.

The general assumption of Gaussians is not too serious in the X-ray case (Iizumi, 1973). Restrictions are due to absorption, which makes the profiles asymmetric. Box-like functions are considered to be better for the spectral distribution or for large apertures (Boysen & Adlhart, 1987). These questions are treated in some detail by Klug & Alexander (1954). The main features, however, may also be derived by the Gaussian approximation. In practice, the function R may be obtained either by calculation from the known instrumental parameters or by measuring Bragg peaks from a perfect unstrained crystal. In the latter case, the intensity profile is given solely by the resolution function. Normalization with the Bragg intensities is also useful in order to place the diffuse-scattering intensity on an absolute scale.

In conventional single-crystal diffractometry the measured intensity is given by the convolution product of $\mathrm{d}\sigma/\mathrm{d}\Omega$ with R,

$$I(\mathbf{H}_0) = \int \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}(\mathbf{H})[R(\mathbf{H}-\mathbf{H}_0)]\,\mathrm{d}\mathbf{H}, \tag{4.2.8.1}$$

where $\mathrm{d}\sigma/\mathrm{d}\Omega$ describes the scattering cross section for the disorder problem. In a more accurate form the mosaicity of the sample has to be included:

$$\begin{aligned} I(\mathbf{H}_0) &= \int \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}(\mathbf{H}-\Delta\mathbf{K})[\eta(\Delta\mathbf{K})R(\mathbf{H}-\mathbf{H}_0)]\,\mathrm{d}\mathbf{H}\,\mathrm{d}(\Delta\mathbf{K}) \\ &= \int \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}(\mathbf{H}')[R'(\mathbf{H}'-\mathbf{H}_0)]\,\mathrm{d}\mathbf{H}'. \end{aligned} \tag{4.2.8.1a}$$

$R'(\mathbf{H}'-\mathbf{H}_0) = \int \eta(\Delta\mathbf{K})R(\mathbf{H}'+\Delta\mathbf{K}-\mathbf{H}_0)\,\mathrm{d}(\Delta\mathbf{K})$. The mosaic block distribution around a most probable vector $\mathbf{K}_0$ is described by $\eta(\Delta\mathbf{K})$: $\Delta\mathbf{K} = \mathbf{K}-\mathbf{K}_0$; $\mathbf{H}' = \mathbf{H}-\Delta\mathbf{K}$.

In (4.2.8.1) all factors independent of 2θ are neglected. All intensity expressions have to be calculated from equations (4.2.8.1) or (4.2.8.1a).

The intensity variation of diffuse peaks with 2θ measured with a single detector was studied in detail by Yessik *et al.* (1973). In principle, all special cases are included there. In practice, however, some important simplifications can be made if $\mathrm{d}\sigma/\mathrm{d}\Omega$ is either very broad or very sharp compared with R, *i.e.* for Bragg peaks, sharp streaks, 'thin' diffuse layers or extended 3D diffuse peaks (Boysen & Adlhart, 1987).

In the latter case, the cross section $\mathrm{d}\sigma/\mathrm{d}\Omega$ may be treated as nearly constant over the resolution volume so that the corresponding 'Lorentz' factor is independent of 2θ:

$$L_{3\mathrm{D}} = 1. \tag{4.2.8.2}$$

For a diffuse plane within the scattering plane with very small thickness and slowly varying cross section within the plane, one derives for a point measurement in the plane

$$L_{2\mathrm{D},\parallel} = (\beta_1'^2 + \beta_2^2 + 4\eta_{2\mathrm{v}}^2\sin^2\theta)^{-1/2}, \tag{4.2.8.3}$$

exhibiting an explicit dependence on θ (β_1', β_2 and $\eta_{2\mathrm{v}}$ determine an effective vertical divergence before the sample, the divergence before the detector and the vertical mosaic spread of the sample, respectively).

In the case of *relaxed* vertical collimations $\beta_1', \beta_2 \gg \eta_{2\mathrm{v}}$

$$L_{2\mathrm{D},\parallel} = (\beta_1'^2 + \beta_2^2)^{-1/2}, \tag{4.2.8.3a}$$

i.e. again independent of θ.

Scanning across the diffuse layer in a direction perpendicular to it one obtains an integrated intensity which is also independent of 2θ. This is even true if approximations other than Gaussians are used.

If, on the other hand, an equivalent diffuse plane is positioned perpendicular to the scattering plane, the equivalent expression for $L_{2\mathrm{D},\perp}$ of a point measurement is given by

$$\begin{aligned} L_{2\mathrm{D},\perp} \simeq [&4\eta_{2\mathrm{H}}^2\sin^2\theta\cos^2\psi + \alpha_2^2\sin^2(\psi-\theta) \\ &+ \alpha_1'^2\sin^2(\psi+\theta) + 4\eta_0'\sin^2\theta\sin^2\psi \\ &- 4\alpha_1''\sin\theta\sin\psi\sin(\theta+\psi)], \end{aligned} \tag{4.2.8.4}$$

where ψ gives the angle between the vector $\mathbf{H}_0$ and the line of intersection between the diffuse plane and the scattering plane. The coefficients $\eta_{2\mathrm{H}}$, α_2, α_1', α_1'' and η are either instrumental parameters or functions of them, defining horizontal collimations and mosaic spreads. In the case of a sharp X-ray line (produced, for example, by filtering) the last two terms in equation (4.2.8.4) vanish.

The use of integrated intensities from individual scans perpendicular to the diffuse plane, now carried out within the scattering plane, again gives a Lorentz factor independent of 2θ.

In the third fundamental special case, diffuse streaking along one reciprocal direction within the scattering plane (with a narrow cross section and slowly varying intensity along the streak), the Lorentz factor for a point measurement may be expressed by the product

$$L_{1\mathrm{D},\parallel} \simeq L_{2\mathrm{D},\parallel}L_{2\mathrm{D},\perp}, \tag{4.2.8.5}$$

where ψ now defines the angle between the streak and $\mathbf{H}_0$. The integrated intensity taken from an H scan perpendicular to the streak has to be corrected by a Lorentz factor which is equal to $L_{2\mathrm{D},\parallel}$ [equation (4.2.8.3)]. In the case of a diffuse streak perpendicular to the scattering plane, a relatively complicated equation holds for the corresponding Lorentz factor (Boysen & Adlhart, 1987). Again, simpler expressions hold for integrated intensities from H scans perpendicular to the streaks. Such scans may be performed in the radial direction (corresponding to a θ–2θ scan),

$$L_{1\mathrm{D},\perp,\mathrm{rad}} = (4\eta_{2\mathrm{H}}^2 + \alpha_2^2 + \alpha_1'^2)^{-1/2}(1/\sin\theta), \tag{4.2.8.6}$$

or perpendicular to the radial direction (within the scattering plane) (corresponding to an ω scan),

$$L_{1\mathrm{D},\perp,\mathrm{per}} = (\alpha_2^2 + \alpha_1^2 + 4\eta_0' \tan^2\theta - 4\alpha_1'' \tan\theta)^{-1/2}(1/\cos\theta). \quad (4.2.8.7)$$

Note that only the radial scan yields a simple θ dependence ($\sim 1/\sin\theta$).

From these considerations it is recommended that integrated intensities from scans perpendicular to a diffuse plane or a diffuse streak should be used in order to extract the disorder cross sections. For other scan directions, which make an angle α with the intersection line (diffuse plane) or with a streak, the L factors are simply $L_{2\mathrm{D},\perp}/\sin\alpha$ and $L_{1\mathrm{D},\perp}/\sin\alpha$, respectively.

One point should be emphasized: since in a usual experiment with a single counter the integration is performed over an angle $\Delta\omega$ *via* a general $\delta\omega{:}(g\delta 2\theta)$ scan, an additional correction factor arises:

$$\Delta\omega/\Delta\mathbf{H}_\beta = \sin(\beta+\theta)/(\mathbf{k}_0 \sin 2\theta). \quad (4.2.8.8)$$

β is the angle between $\mathbf{H}_0$ and the scan direction $\mathbf{H}_\beta$, and $g = (\tan\beta + \tan\theta)/(2\tan\theta)$ defines the coupling ratio between the rotation of the crystal around a vertical axis and the rotation of the detector shaft. The so-called 1:2 and ω-scan techniques are most frequently used, where $\beta = 0$ and 90°, respectively.

White-beam techniques: Techniques for the measurement of diffuse scattering using a *white* spectrum are common in neutron diffraction. Owing to the relatively low velocity of thermal or cold neutrons, TOF methods in combination with time-resolving detector systems placed at a fixed angle 2θ allow for a simultaneous recording along a radial direction through the origin of reciprocal space (see, *e.g.*, Turberfield, 1970; Bauer *et al.*, 1975). The scan range is limited by the Ewald spheres corresponding to $\lambda_{\max}$ and $\lambda_{\min}$, respectively. With several such detector systems placed at different angles or a 2D detector several scans may be carried out simultaneously during one neutron pulse.

An analogue of neutron TOF diffractometry in the X-ray case is a combination of a white source of X-rays and an energy-dispersive detector. This technique, which has been known in principle for a long time, suffered from relatively weak white sources. With the development of high-power X-ray generators and synchrotron sources this method has now become highly interesting. Its use in diffuse-scattering work (in particular, the effects on resolution) is discussed by Harada *et al.* (1984).

Some examples of neutron instruments dedicated to diffuse scattering are the diffractometers D7 at the Institut Laue–Langevin (ILL, Grenoble), DNS at the Forschungsneutronenquelle Heinz Maier-Leibnitz (FRM-II, Munich), G4-4 at the Laboratoire Léon Brillouin (LLB, Saclay) or SXD at ISIS, Rutherford Appleton Laboratory (RAL, UK). The instrument DNS uses a polarization analysis for diffuse scattering (Schweika & Böni, 2001; Schweika, 2003) and the SXD diffractometer is a TOF instrument using a (pulsed) white beam (Keen & Nield, 2004). All these instruments are equipped with banks of detectors. The single-crystal diffractometer D19 at the ILL, equipped with a multiwire area detector, is also suitable for collecting diffuse data. The flat-cone machine E2 at the Hahn–Meitner Institut (HMI, Berlin) is equipped with a bank of area detectors, has an option to record higher-order layers and can also be operated in an 'elastic' mode with a multicrystal analyser. The instrument D10 at the ILL is a versatile instrument which can be operated as a low-background two-axis or three-axis diffractometer with several further options. Neutron diffractometers that have recently become operational are BIX-3 at the Japan Atomic Energy Research Institute (JAERI, Japan), LADI at the ILL, where neutron-sensitive IPs are used for macromolecular work (for a comparison see Niimura *et al.*, 2003), and RESI at the Forschungsneutronenquelle Heinz Maier-Leibnitz (FRM-II, Munich) for common solid-state investigations. Information about all these instruments can be found in the respective handbooks or on the websites of the facilities.

4.2.8.2. Powders and polycrystals

The diffuse background in powder diagrams also contains valuable information about disorder. Only in very simple cases can a model be deduced from a powder pattern alone, but a refinement of a known disorder model can favourably be carried out, *e.g.* the temperature dependence may be studied. On account of the intensity integration, the ratio of diffuse intensity to Bragg intensity is enhanced in a powder pattern. Moreover, a powder pattern contains, in principle, all the information about the sample and might thus reveal more than single-crystal work. However, in powder-diffractometer experiments preferred orientations and textures could lead to a complete misidentification of the problem. Single-crystal experiments are generally preferable in this respect. Nevertheless, high-resolution powder investigations may give quick supporting information, *e.g.* about superlattice peaks, split reflections, lattice strains, domain-size effects, lattice-constant changes related to a disorder effect *etc*.

Evaluation of diffuse-scattering data from powder diffraction follows the same theoretical formulae developed for the determination of the radial distribution function for glasses and liquids. The final formula for random distributions may be given as (Fender, 1973)

$$I_D^p = \{\langle|F(\mathbf{H})|^2\rangle - |\langle F(\mathbf{H})\rangle|^2\} \sum_i s_i \sin(2\pi H r_i)/(2\pi H r_i). \quad (4.2.8.9)$$

s_i represents the number of atoms at distance r_i from the origin. An equivalent expression for a substitutional binary alloy is

$$I_D^p = \alpha(1-\alpha)\{|f_2(\mathbf{H}) - f_2(\mathbf{H})|^2\} \sum_i s_i \sin(2\pi H r_i)/(2\pi H r_i). \quad (4.2.8.10)$$

A quantitative calculation of a diffuse background is also helpful in combination with Rietveld's method (1969) for refining an averaged structure by fitting Bragg data. In particular, for highly anisotropic diffuse phenomena characteristic asymmetric line shapes occur.

The calculation of these line shapes is treated in the literature, mostly neglecting the instrumental resolution (see, *e.g.*, Warren, 1941; Wilson, 1949; Jones, 1949; and de Courville-Brenasin *et al.*, 1981). This is not justified if the variation of the diffuse intensity becomes comparable with that of the resolution function, as is often the case in neutron diffraction. The instrumental resolution may be incorporated using the resolution function of a powder instrument (Caglioti *et al.*, 1958). A detailed analysis of diffuse peaks is given by Yessik *et al.* (1973) and the equivalent considerations for diffuse planes and streaks are discussed by Boysen (1985). The case of 3D random disorder (incoherent neutron scattering, monotonous Laue scattering, averaged TDS, multiple scattering or short-range-order modulations) is treated by Sabine & Clarke (1977).

In polycrystalline samples the cross section has to be averaged over all orientations:

$$\frac{\mathrm{d}\sigma_\mathrm{p}}{\mathrm{d}\Omega}(\mathbf{H}') = \frac{n_\mathrm{c}}{H^2}\int \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}(\mathbf{H}') R'(|\mathbf{H}'| - |\mathbf{H}_0|)\,\mathrm{d}\mathbf{H}', \quad (4.2.8.11)$$

where n_c is number of crystallites in the sample; this averaged cross section enters the relevant expressions for the convolution product with the resolution function.

A general intensity expression may be written as (Boysen, 1985)

$$I_n(H_0) = P \sum_T m(T) A_n \Phi_n(H_0, T). \quad (4.2.8.12)$$

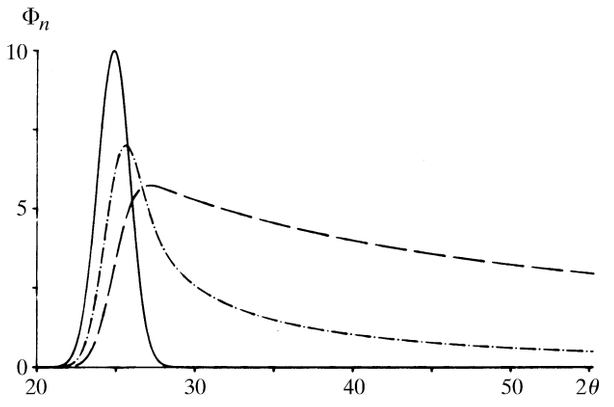

Fig. 4.2.8.2. Line profiles in powder diffraction for diffuse peaks (full line), continuous streaks (dot–dash lines) and continuous planes (broken lines). For explanation see text.

P denotes a scaling factor that depends on the instrumental luminosity, T is the shortest distance to the origin of the reciprocal lattice, $m(T)$ is the corresponding symmetry-induced multiplicity, A_n contains the structure factor of the structural units and the type of disorder, and Φ_n describes the characteristic modulation of the diffuse phenomenon of dimension n in the powder pattern. These expressions are given below with the assumption of Gaussian line shapes of width D for the narrow extension(s). The formulae depend on a factor $M = A_{1/2}(4k_1^2 - H_0^2)/(32\ln 2)$, where $A_{1/2}$ describes the dependence of the Bragg peaks on the instrumental parameters U, V and W (see Caglioti *et al.*, 1958),

$$A_{1/2}^2 = U\tan^2\theta + V\tan\theta + W, \qquad (4.2.8.13)$$

and $k_1 = 1/\lambda$.

(*a*) *Isotropic diffuse peak around T*

$$\Phi_0 = [2\pi(M^2 + D^2)]^{-1/2}(1/T^2) \times \exp\{-(H_0 - T)^2/2(M^2 + D^2)\}. \qquad (4.2.8.14)$$

The moduli $|\mathbf{H}_0|$ and T enter the exponential, *i.e.* the variation of $d\sigma/d\Omega$ along $|\mathbf{H}_0|$ is essential. For broad diffuse peaks ($M \ll D$) the angular dependence is due to $1/T^2$, *i.e.* proportional to $1/\sin^2\theta$. This result is valid for diffuse peaks of any shape.

(*b*) *Diffuse streak*

$$\Phi_1 = [2\pi(M^2 + D^2)]^{-1/2} \int_{-\infty}^{\infty} (T^2 + H^2)^{-1/2} \times \exp\{-H_0 - (T^2 + H^2)^{1/2}/2(M^2 + D^2)\}\,dH. \qquad (4.2.8.15)$$

The integral has to be evaluated numerically. If $(M^2 + D^2)$ is not too large, the term $1/(T^2 + H^2)$ varies only slowly compared to the exponential term and may be kept outside the integral, setting it approximately to $1/H_0^2$.

(*c*) *Diffuse plane (with $R^2 = H_x^2 + H_y^2$)*

$$\Phi_2 = (M^2 + D^2)^{-1/2} \int R^2/(T^2 + R^2) \times \exp\{-H_0 - (T^2 + R^2)^{1/2}/2(M^2 + D^2)\}\,dR. \qquad (4.2.8.16)$$

With the same approximation as in (*b*) the expression may be simplified to

$$\Phi_2 = \pi/H_0[1 - \mathrm{erf}\{(T - H_0)/[2(M^2 + D^2)]^{1/2}\} + 1/H_0^2[2\pi(M^2 + D^2)]^{1/2} \times \exp\{-(H_0 - T)^2/2(M^2 + D^2)\}]. \qquad (4.2.8.17)$$

(*d*) *Slowly varying diffuse scattering in three dimensions*

Φ_3 = constant. Consequently, the intensity is directly proportional to the cross section. The characteristic functions Φ_0, Φ_1 and Φ_2 are shown in Fig. 4.2.8.2 for equal values of T and D. Note the relative peak shifts and the high-angle tail.

4.2.8.3. Total diffraction pattern

As mentioned in Section 4.2.7.3.2, the atomic pair-distribution function (PDF), which is classically used for the analysis of the atomic distributions in liquids, melts or amorphous samples, can also be used to gain an understanding of disorder in crystals. The PDF is the Fourier transform of the total scattering. The measurement of total scattering is basically similar to recording X-ray or neutron powder patterns. The success of the method depends, however, decisively on various factors: (i) The availability of a large data set, *i.e.* reliable intensities up to high H values, in order to get rid of truncation ripples, which heavily influence the interpretation. Currently, values of $H_{\max}$ of more than 7 Å^{-1} can be achieved either with synchrotron X-rays [at the European Synchrotron Radiation Facility (ESRF) or Cornell High Energy Synchrotron Source (CHESS)] or with neutrons from reactors (*e.g.* instrument D4 at the ILL) and spallation sources [at ISIS or at LANSCE (instrument NPDF)]. (ii) High H resolution. (iii) High intensities, in particular at high H values. (iv) Low background of any kind which does not originate from the sample. High-quality intensities are therefore to be extracted from the raw data by taking care of an adequate absorption correction, correction of multiple-scattering effects, separation of inelastically scattered radiation (*e.g.* Compton scattering) and careful subtraction of 'diffuse' background which is not the 'true' diffuse scattering from the sample. These conditions are in practice rather demanding. A further detailed discussion is beyond the scope of this chapter, but a more thorough discussion is given, *e.g.*, by Egami (2004), and some examples are given by Egami & Billinge (2003).

4.3. Diffuse scattering in electron diffraction

By J. M. Cowley† and J. K. Gjønnes

4.3.1. Introduction

The origins of diffuse scattering in electron-diffraction patterns are the same as in the X-ray case: inelastic scattering due to electronic excitations, thermal diffuse scattering (TDS) from atomic motions, scattering from crystal defects or disorder. For diffraction by crystals, the diffuse scattering can formally be described in terms of a nonperiodic deviation $\Delta\varphi$ from the periodic, average crystal potential, $\bar{\varphi}$:

$$\varphi(\mathbf{r}, t) = \bar{\varphi}(\mathbf{r}) + \Delta\varphi(\mathbf{r}, t), \qquad (4.3.1.1)$$

where $\Delta\varphi$ may have a static component from disorder in addition to time-dependent fluctuations of the electron distribution or atomic positions.

In the kinematical case, the diffuse scattering can be treated separately. The intensity I_d as a function of the scattering variable $\mathbf{u}$ ($|\mathbf{u}| = 2\sin\theta/\lambda$) and energy transfer $h\nu$ is then given by the Fourier transform $\mathscr{F}$ of $\Delta\varphi$

$$I(\mathbf{u}, \nu) = |\Delta\Phi(\mathbf{u}\nu)|^2 = |\mathscr{F}\{\Delta\varphi(\mathbf{r}, t)\}|^2 = \mathscr{F}\{P_d(\mathbf{r}, \nu)\} \qquad (4.3.1.2)$$

and may also be written as the Fourier transform of a correlation function P_d representing fluctuations in space and time (see Cowley, 1981). When the energy transfers are small – as with TDS – and hence not measured, the observed intensity corresponds to an integral over ν:

$$I(\mathbf{u}) = I_d(\mathbf{u}) + I_{av}(\mathbf{u})$$
$$I_d(\mathbf{u}) = \int I_d(\mathbf{u}, \nu)\,d\nu = \mathscr{F}\{P_d(\mathbf{r}, \mathbf{0})\}$$

and also

$$I_d(\mathbf{u}) = \langle|\Phi(\mathbf{u})|^2\rangle - |\langle\Phi(\mathbf{u})\rangle|^2, \qquad (4.3.1.3)$$

where the brackets may indicate a time average, an expectation value, or a spatial average over the periodicity of the lattice in the case of static deviations from a periodic structure.

The considerations of TDS and static defects and disorder of Chapters 4.1 and 4.2 thus may be applied directly to electron diffraction in the kinematical approximation when the differences in experimental conditions and diffraction geometry are taken into account.

The most prominent contribution to the diffuse background in electron diffraction, however, is the inelastic scattering at low angles arising mainly from the excitation of outer electrons. This is quite different from the X-ray case where the inelastic ('incoherent') scattering, $S(\mathbf{u})$, goes to zero at small angles and increases to a value proportional to Z for high values of $|\mathbf{u}|$. The difference is due to the Coulomb nature of electron scattering, which leads to the kinematical intensity expression S/u^4, emphasizing the small-angle region. At high angles, the inelastic scattering from an atom is then proportional to Z/u^4, which is considerably less than the corresponding elastic scattering $(Z - f)^2/u^4$ which approaches Z^2/u^4 (Section 2.5.2) (see Fig. 4.3.1.1).

† Deceased.

The kinematical description can be used for electron scattering only when the crystal is very thin (10 nm or less) and composed of light atoms. For heavy atoms such as Au or Pb, crystals of thickness 1 nm or more in principal orientations show strong deviations from kinematical behaviour. With increasing thickness, dynamical scattering effects first modify the sharp Bragg reflections and then have increasingly significant effects on the diffuse scattering. Bragg scattering of the diffuse scattering produces Kikuchi lines and other effects. Multiple diffuse scattering broadens the distribution and smears out detail. As the thickness increases further, the diffuse scattering increases and the Bragg beams are reduced in intensity until there is only a diffuse 'channelling pattern' where the features depend in only a very indirect way on the incident-beam direction or on the sources of the diffuse scattering (Uyeda & Nonoyama, 1968).

The multiple-scattering effects make the quantitative interpretation of diffuse scattering more difficult and complicate the extraction of particular components, *e.g.* disorder scattering. Much of the multiple scattering involves inelastic scattering processes. However, electrons that have lost energy of the order of 1 eV or more can be subtracted experimentally by use of electron energy filters (Krahl *et al.*, 1990; Krivanek *et al.*, 1992) which are commercially available. Measurement can be made also of the complete scattering function $I(\mathbf{u}, \nu)$, but such studies have been rare. Another significant improvement to quantitative measurement of diffuse electron scattering is offered by new recording devices: slow-scan charge-couple-device cameras (Krivanek & Mooney, 1993) and imaging plates (Mori *et al.*, 1990).

There are some advantages in the use of electrons which make it uniquely valuable for particular applications.

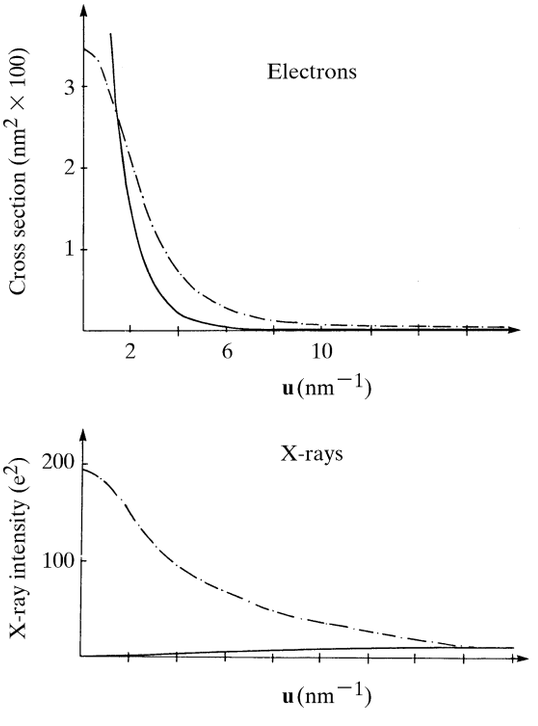

Fig. 4.3.1.1. Comparison between the kinematical inelastic scattering (full line) and elastic scattering (broken) for electrons and X-rays. Values for silicon [Freeman (1960) and *IT* C (2004)].

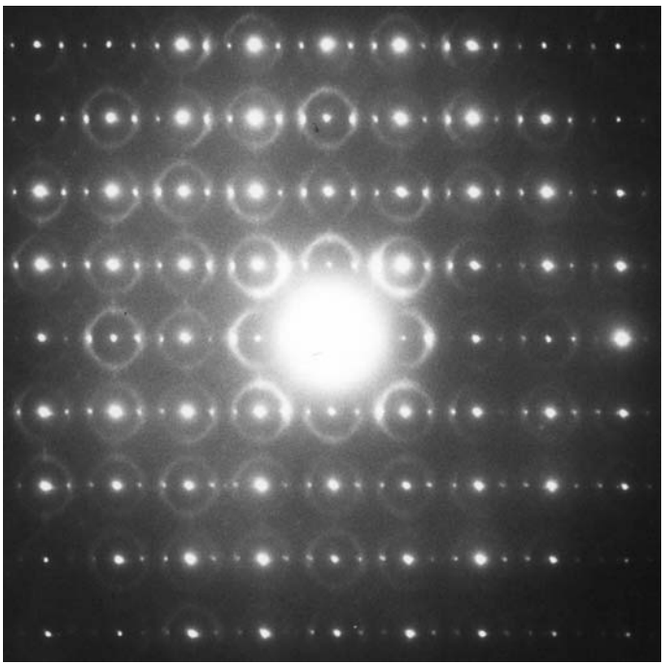

Fig. 4.3.1.2. Electron-diffraction pattern from a disordered crystal of $17Nb_2O_5{\cdot}48WO_3$ close to the [001] orientation of the tetragonal tungsten-bronze-type structure (Iijima & Cowley, 1977).

(1) Diffuse-scattering distributions can be recorded from very small specimen regions, a few nm in diameter and a few nm thick. The diameter of the specimen area may be varied readily up to several μm.

(2) Diffraction information on defects or disorder may be correlated with high-resolution electron-microscope imaging of the same specimen area [see Section 4.3.8 in *IT* C (2004)].

(3) The electron-diffraction pattern approximates to a planar section of reciprocal space, so that complicated configurations of diffuse scattering may be readily visualized (see Fig. 4.3.1.2).

(4) Dynamical effects may be exploited to obtain information about localization of sources of the diffuse scattering within the unit cell.

These experimental and theoretical aspects of electron diffraction have influenced the ways in which it has been applied in studies of diffuse scattering.

In general, we may distinguish three different approaches to the interpretation of diffuse scattering:

(*a*) The crystallographic way, in which the Patterson- or correlation-function representation of the local order is emphasized, *e.g.* by use of short-range-order parameters.

(*b*) The physical model in terms of excitations. These are usually described in reciprocal (momentum) space: phonons, plasmons *etc.*

(*c*) Structure models in direct space. These must be derived by trial or by chemical considerations of bonds, coordinates *etc.*

Owing to the difficulties of separating the different components in the diffuse scattering, most work on diffuse scattering of electrons has followed one or both of the two last approaches, although Patterson-type interpretation, based upon kinematical scattering including some dynamical corrections, has also been tried.

4.3.2. Inelastic scattering

In the kinematical approximation, a general expression which includes inelastic scattering can be written in the form quoted by Van Hove (1954)

$$I(\mathbf{u}, \nu) = \frac{m^3}{2^2h^6}\frac{k}{k_o} \times W(\mathbf{u}) \sum P_{n_o} \sum_{\eta} \sum_{j=1}^{Z} |\langle n_o| \exp\{2\pi i \mathbf{u}\cdot\mathbf{R}_j\}|n\rangle|^2 \times \delta\left(\nu + \frac{E_n - E_{n_o}}{h}\right) \quad (4.3.2.1)$$

for the intensity of scattering as function of energy transfer and momentum transfer from a system of Z identical particles, $\mathbf{R}_j$. Here m and h have their usual meanings; k_o and k, E_{n_o} and E_n are wavevectors and energies before and after the scattering between object states n_o and n; P_{n_o} are weights of the initial states; $W(\mathbf{u})$ is a form factor (squared) for the individual particle.

In equation (4.3.2.1), $\mathbf{u}$ is essentially momentum transfer. When the energy transfer is small ($\Delta E/E \ll \theta$), we can still write $|\mathbf{u}| = 2\sin\theta/\lambda$, then the sum over final states n is readily performed and an expression of the Waller–Hartree type is obtained for the total inelastic scattering as a function of angle:

$$I_{\text{inel}}(\mathbf{u}) \propto \frac{S}{u^4},$$

where

$$S(u) = Z - \sum_{j=1}^{Z} |f_{jj}(u)|^2 - \sum_{j\neq k}^{Z}\sum^{Z} |f_{jk}(u)|^2, \quad (4.3.2.2)$$

and where the one-electron f's for Hartree–Fock orbitals, $f_{jk}(\mathbf{u}) = \langle j|\exp(2\pi i\mathbf{u}\cdot\mathbf{r})|k\rangle$, have been calculated by Freeman (1959, 1960) for atoms up to $Z = 30$. The last sum is over electrons with the same spin only.

The Waller–Hartree formula may be a very good approximation for Compton scattering of X-rays, where most of the scattering occurs at high angles and multiple scattering is no problem. With electrons, it has several deficiencies. It does not take into account the electronic structure of the solid, which is most important at low values of u. It does not include the energy distribution of the scattering. It does not give a finite cross section at zero angle, if u is interpreted as an angle. In order to remedy this, we should go back to equation (4.3.1.2) and decompose $\mathbf{u}$ into two components, one tangential part which is associated with angle in the usual way and one normal component along the beam direction, u_n, which may be related to the excitation energy $\Delta E = E_n - E_{n_o}$ by the expression $u_n = \Delta E_k/2E$. This will introduce a factor $1/(u^2 + u_n^2)$ in the intensity at small angles, often written as $1/(\theta^2 + \theta_E^2)$, with ΔE estimated from ionization energies *etc.* (Strictly speaking, ΔE is not a constant, not even for scattering from one shell. It is a weighted average which will vary with u.)

Calculations beyond this simple adjustment of the Waller–Hartree-type expression are few. Plasmon scattering has been treated on the basis of a nearly free electron model by Ferrel (1957):

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}(\Delta E)\,\mathrm{d}\Omega} = (1/\pi^2 a_H m v^2 N)(-\mathrm{Im}\{1/\varepsilon\})/(\theta^2 + \theta_E^2), \quad (4.3.2.3)$$

where m, v are relativistic mass and velocity of the incident electron, N is the density of the valence electrons and $\varepsilon(\Delta E, \theta)$ their dielectric constant. Upon integration over ΔE:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{E_p}{2\pi a_H m v N}[1/(\theta^2 + \theta_E^2)G(\theta, \theta_c)], \qquad (4.3.2.4)$$

where $G(\theta, \theta_c)$ takes account of the cut-off angle Θ_c. Inner-shell excitations have been studied because of their importance to spectroscopy. The most realistic calculations may be those of Leapman *et al.* (1980) where one-electron wavefunctions are determined for the excited states in order to obtain 'generalized oscillator strengths' which may then be used to modify equation (4.3.1.2).

At high energies and high momentum transfer, the scattering will approach that of free electrons, *i.e.* a maximum at the so-called Bethe ridge, $E = h^2u^2/2m$.

A complete and detailed picture of inelastic scattering of electrons as a function of energy and angle (or scattering variable) is lacking, and may possibly be the least known area of diffraction by solids. It is further complicated by the dynamical scattering, which involves the incident and diffracted electrons and also the ejected atomic electron (see *e.g.* Maslen & Rossouw, 1984*a*,*b*).

4.3.3. Kinematical and pseudo-kinematical scattering

Kinematical expressions for TDS or defect and disorder scattering according to equation (4.3.1.3) can be obtained by inserting the appropriate atomic scattering factors in place of the X-ray scattering factors in Chapter 4.1. The complications introduced by dynamical diffraction are considerable (see Section 4.3.4). In the most general case, a complete specification of the disordered structure may be needed. However, for thin specimens, approximate treatments of the deviations from kinematical scattering may lead to relatively simple forms. Two such cases are treated in this section, both relying on the small-angle nature of electron scattering. The first is based upon the phase-object approximation, which applies to small angles and thin specimens.

The amplitude at the exit surface of a specimen can always be written as a sum of a periodic and a nonperiodic part, and may in analogy with the kinematical case [equation (4.3.1.1)] be written

$$\psi(\mathbf{r}) = \bar{\psi}(\mathbf{r}) + \Delta\psi(\mathbf{r}), \qquad (4.3.3.1)$$

where $\mathbf{r}$ is a vector in two dimensions. The intensities can be separated in the same way [*cf.* equation (4.3.1.3)].

When the phase-object approximation applies [Section 2.5.2.4(*b*)]

$$\begin{aligned}\psi(\mathbf{r}) &= \exp\{-i\sigma\varphi(\mathbf{r})\} \\ &= \exp\{-i\sigma\bar{\varphi}(\mathbf{r})\}[1 - i\sigma\Delta\varphi(\mathbf{r}) - \ldots]. \qquad (4.3.3.2)\end{aligned}$$

Then the Bragg reflections are given by Fourier transform of the periodic part, *viz*:

$$\langle\exp\{-i\sigma\varphi(\mathbf{r})\}\rangle = \exp\{-i\sigma\bar{\varphi}(\mathbf{r})\}\exp\left\{-\tfrac{1}{2}\sigma^2\langle\Delta\varphi^2(\mathbf{r})\rangle\right\}; \qquad (4.3.3.3)$$

note that an absorption function is introduced.

The diffuse scattering derives from

$$-i\sigma\Delta\varphi(\mathbf{r})\exp\{-i\sigma\bar{\varphi}(\mathbf{r})\}, \qquad (4.3.3.4)$$

so that

$$I_d(\mathbf{u}) = \sigma^2|\Delta\Phi(\mathbf{u}) * \Phi_{av}(\mathbf{u})|^2. \qquad (4.3.3.5)$$

Thus, the kinematical diffuse-scattering amplitude is convoluted with the amplitude function for the average structure, *i.e.* the set of sharp Bragg beams. When the direct beam, $\Phi_{av}(0)$, is relatively strong, the kinematical diffuse scattering will be modified to only a limited extent by convolution with the Bragg reflections. To the extent that the diffuse scattering is periodic in reciprocal space, the effect will be to modify the intensity by a slowly varying function. Thus the shapes of local diffuse maxima will not be greatly affected.

The electron-microscope image contrast derived from the diffuse scattering will be obtained by inserting equation (4.3.3.4) in the appropriate intensity expressions of Section 4.3.8 of *IT* C (2004).

Another approach may be used for extended crystal defects in thin films, *e.g.* faults normal or near-normal to the film surface. Often, an average periodic structure may not readily be defined, as in the case of a set of incommensurate stacking faults. Kinematically, the projection of the structure in the simplest case may be described by convoluting the projection of a unit-cell structure with a nonperiodic set of delta functions which constitute a distribution function:

$$\varphi(\mathbf{r}) = \varphi_0(\mathbf{r}) * \sum_n \delta(\mathbf{r} - \mathbf{r}_n) = \varphi_0(\mathbf{r}) * \mathrm{d}(\mathbf{r}). \qquad (4.3.3.6)$$

Then the diffraction-pattern intensity is

$$I(\mathbf{u}) = |\Phi_0(\mathbf{u})|^2|D(\mathbf{u})|^2. \qquad (4.3.3.7)$$

Here, $\Phi_0(\mathbf{u})$ is the scattering amplitude of the unit whereas the function $|D(\mathbf{u})|^2$, where $D(\mathbf{u}) = \mathscr{F}\{d(\mathbf{r})\}$, gives the configuration of spots, streaks or other diffraction maxima corresponding to the faulted structure (see *e.g.* Marks, 1985).

In the projection (column) approximation to dynamical scattering, the wavefunction at the exit surface may be given by an expression identical to (4.3.3.6), but with a wavefunction, $\psi_0(\mathbf{r})$, for the unit in place of the projected potential, $\varphi_0(\mathbf{r})$.

An intensity expression of the same form as (4.3.3.7) then applies, with a dynamical scattering amplitude Ψ_0 for the scattering unit substituted for the kinematical amplitude Φ_0.

$$I(\mathbf{u}) = |\Psi_0(\mathbf{u})|^2|D(\mathbf{u})|^2, \qquad (4.3.3.8)$$

which in the simplest case describes a diffraction pattern with the same features as in the kinematical case. Note that $\Psi_0(\mathbf{u})$ may have different symmetries when the incident beam is tilted away from a zone axis, leading to diffuse streaks *etc.* appearing also in positions where the kinematical diffuse scattering is zero. More complicated cases have been considered by Cowley (1976*a*) who applied this type of analysis to the case of nonperiodic faulting in magnesium fluorogermanate (Cowley, 1976*b*).

4.3.4. Dynamical scattering: Bragg scattering effects

The distribution of diffuse scattering is modified by higher-order terms in essentially two ways: Bragg scattering of the incident and diffuse beams or multiple diffuse scattering, or by a combination.

Theoretical treatment of the Bragg scattering effects in diffuse scattering has been given by many authors, starting with Kainuma's (1955) work on Kikuchi-line contrast (Howie, 1963; Fujimoto & Kainuma, 1963; Gjønnes, 1966; Rez *et al.*, 1977; Maslen & Rossouw, 1984*a*,*b*; Wang, 1995; Allen *et al.*, 1997). Mathematical formalism may vary but the physical pictures and

results are essentially the same. They may be discussed with reference to a Born-series expansion, *i.e.* by introducing the potential φ in the integral equation, as a sum of a periodic and a nonperiodic part [*cf.* equation (4.3.1.1)] and arranging the terms by orders of $\Delta\varphi$.

$$\begin{aligned}\psi &= \psi_0 + G\varphi\psi \\ &= [1 + G\varphi + (G\varphi)^2 + \ldots]\psi_0 \\ &= [1 + G\bar{\varphi} + (G\bar{\varphi})^2 + \ldots]\psi_0 \\ &\quad + [1 + G\bar{\varphi} + (G\bar{\varphi})^2 + \ldots] \\ &\quad \times G(\Delta\varphi)[1 + G\bar{\varphi} + (G\bar{\varphi})^2 + \ldots]\psi_0 \\ &\quad + \text{higher-order terms.} \qquad (4.3.4.1)\end{aligned}$$

Some of the higher-order terms contributing to the Bragg scattering can be included by adding the essentially imaginary term $\langle\Delta\varphi G(\Delta\varphi)\rangle$ to the static potential $\bar{\varphi}$.

Theoretical treatments have mostly been limited to the first-order diffuse scattering. With the usual approximation to forward scattering, the expression for the amplitude of diffuse scattering in a direction $\mathbf{k}_0 + \mathbf{u} + \mathbf{g}$ can be written as

$$\begin{aligned}\psi(\mathbf{u}+\mathbf{g}) = \sum_g \sum_f \int_0^z & S_{hg}(\mathbf{k}_0 + \mathbf{u}, z - z_1) \\ & \times \Delta\Phi(\mathbf{u} + \mathbf{g} - \mathbf{f}) S_{f0}(\mathbf{k}_0, z_1)\, \mathrm{d}z_1 \qquad (4.3.4.2)\end{aligned}$$

and read (from right to left): S_{f0}, Bragg scattering of the incident beam above the level z_1; $\Delta\Phi$, diffuse scattering within a thin layer $\mathrm{d}z_1$ through the Fourier components $\Delta\Phi$ of the nonperiodic potential $\Delta\Phi$; S_{hg}, Bragg scattering between diffuse beams in the lower part of the crystal. It is commonly assumed that diffuse scattering at different levels can be treated as independent (Gjønnes, 1966), then the intensity expression becomes

$$\begin{aligned}I(\mathbf{u}+\mathbf{g}) = \sum_h \sum_{h'} \sum_f \sum_{f'} \int_0^z & S_{gh}(2) S^*_{gh'}(2) \\ & \times \langle \Delta\Phi(\mathbf{u} + \mathbf{h} - \mathbf{f}) \Delta\Phi^*(\mathbf{u} + \mathbf{h}' - \mathbf{f}') \rangle \\ & \times S_{f0}(1) S^*_{f'0}(1)\, \mathrm{d}z_1, \qquad (4.3.4.3)\end{aligned}$$

where (1) and (2) refer to the regions above and below the diffuse-scattering layer. This expression can be manipulated further, *e.g.* by introducing Bloch-wave expansion of the scattering matrices, *viz*

$$\begin{aligned}I(\mathbf{u}+\mathbf{g}) = \sum_{hh'} \sum_{ff'} \sum_{jj'} \sum_{ii'} & C^j_g(2) C^{j'*}_g(2) C^{j*}_h(2) C^{j'}_{h'}(2) \\ & \times \frac{\exp[i(\gamma^i - \gamma^{i'})z] - \exp[i(\gamma^j - \gamma^{j'})z]}{\gamma^i - \gamma^{i'} - \gamma^j + \gamma^{j'}} \\ & \times \langle f(\mathbf{u} + \mathbf{h} - \mathbf{f}) f^*(\mathbf{u} + \mathbf{h}' - \mathbf{f}') \rangle \\ & \times C^{i*}_f(1) C^{i'}_{f'}(1) C^i_0(1) C^{i*}_0(1), \qquad (4.3.4.4)\end{aligned}$$

which may be interpreted as scattering by $\Delta\varphi$ between Bloch waves belonging to the same branch (intraband scattering) or different branches (interband scattering). Another alternative is to evaluate the scattering matrices by multislice calculations (Section 4.3.5).

Expressions such as (4.3.4.2) contain a large number of terms. Unless very detailed calculations relating to a precisely defined model are to be carried out, attention should be focused on the most important terms.

In Kikuchi-line contrast, the scattering in the upper part of the crystal is usually not considered and frequently the angular variation of the $\Phi(\mathbf{u})$ is also neglected. In diffraction contrast from small-angle inelastic scattering, it may be sufficient to consider the intraband terms [$i = i'$, $j = j'$ in (4.3.4.3)].

In studies of diffuse-scattering distribution, the factor $\langle\Phi(\mathbf{u}+\mathbf{h})\Phi(\mathbf{u}+\mathbf{h}')\rangle$ will produce two types of terms: Those with $\mathbf{h} = \mathbf{h}'$ result only in a redistribution of intensity between corresponding points in the Brillouin zones, with the same total intensity. Those with $\mathbf{h} \neq \mathbf{h}'$ lead to enhancement or reduction of the total diffuse intensity and hence absorption from the Bragg beam and enhanced/reduced intensity of secondary radiation, *i.e.* anomalous absorption and channelling effects. They arise through interference between different Fourier components of the diffuse scattering and carry information about position of the sources of diffuse scattering, referred to the projected unit cell. This is exploited in channelling experiments, where beam direction is used to determine atom reaction (Taftø & Spence, 1982; Taftø & Lehmpfuhl, 1982).

Gjønnes & Høier (1971) expressed this information in terms of the Fourier transform R of the generalized or Kikuchi-line form factor;

$$\langle\Delta\Phi(\mathbf{u})\Delta\Phi^*(\mathbf{u}+\mathbf{h})\rangle\mathbf{u}^2(\mathbf{u}+\mathbf{h})^2 = Q(\mathbf{u}+\mathbf{h}) = \mathscr{F}\{R(\mathbf{r},\mathbf{g})\} \qquad (4.3.4.5)$$

includes information both about correlations between sources of diffuse scattering and about their position in the projected unit cell. It is seen that $Q(\mathbf{u}, 0)$ represents the kinematical intensity, hence $\int R(\mathbf{r},\mathbf{g})\,\mathrm{d}\mathbf{g}$ is the Patterson function. The integral of $Q(\mathbf{u},\mathbf{h})$ in the plane gives the anomalous absorption (Yoshioka, 1957) which is related to the distribution $R(\mathbf{r}, 0)$ of scattering centres across the unit cell.

The scattering factor $\langle\Delta\Phi(\mathbf{u})\Delta\Phi^*(\mathbf{u}-\mathbf{h})\rangle$ can be calculated for different modes. For one-electron excitations as an extension of the Waller–Hartree expression (Gjønnes, 1962; Whelan, 1965):

$$\begin{aligned}\langle\Delta\Phi(\mathbf{u})\Delta\Phi^*(\mathbf{u}-\mathbf{h})\rangle = & \sum_i \frac{f_{ii}(\mathbf{h}) - f_{ii}(\mathbf{u}) f_{ii}(|\mathbf{h}-\mathbf{u}|)}{u^2(\mathbf{h}-\mathbf{u})^2} \\ & - \sum_i \sum_{i\neq j} \frac{f_{ij}(\mathbf{u}) f_{ij}(|\mathbf{h}-\mathbf{u}|)}{u^2(\mathbf{h}-\mathbf{u})^2}, \qquad (4.3.4.6)\end{aligned}$$

where f_{ij} are the one-electron amplitudes (Freeman, 1959).

A similar expression for scattering by phonons is obtained in terms of the scattering factors $G_j(\mathbf{u},\mathbf{g})$ for the branch j, wavevector $\mathbf{g}$ and a polarization vector $\mathbf{l}_{j,q}$ (see Chapter 4.1):

$$\langle\Delta\Phi(\mathbf{u})\Delta\Phi^*(\mathbf{u}-\mathbf{h})\rangle = G_j(\mathbf{u},\mathbf{q})G^*_j(\mathbf{u}-\mathbf{h},\mathbf{q}), \qquad (4.3.4.7)$$

independent phonons being assumed.

For scattering from substitutional order in a binary alloy with ordering on one site only, we obtain simply

$$\Delta\Phi(\mathbf{u})\Delta\Phi^*(\mathbf{u}-\mathbf{h}) = |\Delta\varphi(\mathbf{u})|^2 \frac{f_A(|\mathbf{u}-\mathbf{h}|) - f_B(|\mathbf{u}-\mathbf{h}|)}{f_A(\mathbf{u}) - f_B(\mathbf{u})}, \qquad (4.3.4.8)$$

where $f_{A,B}$ are atomic scattering factors. It is seen that $Q(\mathbf{u})$ then does not contain any new information; the location of the site involved in the ordering is known.

When several sites are involved in the ordering, the dynamical scattering factor becomes less trivial, since scattering factors for

the different ordering parameters (for different sites) will include a factor $\exp(2\pi i \mathbf{r}_m \cdot \mathbf{h})$ (see Andersson *et al.*, 1974).

From the above expressions, it is found that the Bragg scattering will affect diffuse scattering from different sources differently: Diffuse scattering from substitutional order will usually be enhanced at low and intermediate angles, whereas scattering from thermal and electronic fluctuations will be reduced at low angles and enhanced at higher angles. This may be used to study substitutional order and displacement order (size effect) separately (Andersson, 1979).

The use of such expressions for quantitative or semi-quantitative interpretation raises several problems. The Bragg scattering effects occur in all diffuse components, in particular the inelastic scattering, which thus may no longer be represented by a smooth, monotonic background. It is best to eliminate this experimentally. When this cannot be done, the experiment should be arranged so as to minimize Kikuchi-line excess/deficient terms, by aligning the incident beam along a not too dense zone. In this way, one may optimize the diffuse-scattering information and minimize the dynamical corrections, which then are used partly as guides to conditions, partly as refinement in calculations.

The multiple scattering of the background remains as the most serious problem. Theoretical expressions for multiple scattering in the absence of Bragg scattering have been available for some time (Moliere, 1948), as a sum of convolution integrals

$$I(\mathbf{u}) = [(\mu t)I_1(\mathbf{u}) + (1/2)(\mu t)^2 I_2(\mathbf{u}) + \ldots] \exp(-\mu t), \quad (4.3.4.9)$$

where $I_2(\mathbf{u}) = I_1(\mathbf{u}) * I_1(\mathbf{u}) \ldots$ *etc.*, and $I_1(\mathbf{u})$ is normalized.

A complete description of multiple scattering in the presence of Bragg scattering should include Bragg scattering between diffuse scattering at all levels z_1, z_2, *etc.* This quickly becomes unwieldy. Fortunately, the experimental patterns seem to indicate that this is not necessary: The Kikuchi-line contrast does not appear to be very sensitive to the exact Bragg condition of the incident beam. Høier (1973) therefore introduced Bragg scattering only in the last part of the crystal, *i.e.* between the level z_n and the final thickness z for n-times scattering. He thus obtained the formula:

$$I(\mathbf{u}+\mathbf{h}) = \sum_j |C_h^j|^2 \left\{ A_1^j \sum_g \sum_{g \neq g'} F_1(\mathbf{u}, \mathbf{g}, \mathbf{g}') C_g^j C_{g'}^{j*} + \sum_n \sum_g A_{ng}^j F_n(\mathbf{u}, \mathbf{g}) |C_g^j|^2 \right\}, \quad (4.3.4.10)$$

where F_n are normalized scattering factors for nth-order multiple diffuse scattering and A_n^j are multiple-scattering coefficients which include absorption.

When the thickness is increased, the variation of $F_n(\mathbf{u}, \mathbf{g})$ with angle becomes slower, and an expression for intensity of the channelling pattern is obtained (Gjønnes & Taftø, 1976):

$$I(\mathbf{u}+\mathbf{h}) = \sum_j \sum_g \sum_n |C_h^j|^2 |C_g^j|^2 A_n^j = \sum_j |C_h^j|^2 \sum_n A_n^j \rightarrow |C_h^j|^2 / \mu^j(\mathbf{u}). \quad (4.3.4.11)$$

Another approach is the use of a modified diffusion equation (Ohtsuki *et al.*, 1976).

These expressions seem to reproduce the development of the general background with thickness over a wide range of thicknesses. It may thus appear that the contribution to the diffuse background from known sources can be treated adequately – and that such a procedure must be included together with adequate filtering of the inelastic component in order to improve the quantitative interpretation of diffuse scattering.

4.3.5. Multislice calculations for diffraction and imaging

The description of dynamical diffraction in terms of the progression of a wave through successive thin slices of a crystal (Chapter 5.2) forms the basis for the multislice method for the calculation of electron-diffraction patterns and electron-microscope images [see Section 4.3.6.1 in *IT* C (2004)]. This method can be applied directly to the calculations of diffuse scattering in electron diffraction due to thermal motion and positional disorder and for calculating the images of defects in crystals.

It is essentially an amplitude calculation based on the formulation of equation (4.3.4.1) [or (4.3.4.2)] for first-order diffuse scattering. The Bragg scattering in the first part of the crystal is calculated using a standard multislice method for the set of beams **h**. In the nth slice of the crystal, a diffuse-scattering amplitude $\Psi_d(\mathbf{u})$ is convoluted with the incident set of Bragg beams. For each **u**, propagation of the set of beams $\mathbf{u}+\mathbf{h}$ is then calculated through the remaining slices of the crystal. The intensities for the exit wave at the set of points $\mathbf{u}+\mathbf{h}$ are then calculated by adding either amplitudes or intensities. Amplitudes are added if there is correlation between the defects in successive slices. Intensities are added if there are no such correlations. The process is repeated for all **u** values to obtain a complete mapping of the diffuse scattering.

Calculations have been made in this way, for example, for short-range order in alloys [Fisher (1969); see also Cowley (1981) ch. 17] and also for TDS on the assumption of both correlated and uncorrelated atomic motions (Doyle, 1969). The effects of the correlations were shown to be small.

This computing method is not practical for electron-microscope images in which individual defects are to be imaged. The perturbations of the exit wavefunction due to individual defects (vacancies, replaced atoms, displaced atoms) or small groups of defects may then be calculated with arbitrary accuracy by use of the 'periodic continuation' form of the multislice computer programs in which an artificial, large, superlattice unit cell is assumed [Section 4.3.6.1 in *IT* C (2004)]. The corresponding images and microdiffraction patterns from the individual defects or clusters may then be calculated (Fields & Cowley, 1978). A more recent discussion of the image calculations, particularly in relation to thermal diffuse scattering, is given by Cowley (1988).

In order to calculate the diffuse-scattering distributions from disordered systems or from a crystal with atoms in thermal motion by the multislice method with periodic continuation, it would be necessary to calculate for a number of different defect configurations sufficiently large to provide an adequate representation of the statistics of the disordered system. However, it has been shown by Cowley & Fields (1979) that, if the single-diffuse-scattering approximation is made, the perturbations of the exit wave due to individual defects are characteristic of the defect type and of the slice number and may be added, so that a considerable simplification of the computing process is possible. Methods for calculating diffuse scattering in electron-diffraction patterns using the multislice approach are described by Tanaka & Cowley (1987) and Cowley (1989). Loane *et al.* (1991) introduced the concept of 'frozen phonons' for multislice calculations of thermal scattering.

4.3.6. Qualitative interpretation of diffuse scattering of electrons

Quantitative interpretation of the intensity of diffuse scattering by calculation of *e.g.* short-range-order parameters has been the exception. Most studies have been directed to qualitative features

and their variation with composition, treatment *etc.* Many features in the scattering which pass unrecognized in extensive X-ray or neutron investigations will be observed readily with electrons, frequently inviting other ways of interpretation.

Most such studies have been concerned with substitutional disorder, but the extensive investigations of thermal streaks by Honjo and co-workers should be mentioned (Honjo *et al.*, 1964). Diffuse spots and streaks from disorder have been observed from a wide range of substances. The most frequent may be streaks due to planar faults, one of the most common objects studied by electron microscopy. Diffraction patterns are usually sufficient to determine the orientation and the fault vector; the positions and distribution of faults are more easily seen by dark-field microscopy, whereas the detailed atomic arrangement is best studied by high-resolution imaging of the structure [Section 4.3.8 in *IT* C (2004)].

This combination of diffraction and different imaging techniques cannot be applied in the same way to the study of the essentially three-dimensional substitutional local order. Considerable effort has therefore been made to interpret the details of diffuse scattering, leaving the determination of the short-range-order (SRO) parameters usually to X-ray or neutron studies.

Frequently, characteristic shapes or splitting of the diffuse spots from *e.g.* binary alloys are observed. They reflect order extending over many atomic distances, and have been assumed to arise from forces other than the near-neighbour pair forces invoked in the theory of local order. A relationship between the diffuse-scattering distribution and the Fourier transform of the effective atom-pair-interaction potential is given by the ordering theory of Clapp & Moss (1968). An interpretation in terms of long-range forces carried by the conduction electrons was proposed by Krivoglaz (1969). Extensive studies of alloy systems (Ohshima & Watanabe, 1973) show that the separations, m, observed in split diffuse spots from many alloys follow the predicted variation with the electron/atom ratio e/a:

$$m = \left[\frac{12}{\pi}(e/a)\right]^{1/3} t - \sqrt{2},$$

where m is measured along the [110] direction in units of $2a^*$ and t is a truncation factor for the Fermi surface.

A similarity between the location of diffuse maxima and the shape of the Fermi surface has been noted also for other structures, notably some defect rock-salt-type structures. Although this may offer a clue to the forces involved in the ordering, it entails no description of the local structure. Several attempts have been made to formulate principles for building the disordered structure, from small ordered domains embedded in less ordered regions (Hashimoto, 1974), by a network of antiphase boundaries, or by building the structure from clusters with the average composition and coordination (De Ridder *et al.*, 1976). Evidence for such models may be sought by computer simulations, in the details of the SRO scattering as seen in electron diffraction, or in images.

The cluster model is most directly tied to the location of diffuse scattering, noting that a relation between order parameters derived from clusters consistent with the ordered state can be used to predict the position of diffuse scattering in the form of surfaces in reciprocal space, *e.g.* the relation $\cos h + \cos k + \cos l = 0$ for ordering of octahedral clusters in the rock-salt-type structure (Sauvage & Parthé, 1974).

Some of the models imply local fluctuations in order which may be observable either by diffraction from very small regions or by imaging. Microdiffraction studies (Tanaka & Cowley, 1985) do indeed show that spots from 1–1.5 nm regions in disordered $LiFeO_2$ appear on the locus of diffuse maxima observed in diffraction from larger areas.

Imaging of local variations in the SRO structure has been pursued with different techniques (De Ridder *et al.*, 1976; Tanaka & Cowley, 1985; De Meulenaare *et al.*, 1998), *viz*: dark field using diffuse spots only; bright field with the central spot *plus* diffuse spots; lattice image. With domains of about 3 nm or more, high-resolution images seem to give clear indication of their presence and form. For smaller ordered regions, the interpretation becomes increasingly complex: Since the domains will then usually not extend through the thickness of the foil, they cannot be imaged separately. Since image-contrast calculations essentially demand complete specification of the local structure, a model beyond the statistical description must be constructed in order to be compared with observations. On the other hand, these models of the local structure should be consistent with the statistics derived from diffraction patterns collected from a larger volume.

4.4. Scattering from mesomorphic structures

By P. S. Pershan

4.4.1. Introduction

The term mesomorphic is derived from the prefix 'meso-', which is defined in the dictionary as 'a word element meaning middle', and the term '-morphic', which is defined as 'an adjective termination corresponding to morph or form'. Thus, mesomorphic order implies some 'form', or order, that is 'in the middle', or intermediate between that of liquids and crystals. The name liquid crystalline was coined by researchers who found it to be more descriptive, and the two are used synonymously. It follows that a mesomorphic, or liquid-crystalline, phase must have more symmetry than any one of the 230 space groups that characterize crystals.

A major source of confusion in the early liquid-crystal literature was concerned with the fact that many of the molecules that form liquid crystals also form true three-dimensional crystals with diffraction patterns that are only subtly different from those of other liquid-crystalline phases. Since most of the original mesomorphic phase identifications were performed using a 'miscibility' procedure, which depends on optically observed changes in textures accompanying variation in the sample's chemical composition, it is not surprising that some three-dimensional crystalline phases were mistakenly identified as mesomorphic. Phases were identified as being either the same as, or different from, phases that were previously observed (Liebert, 1978; Gray & Goodby, 1984), and although many of the workers were very clever in deducing the microscopic structure responsible for the microscopic textures, the phases were labelled in the order of discovery as smectic-A, smectic-B *etc.* without any attempt to develop a systematic nomenclature that would reflect the underlying order. Although different groups did not always assign the same letters to the same phases, the problem is now resolved and the assignments used in this article are commonly accepted (Gray & Goodby, 1984).

Fig. 4.4.1.1 illustrates the way in which increasing order can be assigned to the series of mesomorphic phases in three dimensions listed in Table 4.4.1.1. Although the phases in this series are the most thoroughly documented mesomorphic phases, there are others not included in the table which we will discuss below.

The progression from the completely symmetric isotropic liquid through the mesomorphic phases into the crystalline phases can be described in terms of three separate types of order. The first, or the molecular orientational order, describes the fact that the molecules have some preferential orientation analogous to the spin orientational order of ferromagnetic materials. In the present case, the molecular quantity that is oriented is a symmetric second-rank tensor, like the moment of inertia or the electric polarizability, rather than a magnetic moment. This is the only type of long-range order in the nematic phase and as a consequence its physical properties are those of an anisotropic fluid; this is the origin of the name liquid crystal. Fig. 4.4.1.2(*a*) is a schematic illustration of the nematic order if it is assumed that the molecules can be represented by oblong ellipses. The average orientation of the ellipses is aligned; however, there is no long-range order in the relative positions of the ellipses. Nematic phases are also observed for disc-shaped molecules and for clusters of molecules that form micelles. These all share the common properties of being optically anisotropic and fluid-like, without any long-range positional order.

The second type of order is referred to as bond orientational order. Consider, for example, the fact that for dense packing of spheres on a flat surface most of the spheres will have six neighbouring spheres distributed approximately hexagonally around it. If a perfect two-dimensional triangular lattice of indefinite size were constructed of these spheres, each hexagon on the lattice would be oriented in the same way. Within the last few years, we have come to recognize that this type of order, in which the hexagons are everywhere parallel to one another, is possible even when there is no lattice. This type of order is referred to as bond orientational order, and bond orientational order in the absence of a lattice is the essential property defining the hexatic phases (Halperin & Nelson, 1978; Nelson & Halperin, 1979; Young, 1979; Birgeneau & Litster, 1978).

The third type of order is the positional order of an indefinite lattice of the type that defines the 230 space groups of conven-

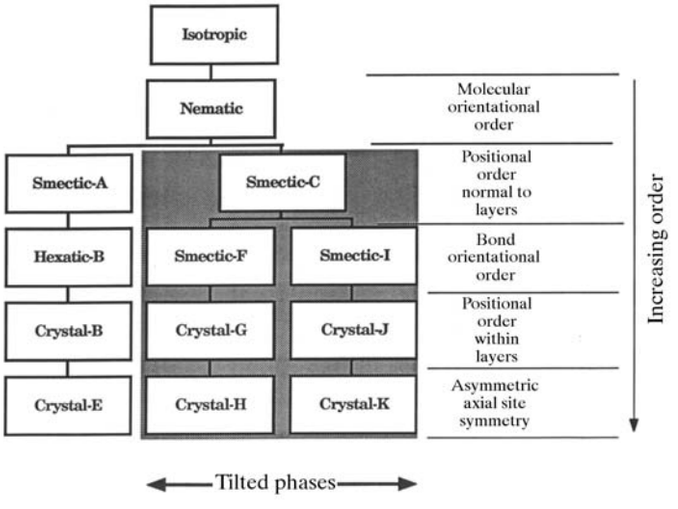

Fig. 4.4.1.1. Illustration of the progression of order throughout the sequence of mesomorphic phases that are based on 'rod-like' molecules. The shaded section indicates phases in which the molecules are tilted with respect to the smectic layers.

Table 4.4.1.1. *Some of the symmetry properties of the series of three-dimensional phases described in Fig. 4.4.1.1*

The terms LRO and SRO imply long-range or short-range order, respectively, and QLRO refers to 'quasi-long-range order' as explained in the text.

Phase	Molecular orientation order within layer	Bond orientation order	Positional order	
			Normal to layer	Within layer
Smectic-A (SmA)	SRO	SRO	SRO	SRO
Smectic-C (SmC)	LRO	LRO†	SRO	SRO
Hexatic-B	LRO†	LRO	QLRO	SRO
Smectic-F (SmF)	LRO	LRO	QLRO	SRO
Smectic-I (SmI)	LRO	LRO	QLRO	SRO
Crystalline-B (CrB)	LRO	LRO	LRO	LRO
Crystalline-G (CrG)	LRO	LRO	LRO	LRO
Crystalline-J (CrJ)	LRO	LRO	LRO	LRO
Crystalline-E (CrE)	LRO	LRO	LRO	LRO
Crystalline-H (CrH)	LRO	LRO	LRO	LRO
Crystalline-K (CrK)	LRO	LRO	LRO	LRO

† Theoretically, the existence of LRO in the molecular orientation, or tilt, implies that there must be some LRO in the bond orientation and *vice versa*.

The scattering cross sections are enclosed in the boxes. Part (*c*) indicates the smectic-C phase for an oriented monodomain and (*d*) indicates a polydomain smectic-C structure in which the molecular axes are aligned.

tional crystals. In view of the fact that some of the mesomorphic phases have a layered structure, it is convenient to separate the positional order into the positional order along the layer normal and perpendicular to it, or within the layers.

Two of the symmetries listed in Tables 4.4.1.1 and 4.4.1.2 are short-range order (SRO), implying that the order is only correlated over a finite distance such as for a simple liquid, and long-range order (LRO) as in either the spin orientation of a ferromagnet or the positional order of a three-dimensional crystal. The third type of symmetry, 'quasi-long-range order' (QLRO), will be explained below. In any case, the progressive increase in symmetry from the isotropic liquid to the crystalline phases for this series of mesomorphic phases is illustrated in Fig. 4.4.1.1. One objective of this chapter is to describe the reciprocal-space structure of the phases listed in the tables and the phase transitions between them.

Finally, in most of the crystalline phases that we wish to discuss, the molecules have considerable amounts of rotational disorder. For example, one series of molecules that form mesomorphic phases consists of long thin molecules which might be described as 'blade shaped'. Although the cross section of these molecules is quite anisotropic, the site symmetry of the molecule is often symmetric, as though the molecule is rotating freely about its long axis. On cooling, many of the mesomorphic systems undergo transitions to the phases, listed at the bottom of Fig. 4.4.1.1, for which the site symmetry is anisotropic as though some of the rotational motions about the molecular axis have been frozen out. A similar type of transition, in which rotational motions are frozen out, occurs on cooling systems such as succinonitrile ($NCCH_2CH_2CN$) that form optically isotropic 'plastic crystals' (Springer, 1977).

Table 4.4.1.2. *The symmetry properties of the two-dimensional hexatic and crystalline phases*

Phase	Molecular orientation order within layer	Bond orientation order	Positional order within layer
Smectic-A (SmA)	SRO	SRO	SRO
Smectic-C (SmC)	QLRO	QLRO	SRO
Hexatic-B	QLRO	QLRO	SRO
Smectic-F (SmF)	QLRO	QLRO	SRO
Smectic-I (SmI)	QLRO	QLRO	SRO
Crystalline-B (CrB)	LRO	LRO	QLRO
Crystalline-G (CrG)	LRO	LRO	QLRO
Crystalline-J (CrJ)	LRO	LRO	QLRO
Crystalline-E (CrE)	LRO	LRO	QLRO
Crystalline-H (CrH)	LRO	LRO	QLRO
Crystalline-K (CrK)	LRO	LRO	QLRO

There are two broad classes of liquid-crystalline systems, the thermotropic and the lyotropic, and, since the former are much better understood, this chapter will emphasize results on thermotropic systems (Liebert, 1978). The historical difference between these two, and also the origin of their names, is that the lyotropic are always mixtures, or solutions, of unlike molecules in which one is a normal, or nonmesogenic, liquid. Solutions of soap and water are prototypical examples of lyotropics, and their mesomorphic phases appear as a function of either concentration or temperature. In contrast, the thermotropic systems are usually formed from a single chemical component, and the mesomorphic phases appear primarily as a function of temperature changes. The molecular distinction between the two is that one of the molecules in the lyotropic solution always has a hydrophilic part, often called the 'head group', and one or more hydrophobic alkane chains called 'tails'. These molecules will often form mesomorphic phases as single-component or neat systems; however, the general belief is that in solution with either water or oil most of the phases are the result of competition between the hydrophilic and hydrophobic interactions, as well as other factors such as packing and steric constraints (Pershan, 1979; Safran & Clark, 1987). To the extent that molecules that form thermotropic liquid-crystalline phases have hydrophilic and hydrophobic parts, the disparity in the affinity of these parts for either water or oil is much less and most of these molecules are relatively insoluble in water. These molecules are called thermotropic because their phase transformations are primarily studied only as a function of temperature. This is not to say that there are not numerous examples of interesting studies of the concentration dependence of phase diagrams involving mixtures of thermotropic liquid crystals.

Fig. 4.4.1.3 displays some common examples of molecules that form lyotropic and thermotropic phases. In spite of the above remarks, it is interesting to observe that different parts of typical

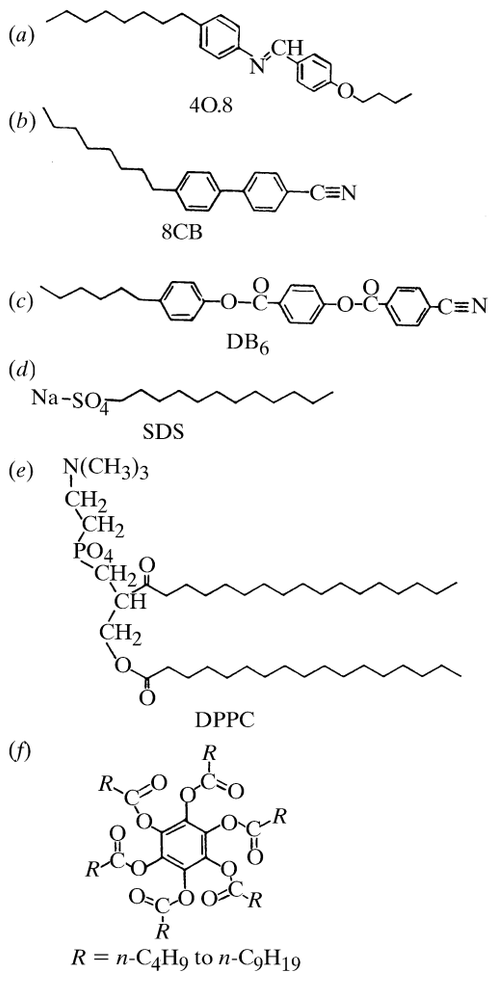

Fig. 4.4.1.3. Chemical formulae for some of the molecules that form thermotropic liquid crystals: (*a*) *N*-[4-(*n*-butyloxy)benzylidene]-4-*n*-octylaniline (4O.8), (*b*) 4′-*n*-octylbiphenyl-4-carbonitrile (8CB), (*c*) 4-hexylphenyl 4-(4-cyanobenzoyloxy)benzoate (DB_6); lyotropic liquid crystals: (*d*) sodium dodecyl sulfate, (*e*) 1,2-dipalmitoyl-L-phosphatidylcholine (DPPC); and a discotic liquid crystal: (*f*) benzenehexayl hexa-*n*-alkanoates.

thermotropic molecules do have some of the same features as the lyotropic molecules. For example, although the rod-like thermotropic molecules always have an alkane chain at one or both ends of a more rigid section, the chain lengths are rarely as long as those of the lyotropic molecules, and although the solubility of the parts of the thermotropic molecules, when separated, are not as disparate as those of the lyotropic molecules, they are definitely different. We suspect that this may account for the subtler features of the phase transformations between the mesomorphic phases to be discussed below. On the other hand, the inhomogeneity of the molecule is probably not important for the nematic phase.

4.4.2. The nematic phase

The nematic phase is a fluid for which the molecules have long-range orientational order. The phase as well as its molecular origin can be most simply illustrated by treating the molecules as long thin rods. The orientation of each molecule can be described by a symmetric second-rank tensor $s_{i,j} = (n_i n_j - \delta_{i,j}/3)$, where $\mathbf{n}$ is a unit vector along the axis of the rod (De Gennes, 1974). For disc-like molecules, such as that shown in Fig. 4.4.1.3(*f*), or for micellar nematic phases, $\mathbf{n}$ is along the principal symmetry axis of either the molecule or the micelle (Lawson & Flautt, 1967). Since physical quantities such as the molecular polarizability, or the moment of inertia, transform as symmetric second-rank tensors, either one of these could be used as specific representations of the molecular orientational order. The macroscopic order, however, is given by the statistical average $S_{i,j} = \langle s_{i,j} \rangle = S(\langle n_i \rangle \langle n_j \rangle - \delta_{i,j}/3)$, where $\langle \mathbf{n} \rangle$ is a unit vector along the macroscopic symmetry axis and S is the order parameter of the nematic phase.

The microscopic origin of the phase can be understood in terms of steric constraints that occur on filling space with highly asymmetric objects such as long rods or flat discs. Maximizing the density requires some degree of short-range orientational order, and theoretical arguments can be invoked to demonstrate long-range order. Onsager presented quantitative arguments of this type to explain the nematic order observed in concentrated solutions of the long thin rods of tobacco mosaic viruses (Onsager, 1949; Lee & Meyer, 1986), and qualitatively similar ideas explain the nematic order for the shorter thermotropic molecules (Maier & Saupe, 1958, 1959).

The existence of nematic order can also be understood in terms of a phenomenological mean-field theory (De Gennes, 1969*b*, 1971; Fan & Stephen, 1970). If the free-energy difference ΔF between the isotropic and nematic phases can be expressed as an analytic function of the nematic order parameter $S_{i,j}$, one can expand $\Delta F(S_{i,j})$ as a power series in which the successive terms all transform as the identity representation of the point group of the isotropic phase, *i.e.* as scalars. The most general form is given by

$$\Delta F(S_{i,j}) = \frac{A}{2}\sum_{ij} S_{ij}S_{ji} + \frac{B}{3}\sum_{ijk} S_{ij}S_{jk}S_{ki} + \frac{D}{4}\left|\sum_{ij} S_{ij}S_{ji}\right|^2 + \frac{D'}{4}\sum_{ijkl} S_{ij}S_{jk}S_{kl}S_{li}. \qquad (4.4.2.1)$$

The usual mean-field treatment assumes that the coefficient of the leading term is of the form $A = a(T - T^*)$, where T is the absolute temperature and T^* is the temperature at which $A = 0$. Taking a, D and $D' > 0$, one can show that for either positive or negative values of B, but for sufficiently large T, the minimum value of $\Delta F = 0$ occurs for $S_{i,j} = 0$, corresponding to the isotropic phase. For $T < T^*$, ΔF can be minimized, at some negative value, for a nonzero $S_{i,j}$ corresponding to nematic order. The details of how this is derived for a tensorial order parameter can be found in the literature (De Gennes, 1974); however, the basic idea can be understood by treating $S_{i,j}$ as a scalar. If we write

$$\Delta F = \tfrac{1}{2}AS^2 + \tfrac{1}{3}BS^3 + \tfrac{1}{4}DS^4 = \left\{\frac{A}{2} - \frac{B^2}{9D}\right\}S^2 + \frac{D}{4}\left(S + \frac{2B}{3D}\right)^2 S^2 \qquad (4.4.2.2)$$

and if T_{NI} is defined by the condition $A = a(T_{NI} - T^*) = 2B^2/9D$, then $\Delta F = 0$ for both $S = 0$ and $S = -2B/3D$. This value for T_{NI} marks the transition temperature from the isotropic phase, when $A > 2B^2/9D$ and the only minimum is at $S = 0$ with $\Delta F = 0$, to the nematic case when $A < 2B^2/9D$ and the absolute minimum with $\Delta F < 0$ is slightly shifted from $S = -2B/3D$. The symmetry properties of second-rank tensors imply that there will usually be a nonvanishing value for B, and this implies that the transition from the isotropic to nematic transition will be first order with a discontinuous jump in the nematic order parameter $S_{i,j}$. Although most nematic systems are uniaxial, biaxial nematic order is theoretically possible (Freiser, 1971; Alben, 1973; Lubensky, 1987) and it has been observed in certain lyotropic nematic liquid crystals (Neto *et al.*,

1985; Hendrikx *et al.*, 1986; Yu & Saupe, 1980) and in one thermotropic system (Malthête *et al.*, 1986).

The X-ray scattering cross section of an oriented monodomain sample of the nematic phase with rod-like molecules usually exhibits a diffuse spot like that illustrated in Fig. 4.4.1.2(*a*), where the maximum of the cross section is along the average molecular axis $\langle \mathbf{n} \rangle$ at a value of $|\mathbf{q}| \approx 2\pi/d$, where $d \approx 20.0$ to 40.0 Å is of the order of the molecular length L. This is a precursor to the smectic-A order that develops at lower temperatures for many materials. In addition, there is a diffuse ring along the directions normal to $\langle \mathbf{n} \rangle$ at $|\mathbf{q}| \approx 2\pi/a$, where $a \approx 4.0$ Å is comparable to the average radius of the molecule. In some nematic systems, the near-neighbour correlations favour antiparallel alignment and molecular centres tend to form pairs such that the peak of the scattering cross section can actually have values anywhere in the range from $2\pi/L$ to $2\pi/2L$. There are also other cases where there are two diffuse peaks, corresponding to both $|\mathbf{q}_1| \approx 2\pi/L$ and $|\mathbf{q}_2| \approx |\mathbf{q}_1|/2$ which are precursors of a richer smectic-A morphology (Prost & Barois, 1983; Prost, 1984; Sigaud *et al.*, 1979; Wang & Lubensky, 1984; Hardouin *et al.*, 1983; Chan, Pershan *et al.*, 1985). In some cases, $|\mathbf{q}_2| \not\approx \frac{1}{2}|\mathbf{q}_1|$ and competition between the order parameters at incommensurate wavevectors gives rise to modulated phases. For the moment, we will restrict the discussion to those systems for which the order parameter is characterized by a single wavevector.

On cooling, many nematic systems undergo a second-order phase transition to a smectic-A phase and as the temperature approaches the nematic to smectic-A transition the widths of these diffuse peaks become infinitesimally small. De Gennes (1972) demonstrated that this phenomenon could be understood by analogy with the transitions from either normal fluidity to superfluidity in liquid helium or normal conductivity to superconductivity in metals. Since the electron density of the smectic-A phase is (quasi-)periodic in one dimension, he represented it by the form

$$\rho(\mathbf{r}) = \langle \rho \rangle + \mathrm{Re}\{\Psi \exp[i(2\pi/d)z]\},$$

where d is the thickness of the smectic layers lying in the xy plane. The complex quantity $\psi = |\psi| \exp(i\varphi)$ is similar to the superfluid wavefunction except that in this analogy the amplitude $|\psi|$ describes the electron-density variations normal to the smectic layers, and the phase φ describes the position of the layers along the z axis. De Gennes proposed a mean-field theory for the transition in which the free-energy difference between the nematic and smectic-A phase $\Delta F(\Psi)$ was represented by

$$\Delta F(\psi) = \frac{A}{2}|\psi|^2 + \frac{D}{4}|\psi|^4 + \frac{E}{2}\left[\left|\left\{\frac{\partial}{\partial z} - i\left(\frac{2\pi}{d}\right)\right\}\psi\right|^2 + \left(\frac{\partial \psi}{\partial x}\right)^2 + \left(\frac{\partial \psi}{\partial y}\right)^2\right]. \quad (4.4.2.3)$$

This mean-field theory differs from the one for the isotropic to nematic transition in that the symmetry for the latter allowed a term that was cubic in the order parameter, while no such term is allowed for the nematic to smectic-A transition. In both cases, however, the coefficient of the leading term is taken to have the form $a(T - T^*)$. If $D > 0$, without the cubic term the free energy has only one minimum when $T > T^*$ at $|\psi| = 0$, and two equivalent minima at $|\psi| = \{a(T^* - T)/D\}^{0.5}$ for $T < T^*$. On the basis of this free energy, the nematic to smectic-A transition can be second order with a transition temperature $T_{\mathrm{NA}} = T^*$ and an order parameter that varies as the square root of $(T_{\mathrm{NA}} - T)$. There are conditions that we will not discuss in detail when D can be negative. In that case, the nematic to smectic-A transition will be first order (McMillan, 1972, 1973*a*,*b*,*c*). McMillan pointed out that, by allowing coupling between the smectic and nematic order parameters, a more general free energy can be developed in which D is negative. McMillan's prediction that for systems in which the difference $T_{\mathrm{IN}} - T_{\mathrm{NA}}$ is small the nematic to smectic-A transition will be first order is supported by experiment (Ocko, Birgeneau & Litster, 1986; Ocko *et al.*, 1984; Thoen *et al.*, 1984). Although the mean-field theory is not quantitatively accurate, it does explain the principal qualitative features of the nematic to smectic-A transition.

The differential scattering cross section for X-rays can be expressed in terms of the Fourier transform of the density–density correlation function $\langle \rho(\mathbf{r})\rho(0) \rangle$. The expectation value is calculated from the thermal average of the order parameter that is obtained from the free-energy density $\Delta F(\psi)$. If one takes the transform

$$\Psi(\mathbf{Q}) \equiv \frac{1}{(2\pi)^3}\int \mathrm{d}^3\mathbf{r} \exp[i(\mathbf{Q}\cdot\mathbf{r})]\rho(\mathbf{r}), \quad (4.4.2.4)$$

the free-energy density in reciprocal space has the form

$$\Delta F(\psi) = \frac{A}{2}|\psi|^2 + \frac{D}{4}|\psi|^4 + \frac{E}{2}\{[Q_z - (2\pi/d)]^2 + Q_x^2 + Q_y^2\}|\psi|^2 \quad (4.4.2.5)$$

and one can show that for $T > T_{\mathrm{NA}}$ the cross section obtained from the above form for the free energy is

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} \approx \frac{\sigma_0}{A + E\{[Q_z - (2\pi/d)]^2 + Q_x^2 + Q_y^2\}}, \quad (4.4.2.6)$$

where the term in $|\psi|^4$ has been neglected. The mean-field theory predicts that the peak intensity should vary as $\sigma_0/A \approx 1/(T - T_{\mathrm{NA}})$ and that the half width of the peak in any direction should vary as $(A/E)^{1/2} \approx (T - T_{\mathrm{NA}})^{1/2}$. The physical interpretation of the half width is that the smectic fluctuations in the nematic phase are correlated over lengths $\xi = (E/A)^{1/2} \sim (T - T_{\mathrm{NA}})^{-1/2}$.

One of the major shortcomings of all mean-field theories is that they do not take into account the difference between the average value of the order parameter $\langle \psi \rangle$ and the instantaneous value $\psi = \langle \psi \rangle + \delta\psi$, where $\delta\psi$ represents the thermal fluctuations (Ma, 1976). The usual effect expected from theories for this type of critical phenomenon is a 'renormalization' of the various terms in the free energy such that the temperature dependence of correlation length has the form $\xi(t) \propto t^{-\nu}$, where $t \equiv (T - T^*)/T^*$, $T^* = T_{\mathrm{NA}}$ is the second-order transition temperature, and ν is expected to have some universal value that is generally not equal to 0.5. One of the major unsolved problems of the nematic to smectic-A phase transition is that the width along the scattering vector $\mathbf{q}$ varies as $1/\xi_\parallel \propto t^{\nu_\parallel}$ with a temperature dependence different from that of the width perpendicular to $\mathbf{q}$, $1/\xi_\perp \propto t^{\nu_\perp}$; also, neither $\nu_\parallel$ nor $\nu_\perp$ have the expected universal values (Lubensky, 1983; Nelson & Toner, 1981).

The correlation lengths are measured by fitting the differential scattering cross sections to the empirical form:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{\sigma}{1 + (\mathbf{Q}_z - |\mathbf{q}|)^2\xi_\parallel^2 + \mathbf{Q}_\perp^2\xi_\perp^2 + c(\mathbf{Q}_\perp^2\xi_\perp^2)^2}. \quad (4.4.2.7)$$

The amplitude $\sigma \propto t^{-\gamma}$, where the measured values of γ are empirically found to be very close to the measured values for the sum $\nu_\parallel + \nu_\perp$. Most of the systems that have been measured to date have values for $\nu_\parallel > 0.66 > \nu_\perp$ and $\nu_\parallel - \nu_\perp \approx 0.1$ to 0.2. Table 4.4.2.1 lists sources of the observed values for γ, $\nu_\parallel$ and $\nu_\perp$. The theoretical and experimental studies of this pretransition effect account for a sizeable fraction of all of the liquid-crystal research in the last 15 or 20 years, and as of this writing the explanation for these two different temperature dependences remains one of the major unresolved theoretical questions in equilibrium statistical physics.

It is very likely that the origin of the problem is the QLRO in the position of the smectic layers. Lubensky attempted to deal with this by introducing a gauge transformation in such a way that the thermal fluctuations of the transformed order parameter did not have the logarithmic divergence. While this approach has been informative, it has not yet yielded an agreed-upon understanding. Experimentally, the effect of the phase can be studied in systems where there are two competing order parameters with wavevectors that are at $\mathbf{q}_2$ and $\mathbf{q}_1 \approx 2\mathbf{q}_2$ (Sigaud *et al.*, 1979; Hardouin *et al.*, 1983; Prost & Barois, 1983; Wang & Lubensky, 1984; Chan, Pershan *et al.*, 1985). On cooling, mixtures of 4-hexylphenyl 4-(4-cyanobenzoyloxy)benzoate (DB_6) and *N*,*N*′-(1,4-phenylenedimethylene)bis(4-butylaniline) (also known as terephthal-bis-butylaniline, TBBA) first undergo a second-order transition from the nematic to a phase that is designated as smectic-A_1. The various smectic-A and smectic-C morphologies will be described in more detail in the following section; however, the smectic-A_1 phase is characterized by a single peak at $q_1 = 2\pi/d$ owing to a one-dimensional density wave with wavelength d of the order of the molecular length L. In addition, however, there are thermal fluctuations of a second-order parameter with a period of $2L$ that give rise to a diffuse peak at $q_2 = \pi/L$. On further cooling, this system undergoes a second second-order transition to a smectic-A_2 phase with QLRO at $q_2 \approx \pi/L$, with a second harmonic that is exactly at $q = 2q_2 \approx 2\pi/L$. The critical scattering on approaching this transition is similar to that of the nematic to smectic-A_1, except that the pre-existing density wave at $q_1 = 2\pi/L$ quenches the phase fluctuations of the order parameter at the subharmonic $q_2 = \pi/L$. The measured values of $\nu_\parallel = \nu_\perp \approx 0.74$ (Chan, Pershan *et al.*, 1985) agree with those expected from the appropriate theory (Huse, 1985). A mean-field theory that describes this effect is discussed in Section 4.4.3.2 below.

It is interesting to note that even those systems for which the nematic to smectic-A transition is first order show some pretransitional lengthening of the correlation lengths $\xi_\parallel$ and $\xi_\perp$. In these cases, the apparent T^* at which the correlation lengths would diverge is lower than T_{NA} and the divergence is truncated by the first-order transition (Ocko *et al.*, 1984).

4.4.3. Smectic-A and smectic-C phases

4.4.3.1. Homogeneous smectic-A and smectic-C phases

In the smectic-A and smectic-C phases, the molecules organize themselves into layers, and from a naive point of view one might describe them as forming a one-dimensional periodic lattice in which the individual layers are two-dimensional liquids. In the smectic-A phase, the average molecular axis $\langle \mathbf{n} \rangle$ is normal to the smectic layers while for the smectic-C it makes a finite angle. It follows from this that the smectic-C phase has lower symmetry than the smectic-A, and the phase transition from the smectic-A to smectic-C can be considered as the ordering of a two-component order parameter, *i.e.* the two components of the projection of the molecular axis on the smectic layers (De Gennes, 1973). Alternatively, Chen & Lubensky (1976) have developed a mean-field theory in which the transition is described by a free-energy density of the Lifshitz form. This will be described in more detail below; however, it corresponds to replacing equation (4.4.2.5) for the free energy $\Delta F(\psi)$ by an expression for which the minimum is obtained when the wavevector $\mathbf{q}$, of the order parameter $\psi \propto \exp[i\mathbf{q} \cdot \mathbf{r}]$, tilts away from the molecular axis.

The X-ray cross section for the prototypical aligned monodomain smectic-A sample is shown in Fig. 4.4.1.2(*b*). It consists of a single sharp spot along the molecular axis at $|\mathbf{q}|$ somewhere between $2\pi/2L$ and $2\pi/L$ that reflects the QLRO along the layer normal, and a diffuse ring in the perpendicular direction at $|\mathbf{q}| \approx 2\pi/a$ that reflects the SRO within the layer. The scattering cross section for an aligned smectic-C phase is similar to that of the smectic-A except that the molecular tilt alters the intensity distribution of the diffuse ring. This is illustrated in Fig. 4.4.1.2(*c*) for a monodomain sample. Fig. 4.4.1.2(*d*) illustrates the scattering pattern for a polydomain smectic-C sample in which the molecular axis remains fixed, but where the smectic layers are randomly distributed azimuthally around the molecular axis.

The naivety of describing these as periodic stacks of two-dimensional liquids derives from the fact that the sharp spot along the molecular axis has a distinct temperature-dependent shape indicative of QLRO that distinguishes it from the Bragg peaks due to true LRO in conventional three-dimensional crystals. Landau and Peierls discussed this effect for the case of two-dimensional crystals (Landau, 1965; Peierls, 1934) and Caillé (1972) extended the argument to the mesomorphic systems.

The usual treatment of thermal vibrations in three-dimensional crystals estimates the Debye–Waller factor by integrating the thermal expectation value for the mean-square amplitude over reciprocal space (Kittel, 1963):

$$W \simeq \frac{k_B T}{c^3} \int_0^{k_D} \frac{k^{(d-1)}}{k^2} \mathrm{d}k, \qquad (4.4.3.1)$$

where c is the sound velocity, $\omega_D \equiv ck_D$ is the Debye frequency and $d = 3$ for three-dimensional crystals. In this case, the integral converges and the only effect is to reduce the integrated intensity of the Bragg peak by a factor proportional to $\exp(-2W)$. For two-dimensional crystals $d = 1$, and the integral, of the form of $\mathrm{d}k/k$, obtains a logarithmic divergence at the lower limit (Fleming *et al.*, 1980). A more precise treatment of thermal vibrations, necessitated by this divergence, is to calculate the relative phase of X-rays scattered from two points in the sample a distance $|\mathbf{r}|$ apart. The appropriate integral that replaces the Debye–Waller integral is

$$\langle [u(\mathbf{r}) - u(0)]^2 \rangle \simeq \frac{k_B T}{c^3} \int \sin^2(\mathbf{k} \cdot \mathbf{r}) \frac{\mathrm{d}k}{k} \mathrm{d}\{\cos(\mathbf{k} \cdot \mathbf{r})\} \qquad (4.4.3.2)$$

and the divergence due to the lower limit is cut off by the fact that $\sin^2(\mathbf{k}\cdot\mathbf{r})$ vanishes as $k \to 0$. More complete analysis obtains $\langle[u(\mathbf{r}) - u(0)]^2\rangle \simeq (k_B T/c^2)\ln(|\mathbf{r}|/a)$, where $a \approx$ atomic size. If this is exponentiated, as for the Debye–Waller factor, the density–density correlation function can be shown to have the form $\langle\rho(\mathbf{r})\rho(0)\rangle \simeq |\mathbf{r}/a|^{-\eta}$, where $\eta \simeq |\mathbf{q}|^2(k_B T/c^2)$ and $|\mathbf{q}| \simeq 2\pi/a$. In place of the usual periodic density–density correlation function of three-dimensional crystals, the periodic correlations of two-dimensional crystals decay as some power of the distance. This type of positional order, in which the correlations decay as some power of the distance, is the quasi-long-range order (QLRO) that appears in Tables 4.4.1.1 and 4.4.1.2. It is distinguished from true long-range order (LRO) where the correlations continue indefinitely, and short-range order (SRO) where the positional correlations decay exponentially as in either a simple fluid or a nematic liquid crystal.

The usual prediction of Bragg scattering for three-dimensional crystals is obtained from the Fourier transform of the three-dimensional density–density correlation function. Since the correlation function is made up of periodic and random parts, it follows that the scattering cross section is made up of a δ function at the Bragg condition superposed on a background of thermal diffuse scattering from the random part. In principle, these two types of scattering can be separated empirically by using a high-resolution spectrometer that integrates all of the δ-function Bragg peak, but only a small part of the thermal diffuse scattering. Since the two-dimensional lattice is not strictly periodic, there is no formal way to separate the periodic and random parts, and the Fourier transform for the algebraic correlation function obtains a cross section that is described by an algebraic singularity of the form $|\mathbf{Q} - \mathbf{q}|^{\eta-2}$ (Gunther *et al.*, 1980). In 1972, Caillé (Caillé, 1972) presented an argument that the X-ray scattering line shape for the one-dimensional periodicity of the smectic-A system in three dimensions has an algebraic singularity that is analogous to the line shapes from two-dimensional crystals.

In three-dimensional crystals, both the longitudinal and the shear sound waves satisfy linear dispersion relations of the form $\omega = ck$. In simple liquids, and also for nematic liquid crystals, only the longitudinal sound wave has such a linear dispersion relation. Shear sound waves are overdamped and the decay rate $1/\tau$ is given by the imaginary part of a dispersion relation of the form $\omega = i(\eta/\rho)k^2$, where η is a viscosity coefficient and ρ is the liquid density. The intermediate order of the smectic-A mesomorphic phase, between the three-dimensional crystal and the nematic, results in one of the modes for shear sound waves having the curious dispersion relation $\omega^2 = c^2 k_\perp^2 k_z^2/(k_\perp^2 + k_z^2)$, where $k_\perp$ and k_z are the magnitudes of the components of the acoustic wavevector perpendicular and parallel to $\langle\mathbf{n}\rangle$, respectively (De Gennes, 1969*a*; Martin *et al.*, 1972). More detailed analysis, including terms of higher order in $k_\perp^2$, obtains the equivalent of the Debye–Waller factor for the smectic-A as

$$W \simeq k_B T \int_0^{k_D} \frac{k_\perp \mathrm{d}k_\perp \mathrm{d}k_z}{Bk_z^2 + Kk_\perp^4}, \qquad (4.4.3.3)$$

where B and K are smectic elastic constants, $k_\perp^2 = k_x^2 + k_y^2$, and k_D is the Debye wavevector. On substitution of $u^2 = (K/B)k_\perp^2 + k_z^2$, the integral can be manipulated into the form $\int \mathrm{d}u/u$, which diverges logarithmically at the lower limit in exactly the same way as the integral for the Debye–Waller factor of the two-dimensional crystal. The result is that the smectic-A phase has a sharp peak, described by an algebraic cusp, at the place in reciprocal space where one would expect a true δ-function Bragg cross section from a truly periodic one-dimensional lattice. In fact, the lattice is not truly periodic and the smectic-A system has only QLRO along the direction $\langle\mathbf{n}\rangle$.

X-ray scattering experiments to test this idea were carried out on one thermotropic smectic-A system, but the results, while consistent with the theory, were not adequate to provide an unambiguous proof of the algebraic cusp (Als-Nielsen *et al.*, 1980). One of the principal difficulties was due to the fact that, when thermotropic samples are oriented in an external magnetic field in the higher-temperature nematic phase and then gradually cooled through the nematic to smectic-A phase transition, the smectic-A samples usually have mosaic spreads of the order of a fraction of a degree and this is not sufficient for detailed line-shape studies near to the peak. A second difficulty is that, in most of the thermotropic smectic-A phases that have been studied to date, only the lowest-order peak is observed. It is not clear whether this is due to a large Debye–Waller-type effect or whether the form factor for the smectic-A layer falls off this rapidly. Nevertheless, since the factor η in the exponent of the cusp $|\mathbf{Q} - \mathbf{q}|^{\eta-2}$ depends quadratically on the magnitude of the reciprocal vector $|\mathbf{q}|$, the shape of the cusp for the different orders would constitute a severe test of the theory.

Fortunately, it is common to observe multiple orders for lyotropic smectic-A systems and such an experiment, carried out on the lyotropic smectic-A system formed from a quaternary mixture of sodium dodecyl sulfate, pentanol, water and dodecane, confirmed the theoretical predictions for the Landau–Peierls effect in the smectic-A phase (Safinya, Roux *et al.*, 1986). The problem of sample mosaic was resolved by using a three-dimensional powder. Although the conditions on the analysis are delicate, Safinya *et al.* demonstrated that for a perfect powder, for which the microcrystals are sufficiently large, the powder line shape does allow unambiguous determination of all of the parameters of the anisotropic line shape.

The only other X-ray study of a critical property on the smectic-A side of the transition has been a measurement of the temperature dependence of the integrated intensity of the peak. For three-dimensional crystals, the integrated intensity of a Bragg peak can be measured for samples with poor mosaic distributions, and because the differences between QLRO and true LRO are only manifest at long distances in real space, or at small wavevectors in reciprocal space, the same is true for the 'quasi-Bragg peak' of the smectic-A phase. Chan *et al.* measured the temperature dependence of the integrated intensity of the smectic-A peak across the nematic to smectic-A phase transition for a number of liquid crystals with varying exponents $\nu_\parallel$ and $\nu_\perp$ (Chan, Deutsch *et al.*, 1985). For the Landau–De Gennes free-energy density (equation 4.4.2.5), the theoretical prediction is that the critical part of the integrated intensity should vary as $|t|^x$, where $x = 1 - \alpha$ when the critical part of the heat capacity diverges according to the power law $|t|^{-\alpha}$. Six samples were measured with values of α varying from 0 to 0.5. Although for samples with $\alpha \approx 0.5$ the critical intensity did vary as $x \approx 0.5$, there were systematic deviations for smaller values of α, and for $\alpha \approx 0$ the measured values of x were in the range 0.7 to 0.76. The origin of this discrepancy is not at present understood.

Similar integrated intensity measurements in the vicinity of the first-order nematic to smectic-C transition cannot easily be made in smectic-C samples since the magnetic field aligns the molecular axis $\langle\mathbf{n}\rangle$, and when the layers form at some angle φ to $\langle\mathbf{n}\rangle$ the layer normals are distributed along the full 2π of azimuthal directions around $\langle\mathbf{n}\rangle$, as shown in Fig. 4.4.1.2(*d*). The X-ray scattering pattern for such a sample is a partial powder with a peak-intensity distribution that forms a ring of radius $|\mathbf{q}|\sin(\varphi)$. The opening of the single spot along the average molecular axis $\langle\mathbf{n}\rangle$ into a ring can be used to study either the nematic to smectic-C or the smectic-A to smectic-C transition (Martinez-Miranda *et al.*, 1986).

The statistical physics in the region of the phase diagram surrounding the triple point, where the nematic, smectic-A and smectic-C phases meet, has been the subject of considerable theoretical speculation (Chen & Lubensky, 1976; Chu &

McMillan, 1977; Benguigui, 1979; Huang & Lien, 1981; Grinstein & Toner, 1983). The best representation of the observed X-ray scattering structure near the nematic to smectic-A, the nematic to smectic-C and the nematic/smectic-A/smectic-C (NAC) multicritical point is obtained from the mean-field theory of Chen and Lubensky, the essence of which is expressed in terms of an energy density of the form

$$\Delta F(\psi) = \frac{A}{2}|\psi|^2 + \frac{D}{4}|\psi|^4 + \tfrac{1}{2}[E_\parallel(Q_\parallel^2 - Q_0^2)^2 + E_\perp Q_\perp^2 + E_{\perp\perp}Q_\perp^4 + E_{\perp\parallel}Q_\perp^2(Q_\parallel^2 - Q_0^2)]|\psi(\mathbf{Q})|^2, \quad (4.4.3.4)$$

where $\psi = \psi(\mathbf{Q})$ is the Fourier component of the electron density:

$$\psi(\mathbf{Q}) \equiv \frac{1}{(2\pi)^3}\int \mathrm{d}^3\mathbf{r}\exp[i(\mathbf{Q}\cdot\mathbf{r})]\rho(\mathbf{r}). \quad (4.4.3.5)$$

The quantities $E_\parallel$, $E_{\perp\perp}$, and $E_{\parallel\perp}$ are all positive definite; however, the sign of A and $E_\perp$ depends on temperature. For $A > 0$ and $E_\perp > 0$, the free energy, including the higher-order terms, is minimized by $\psi(\mathbf{Q}) = 0$ and the nematic is the stable phase. For $A < 0$ and $E_\perp > 0$, the minimum in the free energy occurs for a nonvanishing value for $\psi(\mathbf{Q})$ in the vicinity of $Q_\parallel \approx Q_0$, corresponding to the uniaxial smectic-A phase; however, for $E_\perp < 0$, the free-energy minimum occurs for a nonvanishing $\psi(\mathbf{Q})$ with a finite value of $Q_\perp$, corresponding to smectic-C order. The special point in the phase diagram where two terms in the free energy vanish simultaneously is known as a 'Lifshitz point' (Hornreich *et al.*, 1975). In the present problem, this occurs at the triple point where the nematic, smectic-A and smectic-C phases coexist. Although there have been other theoretical models for this transition, the best agreement between the observed and theoretical line shapes for the X-ray scattering cross sections is based on the Chen–Lubensky model. Most of the results from light-scattering experiments in the vicinity of the NAC triple point also agree with the main features predicted by the Chen–Lubensky model; however, there are some discrepancies that are not explained (Solomon & Litster, 1986).

The nematic to smectic-C transition in the vicinity of this point is particularly interesting in that, on approaching the nematic to smectic-C transition temperature from the nematic phase, the X-ray scattering line shapes first appear to be identical to the shapes usually observed on approaching the nematic to smectic-A phase transition; however, within approximately 0.1 K of the transition, they change to shapes that clearly indicate smectic-C-type fluctuations. Details of this crossover are among the strongest evidence supporting the Lifshitz idea behind the Chen–Lubensky model.

4.4.3.2. Modulated smectic-A and smectic-C phases

Previously, we mentioned that, although the reciprocal-lattice spacing $|\mathbf{q}|$ for many smectic-A phases corresponds to $2\pi/L$, where L is the molecular length, there are a number of others for which $|\mathbf{q}|$ is between π/L and $2\pi/L$ (Leadbetter, Frost, Gaughan, Gray & Mosley, 1979; Leadbetter *et al.*, 1977). This suggests the possibility of different types of smectic-A phases in which the bare molecular length is not the sole determining factor of the period d. In 1979, workers at Bordeaux optically observed some sort of phase transition between two phases that both appeared to be of the smectic-A type (Sigaud *et al.*, 1979). Subsequent X-ray studies indicated that in the nematic phase these materials simultaneously displayed critical fluctuations with two separate periods (Levelut *et al.*, 1981; Hardouin *et al.*, 1980, 1983; Ratna *et al.*, 1985, 1986; Chan, Pershan *et al.*, 1985, 1986; Safinya, Varady *et al.*, 1986; Fontes *et al.*, 1986) and confirmed phase transitions

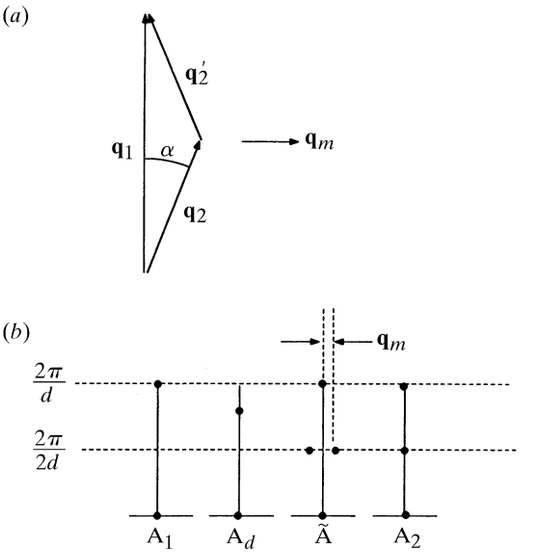

Fig. 4.4.3.1. (*a*) Schematic illustration of the necessary condition for coupling between order parameters when $|\mathbf{q}_2| < 2|\mathbf{q}_1|$; $|\mathbf{q}| = (|\mathbf{q}_2|^2 - |\mathbf{q}_1|^2)^{1/2} = |\mathbf{q}_1|\sin(\alpha)$. (*b*) Positions of the principal peaks for the indicated smectic-A phases.

between phases that have been designated smectic-A_1 with period $d \approx L$, smectic-A_2 with period $d \approx 2L$ and smectic-A_d with period $L < d < 2L$. Stimulated by the experimental results, Prost and co-workers generalized the De Gennes mean-field theory by writing

$$\rho(\mathbf{r}) = \langle\rho\rangle + \mathrm{Re}\{\Psi_1\exp(i\mathbf{q}_1\cdot\mathbf{r}) + \Psi_2\exp(i\mathbf{q}_2\cdot\mathbf{r})\},$$

where 1 and 2 refer to two different density waves (Prost, 1979; Prost & Barois, 1983; Barois *et al.*, 1985). In the special case that $\mathbf{q}_1 \approx 2\mathbf{q}_2$ the free energy represented by equation (4.4.2.3) must be generalized to include terms like

$$(\Psi_2^*)^2\Psi_1\exp[i(\mathbf{q}_1 - 2\mathbf{q}_2)\cdot\mathbf{r}] + \text{c.c.}$$

that couple the two order parameters. Suitable choices for the relative values of the phenomenological parameters of the free energy then result in minima that correspond to any one of these three smectic-A phases. Much more interesting, however, was the observation that even if $|\mathbf{q}_1| < 2|\mathbf{q}_2|$ the two order parameters could still be coupled together if $\mathbf{q}_1$ and $\mathbf{q}_2$ were not collinear, as illustrated in Fig. 4.4.3.1(*a*), such that $2\mathbf{q}_1\cdot\mathbf{q}_2 = |\mathbf{q}_1|^2$. Prost *et al.* predicted the existence of phases that are modulated in the direction perpendicular to the average layer normal with a period $4\pi/[|\mathbf{q}_2|\sin(\varphi)] = 2\pi/|\mathbf{q}_m|$. Such a modulated phase has been observed and is designated as the smectic-A (Hardouin *et al.*, 1981). Similar considerations apply to the smectic-C phases and the modulated phase is designated smectic-$\tilde{C}$; (Hardouin *et al.*, 1982; Huang *et al.*, 1984; Safinya, Varady *et al.*, 1986).

4.4.3.3. Surface effects

The effects of surfaces in inducing macroscopic alignment of mesomorphic phases have been important both for technological applications and for basic research (Sprokel, 1980; Gray & Goodby, 1984). Although there are a variety of experimental techniques that are sensitive to mesomorphic surface order (Beaglehole, 1982; Faetti & Palleschi, 1984; Faetti *et al.*, 1985; Gannon & Faber, 1978; Miyano, 1979; Mada & Kobayashi, 1981; Guyot-Sionnest *et al.*, 1986), it is only recently that X-ray scattering techniques have been applied to this problem. In one form or another, all of the techniques for obtaining surface specificity

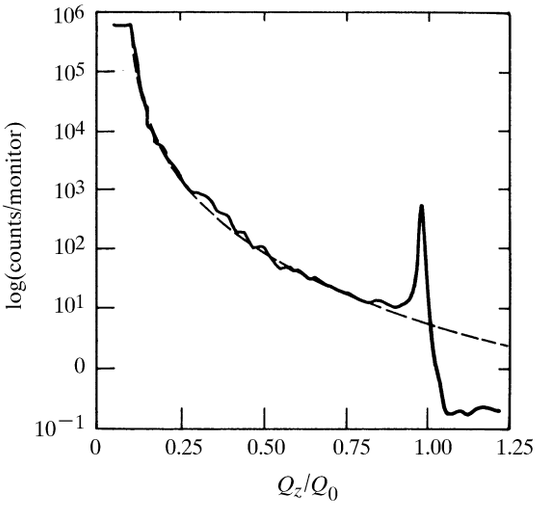

Fig. 4.4.3.2. Specular reflectivity of ∼8 keV X-rays from the air–liquid interface of the nematic liquid crystal 8OCB 0.05 K above the nematic to smectic-A transition temperature. The dashed line is the Fresnel reflection law as described in the text.

in an X-ray measurement make use of the fact that the average interaction between X-rays and materials can be treated by the introduction of a dielectric constant $\varepsilon \approx 1 - (4\pi\rho e^2/m\omega^2) = 1 - \rho r_e \lambda^2/\pi$, where ρ is the electron density, r_e is the classical radius of the electron, and ω and λ are the angular frequency and the wavelength of the X-ray. Since $\varepsilon < 1$, X-rays that are incident at a small angle to the surface θ_0 will be refracted in the material toward a smaller angle $\theta_T \approx (\theta_0^2 - \theta_c^2)^{1/2}$, where the 'critical angle' $\theta_c \approx (\rho r_e \lambda^2/\pi)^{1/2} \approx 0.003$ rad ($\approx 0.2^\circ$) for most liquid crystals (Warren, 1968). Although this is a small angle, it is at least two orders of magnitude larger than the practical angular resolution available in modern X-ray spectrometers (Als-Nielsen *et al.*, 1982; Pershan & Als-Nielsen, 1984; Pershan *et al.*, 1987). One can demonstrate that for many conditions the specular reflection $R(\theta_0)$ is given by

$$R(\theta_0) \approx R_F(\theta_0)|\rho^{-1} \int dz \exp(-iQz)\langle \partial\rho/\partial z\rangle|^2,$$

where $Q \equiv (4\pi/\lambda)\sin(\theta_0)$, $\langle \partial\rho/\partial z\rangle$ is the normal derivative of the electron density averaged over a region in the surface that is defined by the coherence area of the incident X-ray, and

$$R_F(\theta_0) \approx \left(\frac{\theta_0 - \sqrt{\theta_0^2 - \theta_c^2}}{\theta_0 + \sqrt{\theta_0^2 - \theta_c^2}}\right)^2$$

is the Fresnel reflection law that is calculated from classical optics for a flat interface between the vacuum and a material of dielectric constraint ε. Since the condition for specular reflection, that the incident and scattered angles are equal and in the same plane, requires that the scattering vector $\mathbf{Q} = \hat{z}(4\pi/\lambda)\sin(\theta_0)$ be parallel to the surface normal, it is quite practical to obtain, for flat surfaces, an unambiguous separation of the specular reflection signal from all other scattering events.

Fig. 4.4.3.2(*a*) illustrates the specular reflectivity from the free nematic–air interface for the liquid crystal 4′-octyloxybiphenyl-4-carbonitrile (8OCB) 0.050 K above the nematic to smectic-A phase-transition temperature (Pershan & Als-Nielsen, 1984). The dashed line is the Fresnel reflection $R_F(\theta_0)$ in units of $\sin(\theta_0)/\sin(\theta_c)$, where the peak at $\theta_c = 1.39^\circ$ corresponds to surface-induced smectic order in the nematic phase: *i.e.* the selection rule for specular reflection has been used to separate the specular reflection from the critical scattering from the bulk. Since the full width at half maximum is exactly equal to the reciprocal of the correlation length for critical fluctuations in the bulk, $2/\xi_\parallel$ at all temperatures from $T - T_{NA} \approx 0.006$ K up to values near to the nematic to isotropic transition, $T - T_{NA} \approx 3.0$ K, it is clear this is an example where the gravitationally induced long-range order in the surface position has induced mesomorphic order that has long-range correlations parallel to the surface. Along the surface normal, the correlations have only the same finite range as the bulk critical fluctuations. Studies on a number of other nematic (Gransbergen *et al.*, 1986; Ocko *et al.*, 1987) and isotropic surfaces (Ocko, Braslau *et al.*, 1986) indicate features that are specific to local structure of the surface.

4.4.4. Phases with in-plane order

Although the combination of optical microscopy and X-ray scattering studies on unoriented samples identified most of the mesomorphic phases, there remain a number of subtle features that were only discovered by spectra from well oriented samples (see the extensive references contained in Gray & Goodby, 1984). Nematic phases are sufficiently fluid that they are easily oriented by either external electric or magnetic fields, or surface boundary conditions, but similar alignment techniques are not generally successful for the more ordered phases because the combination of strains induced by thermal expansion and the enhanced elasticity that accompanies the order creates defects that do not easily anneal. Other defects that might have been formed during initial growth of the phase also become trapped and it is difficult to obtain well oriented samples by cooling from a higher-temperature aligned phase. Nevertheless, in some cases it has been possible to obtain crystalline-B samples with mosaic spreads of the order of a fraction of a degree by slowing cooling samples that were aligned in the nematic phase. In other cases, mesomorphic phases were obtained by heating and melting single crystals that were grown from solution (Benattar *et al.*, 1979; Leadbetter, Mazid & Malik, 1980).

Moncton & Pindak (1979) were the first to realize that X-ray scattering studies could be carried out on the freely suspended films that Friedel (1922) described in his classical treatise on liquid crystals. These samples, formed across a plane aperture (*i.e.* approximately 1 cm in diameter) in the same manner as soap bubbles, have mosaic spreads that are an order of magnitude smaller. The geometry is illustrated in Fig. 4.4.4.1(*a*). The substrate in which the aperture is cut can be glass (*e.g.* a microscope cover slip), steel or copper sheeting *etc.* A small amount of the material, usually in the high-temperature region of the smectic-A phase, is spread around the outside of an aperture that is maintained at the necessary temperature, and a wiper is used to drag some of the material across the aperture. If a stable film is successfully drawn, it is detected optically by its finite reflectivity. In particular, against a dark background and with the proper illumination it is quite easy to detect the thinnest free films.

In contrast to conventional soap films that are stabilized by electrostatic effects, smectic films are stabilized by their own layer structure. Films as thin as two molecular layers can be drawn and studied for weeks (Young *et al.*, 1978). Thicker films of the order of thousands of layers can also be made and, with some experience in depositing the raw material around the aperture and the speed of drawing, it is possible to draw films of almost any desired thickness (Moncton *et al.*, 1982). For films thinner than approximately 20 to 30 molecular layers (*i.e.* 600 to 1000 Å), the thickness is determined from the reflected intensity of a small helium–neon laser. Since the reflected intensities for films of 2, 3, 4, 5, ... layers are in the ratio of 4, 9, 16, 25, ..., the measurement can be calibrated by drawing and measuring a reasonable number of thin films. The most straightforward method for thick films is to measure the ellipticity of the polarization induced in laser light transmitted through the film at an

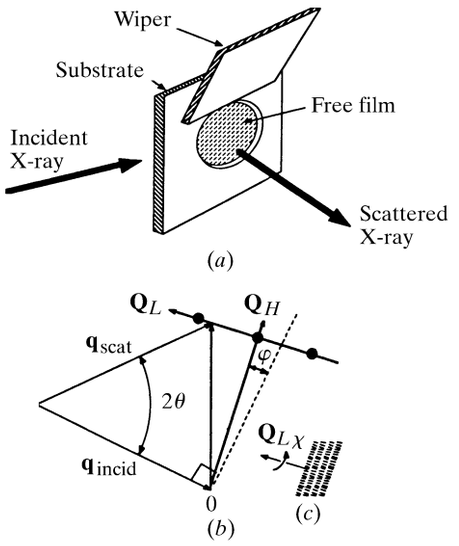

Fig. 4.4.4.1. (*a*) Schematic illustration of the geometry and (*b*) kinematics of X-ray scattering from a freely suspended smectic film. The insert (*c*) illustrates the orientation of the film in real space corresponding to the reciprocal-space kinematics in (*b*). If the angle $\varphi = \theta$, the film is oriented such that the scattering vector is parallel to the surface of the film, *i.e.* parallel to the smectic layers. A 'Q_L scan' is taken by simultaneous adjustment of φ and 2θ to keep $(4\pi/\lambda)\sin(\theta)\cos(\theta - \varphi) = (4\pi/\lambda)\sin(\theta_{100})$, where θ_{100} is the Bragg angle for the 100 reflection. The different in-plane Bragg reflections can be brought into the scattering plane by rotation of the film by the angle χ around the film normal.

oblique angle (Collett, 1983; Collett *et al.*, 1985); however, a subtler method that makes use of the colours of white light reflected from the films is also practical (Sirota, Pershan, Sorensen & Collett, 1987). In certain circumstances, the thickness can also be measured using the X-ray scattering intensity in combination with one of the other methods.

Fig. 4.4.4.1 illustrates the scattering geometry used with these films. Although recent unpublished work has demonstrated the possibility of a reflection geometry (Sorensen, 1987), all of the X-ray scattering studies to be described here were performed in transmission. Since the in-plane molecular spacings are typically between 4 and 5 Å, while the layer spacing is closer to 30 Å, it is difficult to study the 00*L* peaks in this geometry.

Fig. 4.4.4.2 illustrates the difference between X-ray scattering spectra taken on a bulk crystalline-B sample of *N*-[4-(*n*-butyloxy)benzylidene]-4-*n*-octylaniline (4O.8) that was oriented in an external magnetic field while in the nematic phase and then cooled through the smectic-A phase into the crystalline-B phase

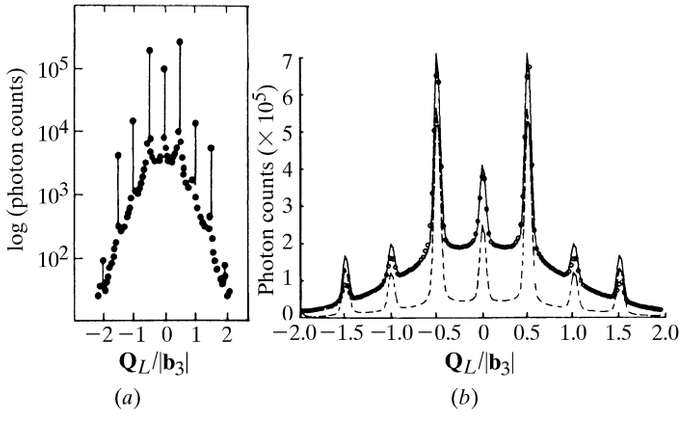

Fig. 4.4.4.2. Typical Q_L scans from the crystalline-B phases of (*a*) a free film of 7O.7, displayed on a logarithmic scale to illustrate the reduced level of the diffuse scattering relative to the Bragg reflection and (*b*) a bulk sample of 4O.8 oriented by a magnetic field.

(Aeppli *et al.*, 1981), and one taken on a thick freely suspended film of *N*-[4-(*n*-heptyloxy)benzylidene]-4-*n*-heptylaniline (7O.7) (Collett *et al.*, 1982, 1985). Note that the data for 7O.7 are plotted on a semi-logarithmic scale in order to display simultaneously both the Bragg peak and the thermal diffuse background. The scans are along the $\mathbf{Q}_L$ direction, at the appropriate value of $\mathbf{Q}_H$ to intersect the peaks associated with the intralayer periodicity. In both cases, the widths of the Bragg peaks are essentially determined by the sample mosaicity and as a result of the better alignment the ratio of the thermal diffuse background to the Bragg peak is nearly an order of magnitude smaller for the free film sample.

4.4.4.1. Hexatic phases in two dimensions

The hexatic phase of matter was first proposed independently by Halperin & Nelson (Halperin & Nelson 1978; Nelson & Halperin 1979) and Young (Young, 1979) on the basis of theoretical studies of the melting process in two dimensions. Following work by Kosterlitz & Thouless (1973), they observed that since the interaction energy between pairs of dislocations in two dimensions decreases logarithmically with their separation, the enthalpy and the entropy terms in the free energy have the same functional dependence on the density of dislocations. It follows that the free-energy difference between the crystalline and hexatic phase has the form $\Delta F = \Delta H - T\Delta \boldsymbol{S} \approx T_c \boldsymbol{S}(\rho) - T\boldsymbol{S}(\rho) = \boldsymbol{S}(\rho)(T_c - T)$, where $\boldsymbol{S}(\rho) \approx \rho \log(\rho)$ is the entropy as a function of the density of dislocations ρ and T_c is defined such that $T_c \boldsymbol{S}(\rho)$ is the enthalpy. Since the prefactor of the enthalpy term is independent of temperature while that of the entropy term is linear, there will be a critical temperature, T_c, at which the sign of the free energy changes from positive to negative. For temperatures greater than T_c, the entropy term will dominate and the system will be unstable against the spontaneous generation of dislocations. When this happens, the two-dimensional crystal, with positional QLRO, but true long-range order in the orientation of neighbouring atoms, can melt into a new phase in which the positional order is short range, but for which there is QLRO in the orientation of the six neighbours surrounding any atom. The reciprocal-space structures for the two-dimensional crystal and hexatic phases are illustrated in Figs. 4.4.4.3(*b*) and (*c*), respectively. That of the two-dimensional solid consists of a hexagonal lattice of sharp rods (*i.e.* algebraic line shapes in the plane of the crystal). For a finite size sample, the reciprocal-space structure of the two-dimensional hexatic phase is a hexagonal lattice of diffuse rods and there are theoretical predictions for the temperature dependence of the in-plane line shapes (Aeppli & Bruinsma, 1984). If the sample were of infinite size, the QLRO of the orientation would spread the six spots continuously around a circular ring, and the pattern would be indistinguishable from that of a well correlated liquid, *i.e.* Fig. 4.4.4.3(*a*). The extent of the patterns along the rod corresponds to the molecular form factor. Figs. 4.4.4.3(*a*), (*b*) and (*c*) are drawn on the assumption that the molecules are normal to the two-dimensional plane of the phase. If the molecules are tilted, the molecular form factor for long thin rod-like molecules will shift the intensity maxima as indicated in Figs. 4.4.4.3(*d*) and (*e*). The phase in which the molecules are normal to the two-dimensional plane is the two-dimensional *hexatic-B phase.* If the molecules tilt towards the position of their nearest neighbours (in real space), or in the direction that is between the lowest-order peaks in reciprocal space, the phase is the two-dimensional *smectic-I*, Fig. 4.4.4.3(*d*). The other tilted phase, for which the tilt direction is between the nearest neighbours in real space or in the direction of the lowest-order peaks in reciprocal space, is the *smectic-F*, Fig. 4.4.4.3(*e*).

Although theory (Halperin & Nelson, 1978; Nelson & Halperin, 1979; Young, 1979) predicts that the two-dimensional crystal can melt into a hexatic phase, it does not say that it must

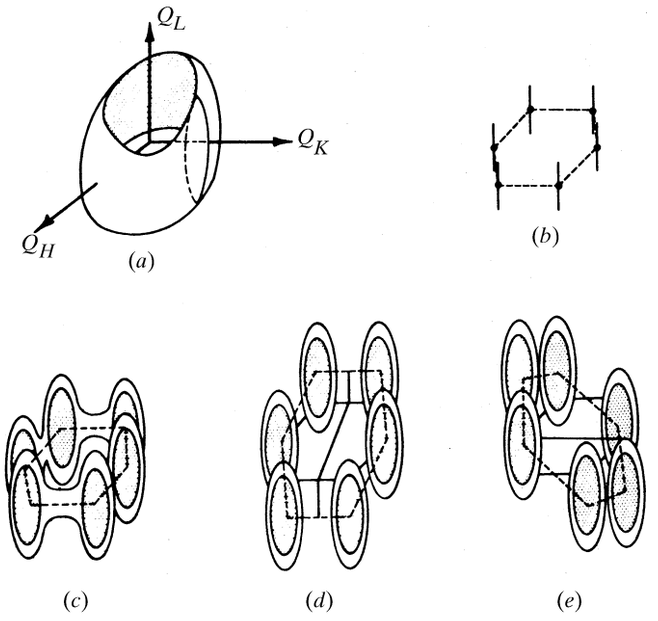

Fig. 4.4.4.3. Scattering intensities in reciprocal space from two-dimensional: (*a*) liquid; (*b*) crystal; (*c*) normal hexatic; and tilted hexatics in which the tilt is (*d*) towards the nearest neighbours as for the smectic-I or (*e*) between the nearest neighbours as for the smectic-F. The thin rods of scattering in (*b*) indicate the singular cusp for peaks with algebraic line shapes in the *HK* plane.

happen, and the crystal can melt directly into a two-dimensional liquid phase. Obviously, the hexatic phases will also melt into a two-dimensional liquid phase. Fig. 4.4.4.3(*a*) illustrates the reciprocal-space structure for the two-dimensional liquid in which the molecules are normal to the two-dimensional surface. Since the longitudinal (*i.e.* radial) width of the hexatic spot could be similar to the width that might be expected in a well correlated fluid, the direct X-ray proof of the transition from the hexatic-B to the normal liquid requires a hexatic sample in which the domains are sufficiently large that the sample is not a two-dimensional powder. On the other hand, the elastic constants must be sufficiently large that the QLRO does not smear the six spots into a circle. The radial line shape of the powder pattern of the hexatic-B phase can also be subtly different from that of the liquid and this is another possible way that X-ray scattering can detect melting of the hexatic-B phase (Aeppli & Bruinsma, 1984).

Changes that occur on the melting of the tilted hexatics, *i.e.* smectic-F and smectic-I, are usually easier to detect and this will be discussed in more detail below. On the other hand, there is a fundamental theoretical problem concerning the way of understanding the melting of the tilted hexatics. These phases actually have the same symmetry as the two-dimensional tilted fluid phase, *i.e.* the smectic-C. In two dimensions they all have QLRO in the tilt orientation, and since the simplest phenomenological argument says that there is a linear coupling between the tilt order and the near-neighbour positional order (Nelson & Halperin, 1980; Bruinsma & Nelson, 1981), it follows that the QLRO of the smectic-C tilt should induce QLRO in the near-neighbour positional order. Thus, by the usual arguments, if there is to be a phase transition between the smectic-C and one of the tilted hexatic phases, the transition must be a first-order transition (Landau & Lifshitz, 1958). This is analogous to the three-dimensional liquid-to-vapour transition which is first order up to a critical point, and beyond the critical point there is no real phase transition.

4.4.4.2. Hexatic phases in three dimensions

Based on both this theory and the various X-ray scattering patterns that had been reported in the literature (Gray & Goodby, 1984), Litster & Birgeneau (Birgeneau & Litster, 1978) suggested that some of the three-dimensional systems that were previously identified as mesomorphic were actually three-dimensional hexatic systems. They observed that it is not theoretically consistent to propose that the smectic phases are layers of two-dimensional crystals randomly displaced with respect to each other since, in thermal equilibrium, the interactions between layers of two-dimensional crystals must necessarily cause the layers to lock together to form a three-dimensional crystal.[1] On the other hand, if the layers were two-dimensional hexatics, then the interactions would have the effect of changing the QLRO of the hexagonal distribution of neighbours into the true long-range-order orientational distribution of the three-dimensional hexatic. In addition, interactions between layers in the three-dimensional hexatics can also result in interlayer correlations that would sharpen the width of the diffuse peaks in the reciprocal-space direction along the layer normal.

4.4.4.2.1. Hexatic-B

Although Leadbetter, Frost & Mazid (1979) had remarked on the different types of X-ray structures that were observed in materials identified as 'smectic-B', the first proof for the existence of the hexatic-B phase of matter was the experiment by Pindak *et al.* (1981) on thick freely suspended films of the liquid crystal *n*-hexyl 4′-pentyloxybiphenyl-4-carboxylate (65OBC). A second study on free films of the liquid crystal *n*-butyl 4′-*n*-hexyloxybiphenyl-4-carboxylate (46OBC) demonstrated that, as the hexatic-B melts into the smectic-A phase, the position and the in-plane width of the X-ray scattering peaks varied continuously. In particular, the in-plane correlation length evolved continuously from 160 Å, nearly 10 K below the hexatic to smectic-A transition, to only 17 Å, a few degrees above. Similar behaviour was also observed in a film only two layers thick (Davey *et al.*, 1984). Since the observed width of the peak along the layer normal corresponded to the molecular form factor, these systems have negligible interlayer correlations.

4.4.4.2.2. Smectic-F, smectic-I

In contrast to the hexatic-B phase, the principal reciprocal-space features of the smectic-F phase were clearly determined before the theoretical work that proposed the hexatic phase. Demus *et al.* (1971) identified a new phase in one material, and subsequent X-ray studies by Leadbetter and co-workers (Leadbetter, Mazid & Richardson, 1980; Leadbetter, Gaughan *et al.*, 1979; Gane & Leadbetter, 1981) and by Benattar and co-workers (Benattar *et al.*, 1978, 1980, 1983; Guillon *et al.*, 1986) showed it to have the reciprocal-space structure illustrated in Fig. 4.4.4.4(*b*). There are interlayer correlations in the three-dimensional smectic-F phases, and as a consequence the reciprocal-space structure has maxima along the diffuse rods. Benattar *et al.* (1979) obtained monodomain smectic-F samples of the liquid crystal *N*,*N*′-(1,4-phenylenedimethylene)bis(4-*n*-pentylaniline) by melting a single crystal that was previously precipitated from solution. One of the more surprising results of this work was the demonstration that the near-neighbour packing was very close to what would be expected from a model in which rigid closely packed rods were simply tilted away from the layer normal. In view of the facts that the molecules are clearly not cylindrical, and that the molecular tilt indicates that the macroscopic symmetry has been broken, it would have been reasonable to expect significant deviations from local hexagonal symmetry when the system is viewed along the molecular axis. The fact that this is not the case indicates that this phase has a considerable amount of rotational disorder around the long axis of the molecules.

[1] Prior to the paper by Birgeneau & Litster, it was commonly believed that some of the smectic phases consisted of uncorrelated stacks of two-dimensional crystals.

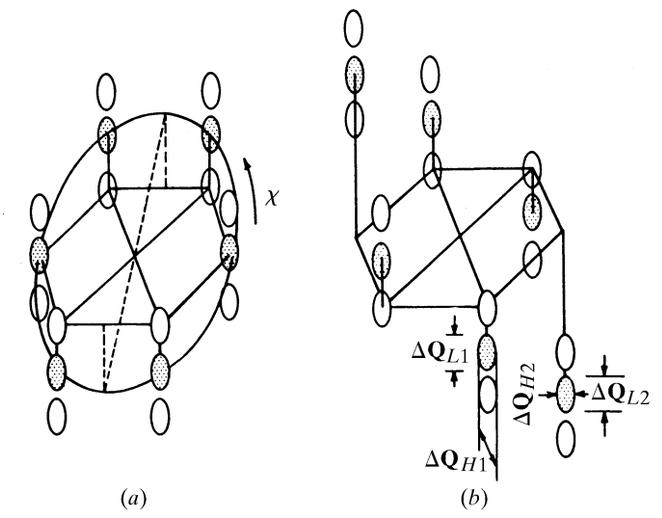

Fig. 4.4.4.4. Scattering intensities in reciprocal space from three-dimensional tilted hexatic phases: (*a*) the smectic-I and (*b*) the smectic-F. The variation of the intensity along the Q_L direction indicates interlayer correlations that are absent in Figs. 4.4.4.1(*d*) and (*e*). The peak widths $\Delta\mathbf{Q}_{L1,2}$ and $\Delta\mathbf{Q}_{H1,2}$ correspond to the four inequivalent widths in the smectic-F phase. Similar inequivalent widths exist for the smectic-I phase. The circle through the shaded points in (*a*) indicates the reciprocal-space scan that directly measures the hexatic order. A similar scan in the smectic-C phase would have intensity independent of χ.

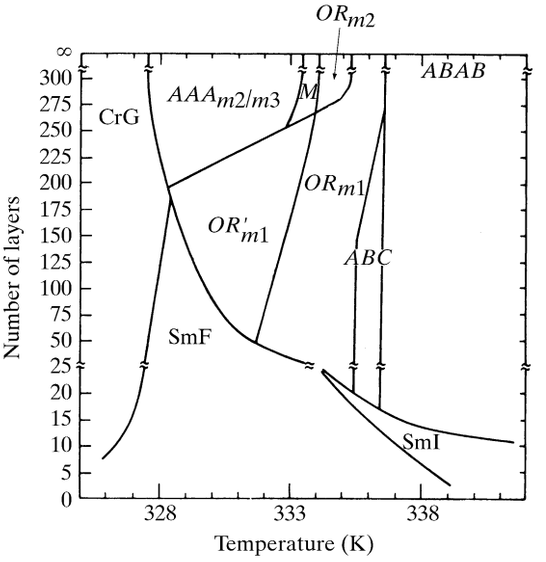

Fig. 4.4.4.5. The phase diagram for free films of 7O.7 as a function of thickness and temperature. The phases *ABAB*, *AAA*, OR_{m1}, OR_{m2}, OR'_{m1}, *M* and *ABAB* are all crystalline-B with varying interlayer stacking, or long-wavelength modulations; CrG, SmF and SmI are crystalline-G, smectic-F and smectic-I, respectively (Sirota *et al.*, 1985; Sirota, Pershan & Deutsch, 1987; Sirota, Pershan, Sorensen & Collett, 1987).

Other important features of the smectic-F phase are, firstly, that the local molecular packing is identical to that of the tilted crystalline-G phase (Benattar *et al.*, 1979; Sirota *et al.*, 1985; Guillon *et al.*, 1986). Secondly, there is considerable temperature dependence of the widths of the various diffuse peaks. Fig. 4.4.4.4(*b*) indicates the four inequivalent line widths that Sirota and co-workers measured in freely suspended films of the liquid crystal *N*-[4-(*n*-heptyloxy)benzylidene]-4-*n*-heptyl aniline (7O.7). Parenthetically, bulk samples of this material do not have a smectic-F phase; however, the smectic-F is observed in freely suspended films as thick as ∼200 layers. Fig. 4.4.4.5 illustrates the thickness–temperature phase diagram of 7O.7 between 325 and 342 K (Sirota *et al.*, 1985; Sirota, Pershan & Deutsch, 1987). Bulk samples and thick films have a first-order transition from the crystalline-B to the smectic-C at 342 K. Thinner films indicate a surface phase above 342 K that will be discussed below. Furthermore, although there is a strong temperature dependence of the widths of the diffuse scattering peaks, the widths are independent of film thickness. This demonstrates that, although the free film boundary conditions have stabilized the smectic-F phase, the properties of the phase are not affected by the boundaries. Finally, the fact that the widths $\Delta\mathbf{Q}_{L1}$ and $\Delta\mathbf{Q}_{L2}$ along the **L** direction and $\Delta\mathbf{Q}_{H1}$ and $\Delta\mathbf{Q}_{H2}$ along the in-plane directions are not equal indicates that the correlations are very anisotropic (Brock *et al.*, 1986; Sirota *et al.*, 1985). We will discuss one possible model for these properties after presenting other data on thick films of 7O.7. From the fact that the positions of the intensity maxima for the diffuse spots of the smectic-F phase of 7O.7 correspond exactly to the positions of the Bragg peaks in the crystalline-G phase, we learn that the local molecular packing must be identical in the two phases. The major difference between the crystalline-G and the tilted hexatic smectic-F phase is that, in the latter, defects destroy the long-range positional order of the former (Benattar *et al.*, 1979; Sirota *et al.*, 1985). Although this is consistent with the existing theoretical model that attributes hexatic order to a proliferation of unbounded dislocations, it is not obvious that the proliferation is attributable to the same Kosterlitz–Thouless mechanism that Halperin & Nelson and Young discussed for the transition from the two-dimensional crystal to the hexatic phase. We will say more on this point below.

The only identified difference between the two tilted hexatic phases, the smectic-F and the smectic-I, is the direction of the molecular tilt relative to the near-neighbour positions. For the smectic-I, the molecules tilt towards one of the near neighbours, while for the smectic-F they tilt between the neighbours (Gane & Leadbetter, 1983). There are a number of systems that have both smectic-I and smectic-F phases, and in all cases of which we are aware the smectic-I is the higher-temperature phase (Gray & Goodby, 1984; Sirota *et al.*, 1985; Sirota, Pershan, Sorensen & Collett, 1987).

Optical studies of freely suspended films of materials in the *n*O.*m* series indicated tilted surface phases at temperatures for which the bulk had uniaxial phases (Farber, 1985). As mentioned above, X-ray scattering studies of 7O.7 demonstrated that the smectic-F phase set in for a narrow temperature range in films as thick as 180 layers, and that the temperature range increases with decreasing layer number. For films of the order of 25 layers thick, the smectic-I phase is observed at approximately 334 K, and with decreasing thickness the temperature range for this phase also increases. Below approximately 10 to 15 layers, the smectic-I phase extends up to ∼342 K where bulk samples undergo a first-order transition from the crystalline-B to the smectic-C phase. Synchrotron X-ray scattering experiments show that, in thin films (five layers for example), the homogeneous smectic-I film undergoes a first-order transition to one in which the two surface layers are smectic-I and the three interior layers are smectic-C (Sirota *et al.*, 1985; Sirota, Pershan, Sorensen & Collett, 1987). The fact that two phases with the same symmetry can coexist in this manner tells us that in this material there is some important microscopic difference between them. This is reaffirmed by the fact that the phase transition from the surface smectic-I to the homogeneous smectic-C phase has been observed to be first order (Sorensen *et al.*, 1987).

In contrast to 7O.7, Birgeneau and co-workers found that in racemic 4-(2-methylbutyl)phenyl 4′-octyloxylbiphenyl-4-carboxylate (8OSI) (Brock *et al.*, 1986), the X-ray structure of the smectic-I phase evolves continuously into that of the smectic-C. By applying a magnetic field to a thick freely suspended sample, Brock *et al.* were able to obtain a large monodomain sample.

They measured the X-ray scattering intensity around the circle in the reciprocal-space plane shown in Fig. 4.4.4.4(*b*) that passes through the peaks. For higher temperatures, when the sample is in the smectic-C phase, the intensity is essentially constant around the circle; however, on cooling, it gradually condenses into six peaks, separated by 60°. The data were analysed by expressing the intensity as a Fourier series of the form

$$S(\chi) = I_0\left[\tfrac{1}{2} + \sum_{n=1}^{\infty} C_{6n}\cos 6n(90^\circ - \chi)\right] + I_{\rm B},$$

where I_0 fixes the absolute intensity and $I_{\rm B}$ fixes the background. The temperature variation of the coefficients scaled according to the relation $C_{6n} = C_6^{\sigma n}$ where the empirical relation $\sigma_n = 2.6(n-1)$ is in good agreement with a theoretical form predicted by Aharony *et al.* (1986). The only other system in which this type of measurement has been made was the smectic-C phase of 7O.7 (Collett, 1983). In that case, the intensity around the circle was constant, indicating the absence of any tilt-induced bond orientational order (Aharony *et al.*, 1986).

It would appear that the near-neighbour molecular packing of the smectic-I and the crystalline-J phases is the same, in just the same way as for the packing of the smectic-F and the crystalline-G phases. The four smectic-I widths analogous to those illustrated in Fig. 4.4.4.4(*a*) are, like that of the smectic-F, both anisotropic and temperature dependent (Sirota *et al.*, 1985; Sirota, Pershan, Sorensen & Collett, 1987; Brock *et al.*, 1986; Benattar *et al.*, 1979).

4.4.4.3. Crystalline phases with molecular rotation

4.4.4.3.1. Crystal-B

Recognition of the distinction between the hexatic-B and crystalline-B phases provided one of the more important keys to understanding the ordered mesomorphic phases. There are a number of distinct phases called crystalline-B that are all true three-dimensional crystals, with resolution-limited Bragg peaks (Moncton & Pindak, 1979; Aeppli *et al.*, 1981). The feature common to them all is that the average molecular orientation is normal to the layers, and within each layer the molecules are distributed on a triangular lattice. In view of the 'blade-like' shape of the molecule, the hexagonal site symmetry implies that the molecules must be rotating rapidly (Levelut & Lambert, 1971; Levelut, 1976; Richardson *et al.*, 1978). We have previously remarked that this apparent rotational motion characterizes all of the phases listed in Table 4.4.1.1 except for the crystalline-E, -H and -K. In the most common crystalline-B phase, adjacent layers have *ABAB*-type stacking (Leadbetter, Gaughan *et al.*, 1979; Leadbetter, Mazid & Kelly, 1979). High-resolution studies on well oriented samples show that in addition to the Bragg peaks the crystalline-B phases have rods of relatively intense diffuse scattering distributed along the 10*L* Bragg peaks (Moncton & Pindak, 1979; Aeppli *et al.*, 1981). The widths of these rods in the reciprocal-space direction, parallel to the layers, are very sharp, and without a high-resolution spectrometer their widths would appear to be resolution limited. In contrast, along the reciprocal-space direction normal to the layers, their structure corresponds to the molecular form factor.

If the intensity of the diffuse scattering can be represented as proportional to $\langle \mathbf{Q}\cdot\mathbf{u}\rangle^2$, where $\mathbf{u}$ describes the molecular displacement, the fact that there is no rod of diffuse scattering through the 00*L* peaks indicates that the rods through the 10*L* peaks originate from random disorder in 'sliding' displacements of adjacent layers. It is likely that these displacements are thermally excited phonon vibrations; however, we cannot rule out some sort of non-thermal static defect structure. In any event, assuming this diffuse scattering originates in a thermal vibration for which adjacent layers slide over one another with some amplitude $\langle \mathbf{u}^2\rangle^{1/2}$, and assuming strong coupling between this shearing motion and the molecular tilt, we can define an angle $\varphi = \tan^{-1}(\langle \mathbf{u}^2\rangle^{1/2}/d)$, where d is the layer thickness. The observed diffuse intensity corresponds to angles φ between 3 and 6° (Aeppli *et al.*, 1981).

Leadbetter and co-workers demonstrated that in the *n*O.*m* series various molecules undergo a series of restacking transitions and that crystalline-B phases exist with *ABC* and *AAA* stacking as well as the more common *ABAB* (Leadbetter, Mazid & Richardson 1980; Leadbetter, Mazid & Kelly, 1979). Subsequent high-resolution studies on thick freely suspended films revealed that the restacking transitions were actually subtler, and in 7O.7, for example, on cooling the hexagonal *ABAB* phase one observes an orthorhombic and then a monoclinic phase before the hexagonal *AAA* (Collett *et al.*, 1982, 1985). Furthermore, the first transition from the hexagonal *ABAB* to the monoclinic phase is accompanied by the appearance of a relatively long-wavelength modulation within the plane of the layers. The polarization of this modulation is along the layer normal, or orthogonal to the polarization of the displacements that gave rise to the rods of thermal diffuse scattering (Gane & Leadbetter, 1983).

It is also interesting to note that the *AAA* simple hexagonal structure does not seem to have been observed outside liquid-crystalline materials and, were it not for the fact that the crystalline-B hexagonal *AAA* is always accompanied by long-wavelength modulations, it would be the only case of which we are aware.

Figs. 4.4.4.6(*a*) and (*b*) illustrate the reciprocal-space positions of the Bragg peaks (dark dots) and modulation-induced side bands (open circles) for the unmodulated hexagonal *ABAB* and the modulated orthorhombic phase (Collett *et al.*, 1984). For convenience, we only display one 60° sector. Hirth *et al.* (1984) explained how both the reciprocal-space structure and the modulation of the orthorhombic phase could result from an ordered array of partial dislocations. They were not, however, able to provide a specific model for the microscopic driving force for the transition. Sirota, Pershan & Deutsch (1987) proposed a variation of the Hirth model in which the dislocations pair up to form a wall of dislocation dipoles such that within the wall the local molecular packing is essentially identical to the packing in the crystalline-G phase that appears at temperatures just below the crystalline-B phase. This model explains: (1) the macroscopic symmetry of the phase; (2) the period of the modulation; (3) the polarization of the modulation; and (4) the size of the observed deviations of the reciprocal-space structure from the hexagonal symmetry of the *ABAB* phase and suggests a microscopic driving mechanism that we will discuss below.

On further cooling, there is a first-order transition in which the one-dimensional modulation that appeared at the transition to orthorhombic symmetry is replaced by a two-dimensional modulation as shown in Fig. 4.4.4.6(*c*). On further cooling, there is another first-order transition in which the positions of the principal Bragg spots change from having orthorhombic to monoclinic symmetry as illustrated in Fig. 4.4.4.6(*d*). On further cooling, the Bragg peaks shift continually until there is one more first-order transition to a phase with hexagonal *AAA* positions as illustrated in Fig. 4.4.4.6(*f*). On further cooling, the *AAA* symmetry remains unchanged, and the modulation period is only slightly dependent on temperature, but the modulation amplitude increases dramatically. Eventually, as indicated in the phase diagram shown in Fig. 4.4.4.5, the system undergoes another first-order transition to the tilted crystalline-G phase. The patterns in Figs. 4.4.4.6(*e*) and (*g*) are observed by rapid quenching from the temperatures at which the patterns in Fig. 4.4.4.6(*b*) are observed.

Although there is not yet an established theoretical explanation for the origin of the 'restacking-modulation' effects, there are a number of experimental facts that we can summarize, and which indicate a probable direction for future research. Firstly, if one ignores the long-wavelength modulation, the hexagonal *ABAB* phase is the only phase in the diagram for 7O.7 for which

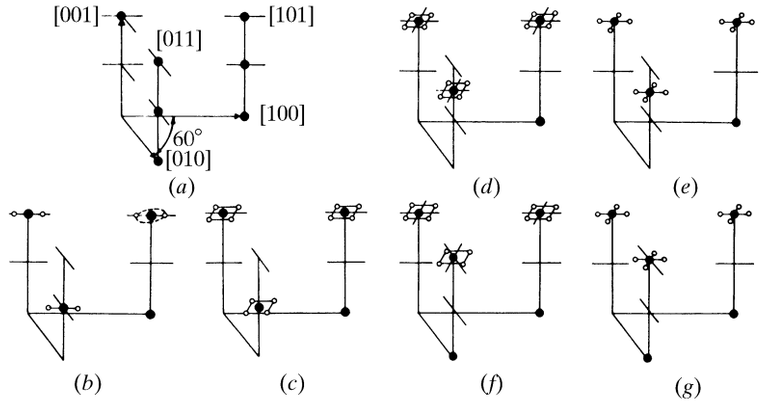

Fig. 4.4.4.6. Location of the Bragg peaks in one 60° section of reciprocal space for the three-dimensional crystalline-B phases observed in thick films of 7O.7. (*a*) The normal hexagonal crystalline-B phase with *ABAB* stacking. (*b*) The one-dimensional modulated phase with orthorhombic symmetry. The closed circles are the principal Bragg peaks and the open circles indicate side bands associated with the long-wavelength modulation. (*c*) The two-dimensional modulated phase with orthorhombic symmetry. Only the lowest-order side bands are shown. They are situated on the corners of squares surrounding the Bragg peak. The squares are oriented as shown and the amplitude of the square diagonal is equal to the distance between the two side bands illustrated in (*b*). (*d*) The two-dimensional modulated phase with monoclinic symmetry. Note that the *L* position of one of the peaks has shifted relative to (*c*). (*e*) A two-dimensional modulated phase with orthorhombic symmetry that is only observed on heating the quenched phase illustrated in (*g*). (*f*) The two-dimensional modulated phase with hexagonal symmetry and *AAA* layer stacking. (*g*) A two-dimensional hexagonal phase with *AAA* layer stacking that is only observed on rapid cooling from the phase shown in (*c*).

there are two molecules per unit cell. There must be some basic molecular effect that determines this particular coupling between every other layer. In addition, it is particularly interesting that it only manifests itself for a small temperature range and then vanishes as the sample is cooled. Secondly, any explanation for the driving force of the restacking transition must also explain the modulations that accompany it. In particular, unless one cools rapidly, the same modulation structures with the same amplitudes always appear at the same temperature, regardless of the sample history, *i.e.* whether heating or cooling. No significant hysteresis is observed and Sirota argued that the structures are in thermal equilibrium.

There are a number of physical systems for which the development of long-wavelength modulations is understood, and in each case they are the result of two or more competing interaction energies that cannot be simultaneously minimized (Blinc & Levanyuk, 1986; Safinya, Varady *et al.*, 1986; Lubensky *et al.*, 1988; Winkor & Clarke, 1986; Moncton *et al.*, 1981; Fleming *et al.*, 1980; Villain, 1980; Frank & van der Merwe, 1949; Bak *et al.*, 1979; Pokrovsky & Talapov, 1979). The easiest to visualize is epitaxic growth of one crystalline phase on the surface of another when the two lattice vectors are slightly incommensurate. The first atomic row of adsorbate molecules can be positioned to minimize the attractive interactions with the substrate. This is slightly more difficult for the second row, since the distance that minimizes the interaction energy between the first and second rows of adsorbate molecules is not necessarily the same as the distance that would minimize the interaction energy between the first row and the substrate. As more and more rows are added, the energy price of this incommensurability builds up, and one possible configuration that minimizes the global energy is a modulated structure.

In all known cases, the very existence of modulated structures implies that there must be competing interactions, and the only real question about the modulated structures in the crystalline-B phases is the identification of the competing interactions. It appears that one of the more likely possibilities is the difficulty in packing the 7O.7 molecules within a triangular lattice while simultaneously optimizing the area per molecule of the alkane tails and the conjugated rings in the core (Carlson & Sethna, 1987; Sadoc & Charvolin, 1986). Typically, the mean cross-sectional area for a straight alkane in the all-*trans* configuration is between 18 and 19 Å^2, while the mean area per molecule in the crystalline-B phase is closer to 24 Å^2. While these two could be reconciled by assuming that the alkanes are tilted with respect to the conjugated core, there is no reason why the angle that reconciles the two should also be the same angle that minimizes the internal energy of the molecule. Even if it were the correct angle at some temperature by accident, the average area per chain is certainly temperature dependent. Even without attempting to include the rotational dynamics that are necessary to understanding the axial site symmetry, it is obvious that there can be a conflict in the packing requirements of the two different parts of the molecule.

A possible explanation of these various structures might be as follows: at high temperatures, both the alkane chain, as well as the other degrees of freedom, have considerable thermal motions that make it possible for the conflicting packing requirements to be simultaneously reconciled by one or another compromise. On the other hand, with decreasing temperature, some of the thermal motions become frozen out, and the energy cost of the reconciliation that was possible at higher temperatures becomes too great. At this point, the system must find another solution, and the various modulated phases represent the different compromises. Finally, all of the compromises involving inhomogeneities, like the modulations or grain boundaries, become impossible and the system transforms into a homogeneous crystalline-G phase.

If this type of argument could be made more specific, it would also provide a possible explanation for the molecular origin of the three-dimensional hexatic phases. The original suggestion for the existence of hexatic phases in two dimensions was based on the fact that the interaction energy between dislocations in two dimensions was logarithmic, such that the entropy and the enthalpy had the same functional dependence on the density of dislocations. This gave rise to the observation that above a certain temperature two-dimensional crystals would be unstable against thermally generated dislocations. Although Litster and Birgeneau's suggestion that some of the observed smectic phases might be stacks of two-dimensional hexatics is certainly correct, it is not necessary that the observed three-dimensional hexatics originate from entropy-driven thermally excited dislocations. For example, the temperature–layer-number phase diagram for 7O.7 that is shown in Fig. 4.4.4.5 has the interesting property that the temperature region over which the tilted hexatic phases exist in thin films is almost the same as the temperature region for which the modulated phases exist in thick films and in bulk samples.

From the fact that molecules in the *n*O.*m* series that only differ by one or two $-CH_2-$ groups have different sequences of mesomorphic phases, we learn that within any one molecule the

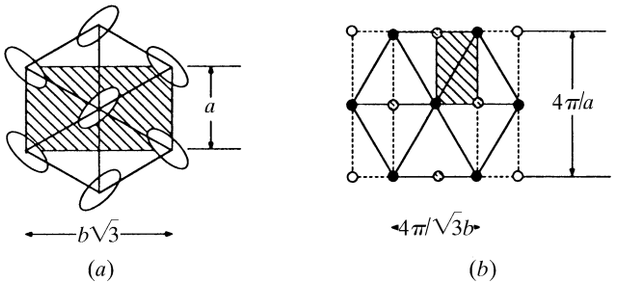

Fig. 4.4.4.7. (*a*) The 'herringbone' stacking suggested for the crystalline-E phase in which molecular rotation is partially restricted. The primitive rectangular unit cell containing two molecules is illustrated by the shaded region. The lattice has rectangular symmetry and $a \neq b$. (*b*) The position of the Bragg peaks in the plane in reciprocal space that is parallel to the layers. The dark circles indicate the principal Bragg peaks that would be the only ones present if all molecules were equivalent. The open circles indicate additional peaks that are observed for the model illustrated in (*a*). The cross-hatched circles indicate peaks that are missing because of the glide plane in (*a*).

difference in chemical potentials between the different mesomorphic phases must be very small (Leadbetter, Mazid & Kelly, 1979; Doucet & Levelut, 1977; Leadbetter, Frost & Mazid, 1979; Leadbetter, Mazid & Richardson, 1980; Smith *et al.*, 1973; Smith & Garland, 1973). For example, although in 7O.7 the smectic-F phase is only observed in finite-thickness films, both 5O.6 and 9O.4 have smectic-F phase in bulk. Thus, in bulk 7O.7 the chemical potential for the smectic-F phase must be only slightly larger than that of the modulated crystalline-B phases, and the effect of the surfaces must be sufficient to reverse the order in samples of finite thickness.

As far as the appearance of the smectic-F phase in 7O.7 is concerned, it is well known that the interaction energy between dislocation pairs is very different near a free surface from that in the bulk (Pershan, 1974; Pershan & Prost, 1975). The origin of this is that the elastic properties of the surface will usually cause the stress field of a dislocation near to the surface either to vanish or to be considerably smaller than it would in the bulk. Since the interaction energy between dislocations depends on this stress field, the surface significantly modifies the dislocation–dislocation interaction. This is a long-range effect, and it would not be surprising if the interactions that stabilized the dislocation arrays to produce the long-wavelength modulations in the thick samples were sufficiently weaker in the samples of finite thickness that the dislocation arrays are disordered. Alternatively, there is evidence that specific surface interactions favour a finite molecular tilt at temperatures where the bulk phases are uniaxial (Farber, 1985). Incommensurability between the period of the tilted surface molecules and the crystalline-B phases below the surface would increase the density of dislocations, and this would also modify the dislocation–dislocation interactions in the bulk.

Sirota *et al.* (1985) and Sirota, Pershan, Sorensen & Collett (1987) demonstrated that, while the correlation lengths of the smectic-F phase have a significant temperature dependence, the lengths are independent of film thickness, and this supports the argument that although the effects of the surface are important in stabilizing the smectic-F phase in 7O.7, once the phase is established it is essentially no different from the smectic-F phases observed in bulk samples of other materials. Brock *et al.* (1986) observed anisotropies in the correlation lengths of thick samples of 8OSI that are similar to those observed by Sirota.

These observations motivate the hypothesis that the dislocation densities in the smectic-F phases are determined by the same incommensurability that gives rise to the modulated crystalline-B structures. Although all of the experimental evidence supporting this hypothesis was obtained from the smectic-F tilted hexatic phase, there is no reason why this speculation could not apply to both the tilted smectic-I and the untilted hexatic-B phase.

4.4.4.3.2. Crystal-G, crystal-J

The crystalline-G and crystalline-J phases are the ordered versions of the smectic-F and smectic-I phases, respectively. The positions of the principal peaks illustrated in Fig. 4.4.4.4 for the smectic-F(I) are identical to the positions in the smectic-G(J) phase if small thermal shifts are discounted. In both the hexatic and the crystalline phases, the molecules are tilted with respect to the layer normals by approximately 25 to 30° with nearly hexagonal packing around the tilted axis (Doucet & Levelut, 1977; Levelut *et al.*, 1974; Levelut, 1976; Leadbetter, Mazid & Kelly, 1979; Sirota, Pershan, Sorensen & Collett, 1987). The interlayer molecular packing appears to be end to end, in an *AAA* type of stacking (Benattar *et al.*, 1983, 1981; Levelut, 1976; Gane *et al.*, 1983). There is only one molecule per unit cell and there is no evidence for the long-wavelength modulations that are so prevalent in the crystalline-B phase that is the next higher temperature phase above the crystalline-G in 7O.7.

4.4.4.4. Crystalline phases with herringbone packing

4.4.4.4.1. Crystal-E

Fig. 4.4.4.7 illustrates the intralayer molecular packing proposed for the crystalline-E phase (Levelut, 1976; Doucet, 1979; Levelut *et al.*, 1974; Doucet *et al.*, 1975; Leadbetter *et al.*, 1976; Richardson *et al.*, 1978; Leadbetter, Frost, Gaughan & Mazid, 1979; Leadbetter, Frost & Mazid, 1979). The molecules are, on average, normal to the layers; however, from the optical birefringence it is apparent that the site symmetry is not uniaxial. X-ray diffraction studies on single crystals by Doucet and co-workers demonstrated that the biaxiality was not attributable to molecular tilt and subsequent work by a number of others resulted in the arrangement shown in Fig. 4.4.4.7(*a*). The most important distinguishing reciprocal-space feature associated with the intralayer 'herringbone' packing is the appearance of Bragg peaks at $\sin(\theta)$ equal to $\sqrt{7}/2$ times the value for the lowest-order in-plane Bragg peak for the triangular lattice (Pindak *et al.*, 1981). These are illustrated by the open circles in Fig. 4.4.4.7(*b*). The shaded circles correspond to peaks that are missing because of the glide plane that relates the two molecules in the rectangular cell.

Leadbetter, Mazid & Malik (1980) carried out detailed studies on both the crystalline-E phase of isobutyl 4-(4-phenylbenzylideneamino)cinnamate (IBPBAC) and the crystalline phase immediately below the crystalline-E phase. Partially ordered samples of the crystalline-E phase were obtained by melting the lower-temperature crystalline phase. Although the data for the crystalline-E phase left some ambiguity, they argued that the phase they were studying might well have had molecular tilts of the order of 5 or 6°. This is an important distinction, since the crystalline-H and crystalline-J phases are essentially tilted versions of the crystalline-E. Thus, one important symmetry difference that might distinguish the crystalline-E from the others is the presence of a mirror plane parallel to the layers. In view of the low symmetry of the individual molecules, the existence of such a mirror plane would imply residual molecular motions. In fact, using neutron diffraction Leadbetter *et al.* (1976) demonstrated for a different liquid crystal that, even though the site symmetry is not axially symmetric, there is considerable residual rotational motion in the crystalline-E phase about the long axis of the molecules. Since the in-plane spacing is too small for neighbouring molecules to be rotating independently of each other, they proposed what might be interpreted as large partially hindered rotations.

4.4.4.4.2. Crystal-H, crystal-K

The crystalline-H and crystalline-K phases are tilted versions of the crystalline-E. The crystalline-H is tilted in the direction between the near neighbours, with the convenient mnemonic that

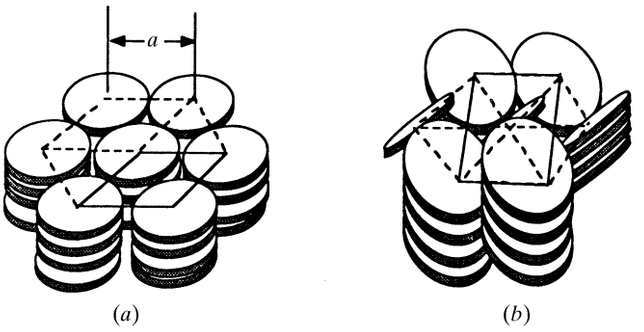

Fig. 4.4.5.1. Schematic illustration of the molecular stacking for the discotic (*a*) D_2 and (*b*) D_1 phases. In neither of these two phases is there any indication of long-range positional order along the columns. The hexagonal symmetry of the D_1 phase is broken by 'herringbone-like' correlations in the molecular tilt from column to column.

on cooling the sequence of phases with the same relative orientation of tilt to near-neighbour position is F → G → H. Similarly, the tilt direction for the crystalline-K phase is similar to that of the smectic-I and crystalline-J so that the expected phase sequence on cooling might be I → J → K. In fact, both of these sequences are only intended to indicate the progression in lower symmetry; the actual transitions vary from material to material.

4.4.5. Discotic phases

In contrast to the long thin rod-like molecules that formed most of the other phases discussed in this chapter, the discotic phases are formed by molecules that are more disc-like [see Fig. 4.4.1.3(*f*), for example]. There was evidence that mesomorphic phases were formed from disc-like molecules as far back as 1960 (Brooks & Taylor, 1968); however, the first identification of a discotic phase was by Chandrasekhar *et al.* (1977) with benzenehexyl hexa-*n*-alkanoate compounds. Disc-like molecules can form either a fluid nematic phase in which the disc normals are aligned, without any particular long-range order at the molecular centre of mass, or more-ordered 'columnar' (Helfrich, 1979) or 'discotic' (Billard *et al.*, 1981) phases in which the molecular positions are correlated such that the discs stack on top of one another to form columns. Some of the literature designates this nematic phase as N_D to distinguish it from the phase formed by 'rod-like' molecules (Destrade *et al.*, 1983). In the same way that the appearance of layers characterizes order in smectic phases, the order for the discotic phases is characterized by the appearance of columns. Chandrasekhar (1982, 1983) and Destrade *et al.* (1983) have reviewed this area and have summarized the several notations for various phases that appear in the literature. Levelut (1983) has also written a review and presented a table listing the space groups for columnar phases formed by 18 different molecules. Unfortunately, it is not absolutely clear which of these are mesomorphic phases and which are crystals with true long-range positional order.

Fig. 4.4.5.1 illustrates the molecular packing in two of the well identified discotic phases that are designated as D_1 and D_2 (Chandrasekhar, 1982). The phase D_2 consists of a hexagonal array of columns for which there is no intracolumnar order. The system is uniaxial and, as originally proposed, the molecular normals were supposed to be along the column axis. However, recent X-ray scattering studies on oriented free-standing fibres of the D_2 phase of triphenylene hexa-*n*-dodecanoate indicate that the molecules are tilted with respect to the layer normal (Safinya *et al.*, 1985, 1984). The D_1 phase is definitely a tilted phase, and consequently the columns are packed in a rectangular cell. According to Safinya *et al.*, the D_1 to D_2 transition corresponds to an order–disorder transition in which the molecular tilt orientation is ordered about the column axis in the D_1 phase and disordered in the D_2 phase. The reciprocal-space structure of the D_1 phase is similar to that of the crystalline-E phase shown in Fig. 4.4.4.7(*b*).

Other discotic phases that have been proposed would have the molecules arranged periodically along the column, but disordered between columns. This does not seem physically realistic since it is well known that thermal fluctuations rule out the possibility of a one-dimensional periodic structure even more strongly than for the two-dimensional lattice that was discussed above (Landau, 1965; Peierls, 1934). On the other hand, in the absence of either more high-resolution studies on oriented fibres or further theoretical studies, we prefer not to speculate on the variety of possible true discotic or discotic-like crystalline phases that might exist. This is a subject for future research.

4.4.6. Other phases

We have deliberately chosen not to discuss the properties of the cholesteric phase in this chapter because the length scales that characterize the long-range order are of the order of micrometres and are more easily studied by optical scattering than by X-rays (De Gennes, 1974; De Vries, 1951). Nematic phases formed from chiral molecules develop long-range order in which the orientation of the director $\langle \mathbf{n} \rangle$ varies in a plane-wave-like manner that can be described as $\mathbf{x}\cos(2\pi z/\lambda) + \mathbf{y}\sin(2\pi z/\lambda)$, where $\mathbf{x}$ and $\mathbf{y}$ are unit vectors and $\lambda/2$ is the cholesteric 'pitch' that can be anywhere from 0.1 to 10 μm depending on the particular molecule. Even more interesting is that for many cholesteric systems there is a small temperature range, of the order of 1 K, between the cholesteric and isotropic phases for which there is a phase known as the 'blue phase' (Coates & Gray, 1975; Stegemeyer & Bergmann, 1981; Meiboom *et al.*, 1981; Bensimon *et al.*, 1983; Hornreich & Shtrikman, 1983; Crooker, 1983). In fact, there is more than one 'blue phase' but they all have the property that the cholesteric twist forms a three-dimensional lattice twisted network rather than the plane-wave-like twist of the cholesteric phase. Three-dimensional Bragg scattering from blue phases using laser light indicates cubic lattices; however, since the optical cholesteric interactions are much stronger than the usual interactions between X-rays and atoms, interpretation of the results is subtler.

Gray and Goodby discuss a 'smectic-D' phase that is otherwise omitted from this chapter (Gray & Goodby, 1984). Gray and coworkers first observed this phase in the homologous series of 4′-*n*-alkoxy-3′-nitrobiphenyl-4-carboxylic acids (Gray *et al.*, 1957). In the hexadecyloxy compound, this phase exists for a region of about 26 K between the smectic-C and smectic-A phases: smectic-C (444.2 K) smectic-D (470.4 K) smectic-A. It is optically isotropic and X-ray studies by Diele *et al.* (1972) and by Tardieu & Billard (1976) indicate a number of similarities to the 'cubic–isotropic' phase observed in lyotropic systems (Luzzati & Riess-Husson, 1966; Tardieu & Luzzati, 1970). More recently, Etherington *et al.* (1986) studied the 'smectic-D' phase of 3′-cyano-4′-*n*-octadecyloxybiphenyl-4-carboxylic acid. Since this material appears to be more stable than some of the others that were previously studied, they were able to perform sufficient measurements to determine that the space group is cubic $P23$ or $Pm3$ with a lattice parameter of 86 Å. Etherington *et al.* suggested that the 'smectic-D' phase that they studied is a true three-dimensional cubic crystal of micelles and noted that the designation of 'smectic-D' is not accurate. Guillon & Skoulios (1987) have proposed a molecular model for this and related phases.

Fontell (1974) has reviewed the literature on the X-ray diffraction studies of lyotropic mesomorphic systems and the reader is referred there for more extensive information on those cubic systems. The mesomorphic structures of lyotropic systems are much richer than those of the thermotropic and, in addition

to all structures mentioned here, there are lyotropic systems in which the smectic-A lamellae seem to break up into cylindrical rods which seem to have the same macroscopic symmetry as some of the discotic phases. On the other hand, it is also much more difficult to prepare a review for the lyotropic systems in the same type of detail as for the thermotropic. The extra complexity associated with the need to control water concentration as well as temperature has made both theoretical and experimental progress more difficult, and, since there has not been very much experimental work on well oriented samples, detailed knowledge of many of these phases is also limited. Aside from the simpler lamellae systems, which seem to have the same symmetry as the thermotropic smectic-A phase, it is not at all clear which of the other phases are three-dimensional crystals and which are true mesomorphic structures. For example, dipalmitoylphosphatidylcholine has an L_β phase that appears for temperatures and (or) water content that is lower than that of the smectic-A L_α phase (Shipley *et al.*, 1974; Small, 1967; Chapman *et al.*, 1967). The diffraction pattern for this phase contains sharp large-angle reflections that may well correspond to a phase that is like one of the crystalline phases listed in Tables 4.4.1.1 and 4.4.1.2, and Fig. 4.4.1.1. On the other hand, this phase could also be hexatic and we do not have sufficient information to decide. The interested reader is referred to the referenced articles for further detailed information.

4.4.6.1. Phases with intermediate molecular tilt: smectic-L, crystalline-M,N

Following the completion of this manuscript, Smith and coworkers (Smith *et al.*, 1988; Sirota *et al.*, 1988) published an X-ray scattering study of the structure of a freely suspended multilayer film of hydrated phosphatidylcholine in which the phase that had been designated $L_{B'}$ in the literature on lipid phases (Janiak *et al.*, 1979; Luzzati, 1968; Tardieu *et al.*, 1973) was shown to consist of three separate two-dimensional phases in which the positional order in adjacent layers is uncoupled. The three phases are distinguished by the direction of the alkane-chain tilt relative to the nearest neighbours, and in one of these phases the orientation varies continuously with increasing hydration. At the lowest hydration, they observe a phase in which the tilt is towards the second-nearest neighbour; in analogy to the smectic-F phase, they designate this phase $L_{\beta F}$. On increasing hydration, they observe a phase in which the tilt direction is intermediate between the nearest- and next-nearest-neighbour directions, and which varies continuously with hydration. This is a new phase that was not previously known and they designate it $L_{\beta L}$. On further hydration, they observe a phase in which the molecular tilt is towards a nearest neighbour and this is designated $L_{\beta I}$. At maximum hydration, they observe the phase with long-wavelength modulation that was previously designated P_β (Janiak *et al.*, 1979). Selinger & Nelson (1988) have subsequently developed a theory for the phase transitions between phases with varying tilt orientation and have rationalized the existence of phases with intermediate tilt. To be complete, both Fig. 4.4.1.1 and Table 4.4.1.1 should be amended to include this type of hexatic order which is now referred to as the smectic-L. Extension of the previous logic suggests that the crystalline phases with intermediate tilt should be designated M and N, where N has 'herringbone' type of intermolecular order.

4.4.6.2. Nematic to smectic-A phase transition

At the time this manuscript was prepared, there was a fundamental discrepancy between theoretical predictions for the details of the critical properties of the second-order nematic to smectic-A phase transition. This has been resolved. Bouwman & de Jeu (1992) reported an X-ray scattering study of the critical properties of octyloxyphenylcyanobenzyloxybenzoate in which the data were in good agreement with predictions of the three-dimensional *xy* model (Lubensky, 1983; Le Guillou & Zinn-Justin, 1985). The differences between this experiment and others that were discussed previously, and which did not agree with theory, are firstly that this material is much further from the tricritical point that appears to be ubiquitous for most liquid-crystalline materials and, secondly, that they used the Landau–De Gennes theory to argue that the critical-temperature dependence for the $\mathbf{Q}_\perp^4$ term in the differential cross section given in equation (4.4.2.7) is not that of the $c\xi_\perp^4$ term but rather should vary as $[(T - T_{NA})/T]^{-\gamma/4}$, where γ is the exponent that describes the critical-temperature dependence of the smectic order parameter $|\Psi|^2 \simeq [(T - T_{NA})/T]^{-\gamma}$. The experimental results are in good agreement with the Monte Carlo simulation of the N–S_A transition that was reported by Dasgupta (1985, 1987).

4.5. Polymer crystallography

By R. P. Millane and D. L. Dorset

4.5.1. Overview

By R. P. Millane and D. L. Dorset

Linear polymers from natural or synthetic sources are actually polydisperse aggregates of high-molecular-weight chains. Nevertheless, many of these essentially infinite-length molecules can be prepared as solid-state specimens that contain ordered molecular segments or crystalline inclusions (Vainshtein, 1966; Tadokoro, 1979; Mandelkern, 1989; Barham, 1993). In general, ordering can occur in a number of ways. Hence an oriented and/or somewhat ordered packing of chain segments might be found in a stretched fibre, or in the chain-folded arrangement of a lamellar crystallite. Lamellae themselves may exist as single plates or in the more complex array of a spherulite (Geil, 1963). Diffraction data can be obtained from these various kinds of specimens and used to determine molecular and crystal structures.

There are numerous reasons why crystallography of polymers is important. Although it may be possible to crystallize small constituent fragments of these large molecules and determine their crystal structures, one often wishes to study the intact (and biologically or functionally active) polymeric system. The molecular conformations and intermolecular interactions are determinants of parameters such as persistence length which affect, for example, solution conformations (random or worm-like coils) which determine viscosity. Molecular conformations also influence intermolecular interactions, which determine physical properties in gels and melts. Molecular conformations are, of course, of critical importance in many biological recognition processes. Knowledge of the stereochemical constraints that are placed on the molecular packing to maximize unit-cell density is particularly relevant to the fact that many linear molecules (as well as monodisperse substances with low molecular weight) can adopt several different allomorphic forms, depending on the crystallization conditions employed or the biological origin. Since different allomorphs can behave quite differently from one another, it is clear that the mode of chain packing is related to the bulk properties of the polymer (Grubb, 1993). The three-dimensional geometry of the chain packing obtained from a crystal structure analysis can be used to investigate other phenomena such as the possible inclusion of disordered material in *chain-fold* regions (Mandelkern, 1989; Lotz & Wittmann, 1993), the ordered interaction of crystallite sectors across grain boundaries where tight interactions are found between domains, or the specific interactions of polymer chains with another substance in a composite material (Lotz & Wittmann, 1993).

The two primary crystallographic techniques used for studying polymer structure are described in this chapter. The first is X-ray fibre diffraction analysis, described in Section 4.5.2; and the second is polymer electron crystallography, described in Section 4.5.3.

Crystallographic studies of polymers were first performed using X-ray diffraction from oriented fibre specimens. Early applications were to cellulose and DNA from the 1930s to the 1950s, and the technique has subsequently been applied to hundreds of biological and synthetic polymers (Arnott, 1980; Millane, 1988). This technique is now referred to as *X-ray fibre diffraction analysis*. In fact, fibre diffraction analysis can be employed not only for polymers, but for any system that can be oriented. Indeed, one of the first applications of the technique was to tobacco mosaic virus (Franklin, 1955). Fibre diffraction analysis has also utilized, in some cases, neutrons instead of X-rays (*e.g.* Stark *et al.*, 1988; Forsyth *et al.*, 1989). X-ray fibre diffraction analysis is particularly suitable for biological polymers that form natural fibrous superstructures and even for many synthetic polymers that exist in either a fibrous or a liquid-crystalline state. Fibre diffraction has played an important role in structural studies of polynucleotides, polysaccharides, polypeptides and polyesters, as well as rod-like helical viruses, bacteriophages, microtubules and muscle fibres (Arnott, 1980; French & Gardner, 1980; Hall, 1984; Millane, 1988; Atkins, 1989). The common, and unique, feature of these systems is that the molecules (or their aggregates) are randomly rotated about an axis of preferred orientation. As a result, the measured diffraction is the cylindrical average of that from a single molecule or aggregate. The challenge for the structural scientist, therefore, is that of structure determination from cylindrically averaged diffraction intensities. Since a wide range of types and degrees of order (or disorder) occur in fibrous specimens, as well as a wide range of sizes of the repeating units, a variety of methods are used for structure determination.

The second technique used for structural studies of polymers is *polymer electron crystallography*. This involves measuring electron intensity data from individual crystalline regions or lamellae in the diffraction plane of an electron microscope. This is possible because a narrow electron beam can be focused on a single thin microcrystal and because of the enhanced scattering cross section of matter for electrons. By tilting the specimen, three-dimensional diffraction intensities from a single microcrystal can be collected. This means that the unit-cell dimensions and symmetry can be obtained unambiguously in electron-diffraction experiments on individual chain-folded lamellae, and the data can be used for actual single-crystal structure determinations. One of the first informative electron-diffraction studies of crystalline polymer films was made by Storks (1938), who formulated the concept of chain folding in polymer lamellae. Among the first quantitative structure determinations from electron-diffraction intensities was that of Tatarinova & Vainshtein (1962) on the α form of poly-γ-methyl-L-glutamate. Quantitative interpretation of the intensity data may benefit from the assumption of *quasi-kinematical* scattering (Dorset, 1995*a*), as long as the proper constraints are placed on the experiment. Structure determination may then proceed using the traditional techniques of X-ray crystallography. While molecular-modelling approaches (in which atomic level molecular and crystal structure models are constructed and refined) have been employed with single-crystal electron-diffraction data (Brisse, 1989), the importance of *ab initio* structure determination has been established in recent years (Dorset, 1995*b*), demonstrating that no initial assumptions about the molecular geometry need be made before the determination is begun. In some cases too, high-resolution electron micrographs of the polymer crystal structure can be used as an additional means for determining crystallographic phases and/or to visualize lattice defects.

Each of the two techniques described above has its own advantages and disadvantages. While specimen disorder can limit the application of X-ray fibre diffraction analysis, polymer electron diffraction is limited to materials that can be be prepared as crystalline lamallae and that can withstand the high vacuum environment of an electron microscope (although the latter restriction can now be largely overcome by the use of low-temperature specimen holders and/or environmental chambers).

4.5.2. X-ray fibre diffraction analysis

By R. P. Millane

4.5.2.1. Introduction

X-ray fibre diffraction analysis is a collection of crystallographic techniques that are used to determine molecular and crystal structures of molecules, or molecular assemblies, that form specimens (often fibres) in which the molecules, assemblies or crystallites are approximately parallel but not otherwise ordered (Arnott, 1980; French & Gardner, 1980; Hall, 1984; Vibert, 1987; Millane, 1988; Atkins, 1989; Stubbs, 1999). These are usually long, slender molecules and they are often inherently flexible, which usually precludes the formation of regular three-dimensional crystals suitable for conventional crystallographic analysis. X-ray fibre diffraction therefore provides a route for structure determination for certain kinds of specimens that cannot be crystallized. Although it may be possible to crystallize small *fragments* or *subunits* of these molecules, and determine the crystal structures of these, X-ray fibre diffraction provides a means for studying the intact, and often the biologically or functionally active, system. Fibre diffraction has played an important role in the determination of biopolymers such as polynucleotides, polysaccharides (both linear and branched), polypeptides and a wide variety of synthetic polymers (such as polyesters), as well as larger assemblies including rod-like helical viruses, bacteriophages, microtubules and muscle fibres (Arnott, 1980; Arnott & Mitra, 1984; Millane, 1990*c*; Squire & Vibert, 1987).

Specimens appropriate for fibre diffraction analysis exhibit rotational disorder (of the molecules, aggregates or crystallites) about a preferred axis, resulting in cylindrical averaging of the diffracted intensity in reciprocal space. Therefore, fibre diffraction analysis can be thought of as 'structure determination from cylindrically averaged diffraction intensities' (Millane, 1993). In a powder specimen the crystallites are completely (spherically) disordered, so that structure determination by fibre diffraction can be considered to be intermediate between structure determination from single crystals and from powders.

This section is a review of the theory and techniques of structure determination by X-ray fibre diffraction analysis. It includes descriptions of fibre specimens, the theory of diffraction by these specimens, intensity data collection and processing, and the variety of structure determination methods used for the various kinds of specimens studied by fibre diffraction. It does not include descriptions of specimen preparation (those can be found in the references given for specific systems), or of applications of X-ray diffraction to determining polymer morphology (*e.g.* particle or void sizes and shapes, texture, domain structure *etc.*).

4.5.2.2. Fibre specimens

A wide variety of kinds of fibre specimen exist. All exhibit preferred orientation; the variety results from variability in the degree of order (crystallinity) in the lateral plane (the plane perpendicular to the axis of preferred orientation). This leads to categorization of three kinds of fibre specimen: *noncrystalline fibres*, in which there is no order in the lateral plane; *polycrystalline fibres*, in which there is near-perfect crystallinity in the lateral plane; and *disordered fibres*, in which there is disorder either within the molecules or in their crystalline packing (or both). The kind of fibre specimen affects the kind of diffraction pattern obtained, the relationships between the molecular and crystal structures and the diffraction data, methods of data collection, and methods of structure determination.

Noncrystalline fibres are made up of a collection of molecules that are *oriented*. This means that there is a common axis in each molecule (referred to here as the *molecular axis*), the axes being parallel in the specimen. The direction of preferred orientation is called the *fibre axis*. The molecule itself is usually considered to be a rigid body. There is no other ordering within the specimen. The molecules are therefore randomly positioned in the lateral plane and are randomly rotated about their molecular axes. Furthermore, if the molecule does not have a twofold rotation axis normal to the molecular axis, then the molecular axis has a *direction* associated with it, and the molecular axes are oriented randomly parallel or antiparallel to each other. This is often called *directional disorder*, or the molecules are said to be oriented *randomly up and down*. The average length of the ordered molecular segments in a noncrystalline fibre is referred to as the *coherence length*.

Polycrystalline fibres are characterized by molecular segments packing together to form well ordered microcrystallites within the specimen. The crystallites effectively take the place of the molecules in a noncrystalline specimen as described above. The crystallites are oriented, and since the axis within each crystallite that is aligned parallel to those in other crystallites usually corresponds to the long axes of the constituent molecules, it is also referred to here as the molecular axis. The crystallites are randomly positioned in the lateral plane, randomly rotated about the molecular axis, and randomly oriented up or down. The size of the crystalline domains can be characterized by their average dimensions in the directions of the **a**, **b** and **c** unit-cell vectors. However, because of the rotational disorder of the crystallites, any differences between crystallite dimensions in different directions normal to the fibre axis tend to be smeared out in the diffraction pattern, and the crystallite size is usefully characterized by the average dimensions of the crystallites normal and parallel to the fibre axis.

The molecules or crystallites in a fibre specimen are not perfectly oriented, and the variation in inclinations of the molecular axes to the fibre axis is referred to as *disorientation*. Assuming that the orientation is axisymmetric, then it can be described by an *orientation density function* $\Omega(\alpha)$ such that $\Omega(\alpha)\,\mathrm{d}\omega$ is the fraction of molecules in an element of solid angle $\mathrm{d}\omega$ inclined at an angle α to the fibre axis. The exact form of $\Omega(\alpha)$ is generally not known for any particular fibre and it is often sufficient to assume a Gaussian orientation density function, so that

$$\Omega(\alpha) = \frac{1}{2\pi\alpha_0^2}\exp\left(-\frac{\alpha^2}{2\alpha_0^2}\right), \qquad (4.5.2.1)$$

where α_0 is a measure of the degree of disorientation.

Fibre specimens often exhibit various kinds of disorder. The disorder may be within the molecules or in their packing. Disorder affects the relationship between the molecular and crystal structure and the diffracted intensities. Disorder within the molecules may result from a degree of randomness in the chemical sequence of the molecule or from variability in the interactions between the units that make up the molecule. Such molecules may (at least in principle) form noncrystalline, polycrystalline or partially crystalline (described below) fibres. Disordered packing of molecules within crystallites can result from a variety of ways in which the molecules can interact with each other. Fibre specimens made up of disordered crystallites are referred to here as partially crystalline fibres.

4.5.2.3. Diffraction by helical structures

Molecules or assemblies studied by fibre diffraction are usually made up of a large number of identical, or nearly identical, residues, or subunits, that in an oriented specimen are distributed along an axis; this leads naturally to helical symmetry. Since a periodic structure with no helix symmetry can be treated as a onefold helix, the assumption of helix symmetry is not restrictive.

4.5.2.3.1. Helix symmetry

The presence of a unique axis about which there is rotational disorder means that it is convenient to use cylindrical polar coordinate systems in fibre diffraction. We denote by (r, φ, z) a cylindrical polar coordinate system in real space, in which the z axis is parallel to the molecular axes. The molecule is said to have u_v helix symmetry, where u and v are integers, if the electron density $f(r, \varphi, z)$ satisfies

$$f\big(r, \varphi + (2\pi mv/u), z + (mc/u)\big) = f(r, \varphi, z), \qquad (4.5.2.2)$$

where m is any integer. The constant c is the period along the z direction, which is referred to variously as the *molecular repeat distance*, the *crystallographic repeat*, or the *c repeat*. The helix *pitch* P is equal to c/v. Helix symmetry is easily interpreted as follows. There are u subunits, or *helix repeat units*, in one c repeat of the molecule. The helix repeat units are repeated by integral rotations of $2\pi v/u$ about, and translations of c/u along, the molecular (or helix) axis. The helix repeat units may therefore be referenced to a helical lattice that consists of points at a fixed radius, with relative rotations and translations as described above. These points lie on a helix of pitch P, there are v turns (or pitch-lengths) of the helix in one c repeat, and there are u helical lattice points in one c repeat. A u_v helix is said to have 'u residues in v turns'.

Since the electron density is periodic in φ and z, it can be decomposed into a Fourier series as

$$f(r, \varphi, z) = \sum_{l=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} g_{nl}(r) \exp\big(i[n\varphi - (2\pi lz/c)]\big), \qquad (4.5.2.3)$$

where the coefficients $g_{nl}(r)$ are given by

$$g_{nl}(r) = (c/2\pi) \int_0^c \int_0^{2\pi} f(r, \varphi, z) \exp\big(i[-n\varphi + (2\pi lz/c)]\big)\, \mathrm{d}\varphi\, \mathrm{d}z. \qquad (4.5.2.4)$$

Assume now that the electron density has helical symmetry. Denote by $g(r, \varphi, z)$ the electron density in the region $0 < z < c/u$; the electron density being zero outside this region, *i.e.* $g(r, \varphi, z)$ is the electron density of a single helix repeat unit. It follows that

$$f(r, \varphi, z) = \sum_{m=-\infty}^{\infty} g[r, \varphi + (2\pi mv/u), z + (mc/u)]. \qquad (4.5.2.5)$$

Substituting equation (4.5.2.5) into equation (4.5.2.4) shows that $g_{nl}(r)$ vanishes unless $(l - nv)$ is a multiple of u, *i.e.* unless

$$l = um + vn \qquad (4.5.2.6)$$

for any integer m. Equation (4.5.2.6) is called the *helix selection rule*. The electron density in the helix repeat unit is therefore given by

$$g(r, \varphi, z) = \sum_l \sum_n g_{nl}(r) \exp\big(i[n\varphi - (2\pi lz/c)]\big), \qquad (4.5.2.7)$$

where

$$g_{nl}(r) = (c/2\pi) \int\int g(r, \varphi, z) \exp\big(i[-n\varphi + (2\pi l/c)]\big)\, \mathrm{d}\varphi\, \mathrm{d}z, \qquad (4.5.2.8)$$

and where in equation (4.5.2.7) (and in the remainder of this section) the sum over l is over all integers, the sum over n is over all integers satisfying the helix selection rule and the integral in equation (4.5.2.8) is over one helix repeat unit. The effect of helix symmetry, therefore, is to restrict the number of Fourier coefficients $g_{nl}(r)$ required to represent the electron density to those whose index n satisfies the selection rule. Note that the selection rule is usually derived using a rather more complicated argument by considering the convolution of the Fourier transform of a continuous filamentary helix with a set of planes in reciprocal space (Cochran *et al.*, 1952). The approach described above, which follows that of Millane (1991), is much more straightforward.

4.5.2.3.2. Diffraction by helical structures

Denote by (R, ψ, Z) a cylindrical polar coordinate system in reciprocal space (with the Z and z axes parallel), and by $F(R, \psi, Z)$ the Fourier transform of $f(r, \varphi, z)$. Since $f(r, \varphi, z)$ is periodic in z with period c, its Fourier transform is nonzero only on the *layer planes* $Z = l/c$ where l is an integer. Denote $F(R, \psi, l/c)$ by $F_l(R, \psi)$; using the cylindrical form of the Fourier transform shows that

$$F_l(R, \psi) = \int_0^c \int_0^{2\pi} \int_0^{\infty} f(r, \varphi, z) \exp\big(i\, 2\pi\, [Rr\cos(\psi - \varphi) + (lz/c)]\big) r\, \mathrm{d}r\, \mathrm{d}\varphi\, \mathrm{d}z. \qquad (4.5.2.9)$$

It is convenient to rewrite equation (4.5.2.9) making use of the Fourier decomposition described in Section 4.5.2.3.1, since this allows utilization of the helix selection rule. The *Fourier–Bessel structure factors* (Klug *et al.*, 1958), $G_{nl}(R)$, are defined as the Hankel transform of the Fourier coefficients $g_{nl}(r)$, *i.e.*

$$G_{nl}(R) = \int_0^{\infty} g_{nl}(r) J_n(2\pi Rr) 2\pi r\, \mathrm{d}r, \qquad (4.5.2.10)$$

and the inverse transform is

$$g_{nl}(r) = \int_0^{\infty} G_{nl}(R) J_n(2\pi Rr) 2\pi R\, \mathrm{d}R. \qquad (4.5.2.11)$$

Using equations (4.5.2.7) and (4.5.2.11) shows that equation (4.5.2.9) can be written as

$$F_l(R, \psi) = \sum_n G_{nl}(R) \exp\big(in[\psi + (\pi/2)]\big), \qquad (4.5.2.12)$$

where, as usual, the sum is over only those values of n that satisfy the helix selection rule. Using equations (4.5.2.8) and (4.5.2.10) shows that the Fourier–Bessel structure factors may be written in terms of the atomic coordinates as

$$G_{nl}(R) = \sum_j f_j(\rho) J_n(2\pi Rr_j) \exp\big(i[-n\varphi_j + (2\pi lz_j/c)]\big), \qquad (4.5.2.13)$$

where $f_j(\rho)$ is the (spherically symmetric) atomic scattering factor (usually including an isotropic temperature factor) of the jth

atom and $\rho = (R^2 + l^2/Z^2)^{1/2}$ is the spherical radius in reciprocal space. Equations (4.5.2.12) and (4.5.2.13) allow the complex diffracted amplitudes for a helical molecule to be calculated from the atomic coordinates, and are analogous to expressions for the structure factors in conventional crystallography.

The significance of the selection rule is now more apparent. On a particular layer plane l, not all Fourier–Bessel structure factors $G_{nl}(R)$ contribute; only those whose Bessel order n satisfies the selection rule for that value of l contribute. Since any molecule has a maximum radius, denoted here by $r_{\max}$, and since $J_n(x)$ is small for $x < |n| - 2$ and diffraction data are measured out to only a finite value of R, reference to equation (4.5.2.10) [or equation (4.5.2.13)] shows that there is a maximum Bessel order that contributes significant value to equation (4.5.2.12) (Crowther *et al.*, 1970; Makowski, 1982), so that the infinite sum over n in equation (4.5.2.12) can be replaced by a finite sum. On each layer plane there is also a minimum value of $|n|$, denoted by $n_{\min}$, that satisfies the helix selection rule, so that the region $R < R_{\min}$ is devoid of diffracted amplitude where

$$R_{\min} = \frac{n_{\min} - 2}{2\pi r_{\max}}. \qquad (4.5.2.14)$$

The selection rule therefore results in a region around the Z axis of reciprocal space that is devoid of diffraction, the shape of the region depending on the helix symmetry.

4.5.2.3.3. Approximate helix symmetry

In some cases the nature of the subunits and their interactions results in a structure that is not exactly periodic. Consider a helical structure with $u + x$ subunits in v turns, where x is a small ($x \ll 1$) real number; *i.e.* the structure has approximate, but not exact, u_v helix symmetry. Since the molecule has an *approximate* repeat distance c, only those layer planes close to those at $Z = l/c$ show significant diffraction. Denoting by Z_{mn} the Z coordinate of the nth Bessel order and its associated value of m, and using the selection rule shows that

$$Z_{mn} = [(um + vn)/c] + (mx/c) = (l/c) + (mx/c), \qquad (4.5.2.15)$$

so that the positions of the Bessel orders are shifted by mx/c from their positions if the helix symmetry is exactly u_v. At moderate resolution m is small so the shift is small. Hence Bessel orders that would have been coincident on a particular layer plane are now separated in reciprocal space. This is referred to as *layer-plane splitting* and was first observed in fibre diffraction patterns from tobacco mosaic virus (TMV) (Franklin & Klug, 1955). Splitting can be used to advantage in structure determination (Section 4.5.2.6.6).

As an example, TMV has approximately 49_3 helix symmetry with a c repeat of 69 Å. However, close inspection of diffraction patterns from TMV shows that there are actually about 49.02 subunits in three turns (Stubbs & Makowski, 1982). The virus is therefore more accurately described as a 2451_{150} helix with a c repeat of 3450 Å. The layer lines corresponding to this larger repeat distance are not observed, but the effects of layer-plane splitting are detectable (Stubbs & Makowski, 1982).

4.5.2.4. Diffraction by fibres

The kind of diffraction pattern obtained from a fibre specimen made up of helical molecules depends on the kind of specimen as described in Section 4.5.2.2. This section is divided into four parts. The first two describe diffraction patterns obtained from noncrystalline and polycrystalline fibres (which are the most common kinds used for structural analysis), and the last two describe diffraction by partially crystalline fibres.

4.5.2.4.1. Noncrystalline fibres

A noncrystalline fibre is made up of a collection of helical molecules that are oriented parallel to each other, but are otherwise randomly positioned and rotated relative to each other. The recorded intensity, $I_l(R)$, is therefore that diffracted by a single molecule cylindrically averaged about the Z axis in reciprocal space *i.e.*

$$I_l(R) = (1/2\pi)\int_0^{2\pi} |F_l(R, \psi)|^2 \, \mathrm{d}\psi; \qquad (4.5.2.16)$$

using equation (4.5.2.12) shows that

$$I_l(R) = \sum_n |G_{nl}(R)|^2, \qquad (4.5.2.17)$$

where, as usual, the sum is over the values of n that satisfy the helix selection rule. On the diffraction pattern, reciprocal space (R, ψ, Z) collapses to the two dimensions (R, Z). The R axis is called the *equator* and the Z axis the *meridian*. The layer planes collapse to *layer lines*, at $Z = l/c$, which are indexed by l. Equation (4.5.2.17) gives a rather simple relationship between the recorded intensity and the Fourier–Bessel structure factors.

Coherence length and disorientation, as described in Section 4.5.2.2, also affect the form of the diffraction pattern. These effects are described here, although they also apply to other than noncrystalline fibres. A finite coherence length leads to smearing of the layer lines along the Z direction. If the average coherence length of the molecules is l_c, the intensity distribution $I_l(R, Z)$ about the lth layer line can be approximated by

$$I_l(R, Z) = I_l(R) \exp\left(-\pi l_c^2 [Z - (l/c)]^2\right). \qquad (4.5.2.18)$$

It is convenient to express the effects of disorientation on the intensity distribution of a fibre diffraction pattern by writing the latter as a function of the polar coordinates (ρ, σ) (where σ is the angle with the Z axis) in (R, Z) space. Assuming a Gaussian orientation density function [equation (4.5.2.1)], if α_0 is small and the effects of disorientation dominate over those of coherence length (which is usually the case except close to the meridian), then the distribution of intensity about one layer line can be approximated by (Holmes & Barrington Leigh, 1974; Stubbs, 1974)

$$I(\rho, \sigma) \simeq \frac{I_l(R)}{2\pi\alpha_0 l_c \rho} \exp\left[-\frac{(\sigma - \sigma_l)^2}{2\beta^2}\right], \qquad (4.5.2.19)$$

where (Millane & Arnott, 1986; Millane, 1989*c*)

$$\beta^2 = \alpha_0^2 + (1/2\pi l_c^2 \rho^2 \sin^2 \sigma_l) \qquad (4.5.2.20)$$

and σ_l is the polar angle at the centre of the layer line, *i.e.* $R = \rho \sin \sigma_l$. The effect of disorientation, therefore, is to smear each layer line about the origin of reciprocal space.

4.5.2.4.2. Polycrystalline fibres

A polycrystalline fibre is made up of crystallites that are oriented parallel to each other, but are randomly positioned and randomly rotated about their molecular axes. The recorded diffraction pattern is the intensity diffracted by a single crystallite, cylindrically averaged about the Z axis. On a fibre diffraction pattern, therefore, the Bragg reflections are cylindrically projected onto the (R, Z) plane and their positions are described

by the cylindrically projected reciprocal lattice (Finkenstadt & Millane, 1998).

The molecules are periodic and are therefore usually aligned with one of the unit-cell vectors. Since the z axis is defined as the fibre axis, it is usual in fibre diffraction to take the **c** lattice vector as the unique axis and as the lattice vector parallel to the molecular axes. It is almost always the case that the fibre is rotationally disordered about the molecular axes, *i.e.* about **c**. Consider first the case of a monoclinic unit cell ($\alpha = \beta = 90^\circ$) so that the reciprocal lattice is cylindrically projected about $\mathbf{c}^*$. The cylindrical coordinates of the projected reciprocal-lattice points are then given by

$$R_{hkl}^2 = h^2a^{*2} + k^2b^{*2} + 2hka^*b^*\cos\gamma^* \qquad (4.5.2.21)$$

and

$$Z_{hkl} = lc^*, \qquad (4.5.2.22)$$

so that R depends only on h and k, and Z depends only on l. Reflections with fixed h and k lie on straight *row lines*. Certain sets of distinct reciprocal-lattice points will have the same value of R_{hkl} and therefore superimpose in cylindrical projection. For example, for an orthorhombic system ($\gamma = 90^\circ$) the reciprocal-lattice points (hkl), $(\bar{h}kl)$, $(h\bar{k}l)$ and $(\bar{h}\bar{k}l)$ superimpose. Furthermore, the crystallites in a fibre specimen are usually oriented randomly up and down so that the reciprocal-lattice points (hkl) and $(hk\bar{l})$ superimpose, so that in the orthorhombic case eight reciprocal-lattice points superimpose. Also, as described below, reciprocal-lattice points that have similar values of R can effectively superimpose.

If the unit cell is either triclinic, or is monoclinic with $\alpha \neq 90^\circ$ or $\beta \neq 90^\circ$, then $\mathbf{c}^*$ is inclined to **c** and the Z axis, and the reciprocal lattice is not cylindrically projected about $\mathbf{c}^*$. Equation (4.5.2.22) for Z_{hkl} still applies, but the cylindrical radius is given by

$$R_{hkl}^2 = h^2a^{*2} + k^2b^{*2} + l^2[c^{*2} - (1/c^2)] + 2hka^*b^*\cos\gamma^* + 2hla^*c^*\cos\beta^* + 2klb^*c^*\cos\alpha^* \qquad (4.5.2.23)$$

and the row lines are curved (Finkenstadt & Millane, 1998).

The most complicated situation arises if the crystallites are rotationally disordered about an axis that is inclined to **c**. Reciprocal space is then rotated about an axis that is inclined to the normal to the a^*b^* plane, R_{hkl} and Z_{hkl} are both functions of h, k and l, equation (4.5.2.23) does not apply, and reciprocal-lattice points for fixed l do not lie on layer lines of constant Z. Although this situation is rather unusual, it does occur (Daubeny *et al.*, 1954), and is described in detail by Finkenstadt & Millane (1998).

The observed fibre diffraction pattern consists of reflections at the projected reciprocal-lattice points whose intensities are equal to the sums of the intensities of the contributing structure factors. The observed intensity, denoted by $I_l(R_{hk})$, at a projected reciprocal-lattice point on the lth layer line and with $R = R_{hk}$ is therefore given by (assuming, for simplicity, a monoclinic system)

$$I_l(R_{hk}) = \sum_{h',\,k' \in \mathscr{S}(h,\,k)} |F_{h'k'l}|^2, \qquad (4.5.2.24)$$

where $\mathscr{S}(h, k)$ denotes the set of indices (h', k') such that $R_{h'k'} = R_{hk}$. The number of independent reflections contributing in equation (4.5.2.24) depends on the space-group symmetry of the crystallites, because of either systematic absences or structure factors whose values are related.

The effect of a finite crystallite size is to smear what would otherwise be infinitely sharp reflections into broadened reflections of a finite size. If the average crystallite dimensions normal and parallel to the z axis are $l_{\rm lat}$ (*i.e.* in the 'lateral' direction) and $l_{\rm axial}$ (*i.e.* in the 'axial' direction), respectively, the profile of the reflection centred at $(R_{hk}, Z = l/c)$ can be written as (Fraser *et al.*, 1984; Millane & Arnott, 1986; Millane, 1989*c*)

$$I(R, Z) = I_l(R_{hk})S(R - R_{hk}, Z - l/c), \qquad (4.5.2.25)$$

where the profile function $S(R, Z)$ can be approximated by

$$S(R, Z) = \exp[-\pi(l_{\rm lat}^2R^2 + l_{\rm axial}^2Z^2)]. \qquad (4.5.2.26)$$

The effect of crystallite disorientation is to smear the reflections given by equation (4.5.2.26) about the origin of the projected reciprocal space. If the effects of disorientation dominate over those of crystallite size, then the profile of a reflection can be approximated by (Fraser *et al.*, 1984; Millane & Arnott, 1986; Millane, 1989*c*)

$$I(\rho, \sigma) \simeq \frac{I_l(R_{hk})}{2\pi\alpha_0 l_{\rm lat} l_{\rm axial}\rho} \times \exp\left(-\left[\frac{(\rho - \rho_{hkl})^2}{2\beta_\rho^2} + \frac{(\sigma - \sigma_{hkl})^2}{2\beta_\sigma^2}\right]\right), \qquad (4.5.2.27)$$

where $(\rho_{hkl}, \sigma_{hkl})$ are the polar coordinates of the reflection,

$$\beta_\rho^2 = \frac{l_{\rm lat}^2 l_{\rm axial}^2}{2\pi(l_{\rm lat}^2\sin^2\sigma_{hkl} + l_{\rm axial}^2\cos^2\sigma_{hkl})} \qquad (4.5.2.28)$$

and

$$\beta_\sigma^2 = \alpha_0 + \frac{l_{\rm lat}^2 l_{\rm axial}^2}{2\pi\rho_{hkl}^2(l_{\rm axial}^2\sin^2\sigma_{hkl} + l_{\rm lat}^2\cos^2\sigma_{hkl})}. \qquad (4.5.2.29)$$

Reflections that have similar enough (R, Z) coordinates overlap severely with each other and are also included in the sum in equation (4.5.2.24). This is quite common in practice because a number of sets of reflections may have similar values of R_{hk}.

4.5.2.4.3. Random copolymers

Random copolymers are made up of a small number of different *kinds* of monomer, whose sequence along the polymer chain is not regular, but is random, or partially random. A particularly interesting class are synthetic polymers such as copolyesters that form a variety of liquid-crystalline phases and have useful mechanical properties (Biswas & Blackwell, 1988*a*). The structures of these materials have been studied quite extensively using X-ray fibre diffraction analysis. Because the molecules do not have an average c repeat, their diffraction patterns do not consist of equally spaced layer lines. However, as a result of the small number of distinct spacings associated with the monomers, diffracted intensity is concentrated about layer lines, but these are irregularly spaced (along Z) and are *aperiodic*. Since the molecule is not periodic, the basic theory of diffraction by helical molecules described in Section 4.5.2.3.2 does not apply in this case. Cylindrically averaged diffraction from random copolymers is described here. Related approaches have been described independently by Hendricks & Teller (1942) and Blackwell *et al.* (1984). Hendricks & Teller (1942) considered the rather general problem of diffraction by layered structures made up of different kinds of layers, the probability of a layer at a

particular level depending on the layers present at adjacent levels. This is a one-dimensional disordered structure that can be used to describe a random copolymer. Blackwell and co-workers have developed a similar theory in terms of a one-dimensional paracrystalline model (Hosemann & Bagchi, 1962) for diffraction by random copolymers (Blackwell *et al.*, 1984; Biswas & Blackwell, 1988*a*), and this is the theory described here.

Consider a random copolymer made up of monomer units (residues) of N different types. Since the disorder is along the length of the polymer, some of the main characteristics of diffraction from such a molecule can be elucidated by studying the diffraction along the meridian of the diffraction pattern. The meridional diffraction is the intensity of the Fourier transform of the polymer chain projected onto the z axis and averaged over all possible monomer sequences. The diffraction pattern depends on the monomer (molar) compositions, denoted by p_i, the statistics of the monomer sequence (described by the probability of the different possible monomer pairs in this model) and the Fourier transform of the monomer units. Development of this model shows that the meridional diffracted intensity $I(Z)$ can be written in the form (Blackwell *et al.*, 1984; Biswas & Blackwell, 1988*a*; Schneider *et al.*, 1991)

$$I(Z) = \sum_i p_i |F_i(Z)|^2 + 2\sum_i \sum_{j\neq i} \Re\{F_i(Z) F_j^*(Z) T_{ij}(Z)\}, \quad (4.5.2.30)$$

where the summations are over the different monomer types and $F_i(Z)$ is the axial Fourier transform of the ith monomer unit (each referenced to a common origin). The $T_{ij}(Z)$ are most conveniently described by defining them as the ijth element of an $N \times N$ matrix $\mathbf{T}$, which is given by

$$\mathbf{T} = \frac{\mathbf{PMX}(Z)}{\mathbf{I} - \mathbf{MX}(Z)}, \quad (4.5.2.31)$$

where $\mathbf{P}$, $\mathbf{M}$, $\mathbf{X}(Z)$ and $\mathbf{I}$ are $N \times N$ matrices. $\mathbf{I}$ is the unit matrix and $\mathbf{P}$ is a diagonal matrix with elements p_i. The elements M_{ij} of $\mathbf{M}$ are the probabilities of forming ij monomer pairs and can be generated for different kinds of random sequence (*e.g.* chemical restrictions on the occurrence of particular monomer pairs, random chains, varying degrees of blockiness, tendency towards alternating sequences *etc.*) (Schneider *et al.*, 1991). The matrix $\mathbf{X}(Z)$ is diagonal with elements equal to $\langle \exp(i2\pi Z\zeta_i) \rangle$ where the ζ_i are the projected monomer lengths and the average is over all chain conformations.

Equation (4.5.2.30) can be used to calculate the meridional diffraction for a particular random copolymer. The most important result of such a calculation is that intensity maxima are spaced irregularly along the meridian. The positions of the maxima depend on the monomer proportions, the sequence statistics and the projected monomer lengths.

The full cylindrically averaged diffraction pattern, denoted by $I(R, Z)$, from a noncrystalline specimen containing oriented random copolymer chains can be calculated by replacing $F_i(Z)$ in equation (4.5.2.30) by $F_i(R, Z)$, *i.e.*

$$I(R, Z) = \sum_i p_i |F_i(R, Z)|^2 + 2\sum_i \sum_{j\neq i} \Re\{F_i(R, Z) F_j^*(R, Z) T_{ij}(Z)\} \quad (4.5.2.32)$$

(Biswas & Blackwell, 1988*a*). Note that we write $I(R, Z)$ rather than $I_l(Z)$ since the pattern cannot be indexed on the basis of regularly spaced layer lines. The $F_i(R, Z)$ in equation (4.5.2.32) depend on the chain conformation, since this affects the range of monomer orientations and hence their average diffraction. Chivers & Blackwell (1985) have considered two extreme cases, one corresponding to fixed conformations between monomers and the other corresponding to completely random conformations between monomers, and have derived expressions for the diffracted intensity in both cases. Equation (4.5.2.32) allows one to calculate the fibre diffraction pattern from an array of parallel random copolymers that exhibit no lateral ordering. The diffraction pattern consists of irregularly spaced layer lines whose spacings (in Z) are the same as those described above for the meridional maxima. Measurement of layer-line spacings and intensities and comparison with calculations based on the constituent monomers allows chain conformations to be estimated (Biswas & Blackwell, 1988*a*).

Diffraction patterns from liquid-crystalline random copolymers often contain sharp Bragg maxima on the layer lines. This indicates that, despite the random sequence and the possible dissimilarity of the component monomers, the chains are able to pack together in a regular way (Biswas & Blackwell, 1988*b*,*c*). Expressions that allow calculation of diffraction patterns for arrays of polymers with minimal registration, in which short, non-identical sequences form layers, have been derived (Biswas & Blackwell, 1988*b*,*c*). Calculation of diffracted intensities, coupled with molecular-mechanics modelling, allows chain conformations and packing to be investigated (Hofmann *et al.*, 1994).

4.5.2.4.4. Partially crystalline fibres

In this section we address disorder in the packing of the molecules in a polycrystalline fibre. The presence of disorder within the crystallites modifies the intensities of the Bragg reflections, as well as introducing continuous diffraction. The dominant effect, sometimes seen on fibre diffraction patterns (Stroud & Millane, 1995*a*), is for Bragg reflections to remain at low resolution but to be replaced by continuous diffraction at high resolution. There are two distinct cases to consider. The first is where the distortions at different lattice points in the crystallite are uncorrelated, and the second is where they are correlated.

Disorder within a crystallite in a polycrystalline fibre may consist of (1) deviations in the positions of the molecules (which are treated as rigid bodies) from their positions in a regular lattice, (2) rotations of the molecules about their molecular axes from their rotational positions in an ordered crystal, and (3) random orientations (up or down) of the molecules. The first of these is called *lattice disorder*, and the second and third are components of *substitution disorder*.

Uncorrelated disorder has been treated by a number of authors (Clark & Muus, 1962; Tanaka & Naya, 1969; Fraser & MacRae, 1973; Arnott, 1980). A rather complete model has been described by Millane & Stroud (1991) and Stroud & Millane (1995*b*), which is presented here. If the lattice and substitution disorders are independent, and the lattice and substitution distortions at different lattice sites are uncorrelated, then the cylindrically averaged layer-line intensities $I_l(R)$ diffracted from a fibre can be written as a sum of Bragg and diffuse (continuous) intensities (Tanaka & Naya, 1969):

$$I_l(R) = I_l^{\mathrm{B}}(R) + I_l^{\mathrm{D}}(R). \quad (4.5.2.33)$$

The profiles of the Bragg reflections are independent of the position of the reflection in reciprocal space. If the Cartesian components of the lattice distortions are independent, normally distributed, and the x and y components have equal variances, cylindrical averaging of the diffracted intensity can be performed analytically.

The lattice disorder consists of distortions of the two-dimensional lattice (in the lateral plane) into three-dimensional space, and in the *absence* of substitution disorder the Bragg component is given by (Stroud & Millane, 1995*b*)

$$I_l^{\rm B}(R) = I_l(R_{hk}) w_{\rm lattice}(R_{hk}, l/c) \qquad (4.5.2.34)$$

where $I_l(R_{hk})$ is given by equation (4.5.2.24), the *lattice disorder weight*, $w_{\rm lattice}(R, Z)$, is given by

$$w_{\rm lattice}(R, Z) = \exp[-4\pi^2(R^2\sigma_{\rm lat}^2 + Z^2\sigma_{\rm axial}^2)], \qquad (4.5.2.35)$$

where $\sigma_{\rm lat}^2$ and $\sigma_{\rm axial}^2$ are the variances of the lattice distortions normal ('lateral') and parallel ('axial') to the z axis, respectively. The diffuse component is given by

$$I_l^{\rm D}(R) = (1/A_{\rm cryst}) I_l(R)[1 - w_{\rm lattice}(R, l/c)], \qquad (4.5.2.36)$$

where $I_l(R)$ is given by equation (4.5.2.17) and $A_{\rm cryst}$ is the average cross-sectional area of the crystallites. Inspection of equations (4.5.2.34) and (4.5.2.36) shows that the effect of the lattice disorder is to weight the amplitudes of the Bragg reflections down with increasing R and l, and to introduce a continuous intensity component whose amplitude increases with R and Z. Furthermore, the amplitude of the diffuse component relative to the Bragg component is inversely proportional to $A_{\rm cryst}$, and therefore is not significant unless the crystallites are small.

If substitution disorder is also present, then equation (4.5.2.33) still applies but equations (4.5.2.34) and (4.5.2.36) are replaced by

$$I_l^{\rm B}(R) = \left|\sum_n w_{nl} G_{nl}^2(R_{hk}) \exp[in(\psi_{hk} + \pi/2)]\right|^2 w_{\rm lattice}(R_{hk}, l/c) \qquad (4.5.2.37)$$

and

$$I_l^{\rm D}(R) = (1/A_{\rm cryst}) \sum_n |G_{nl}(R)|^2 [1 - |w_{nl}|^2 w_{\rm lattice}(R, l/c)], \qquad (4.5.2.38)$$

respectively, where the *substitution disorder weight*, w_{nl}, is given by

$$w_{nl} = \int_0^{c/u} \int_0^{2\pi} p(\varphi, z) \exp[i(2\pi z l/c - n\varphi)] \, {\rm d}\varphi \, {\rm d}z. \qquad (4.5.2.39)$$

In equation (4.5.2.39), $p(\varphi, z)$ is the probability density function (p.d.f.) that describes the substitution disorder, *i.e.* the p.d.f. for a molecule being rotated by φ about and translated by z along the molecular axis relative to its position in the undistorted lattice. Inspection of equations (4.5.2.37) and (4.5.2.38) shows that the substitution disorder weights the different contributing Bessel terms differently. This can lead to quite complicated effects on the diffraction pattern for various kinds of substitution disorder, resulting in different distributions and amplitudes of Bragg and diffuse diffraction over the diffraction pattern (Stroud & Millane, 1995*b*). If one assumes either uniform or normal distributions for φ and z, then expressions can be obtained for the w_{nl} in terms of the variances of the distributions of φ and z (Stroud & Millane, 1995*b*). The cases where distortions in φ are correlated with distortions in z (*e.g.* 'screw disorder'), and directional (up and down) disorder, can also be accommodated. This model has been shown to be capable of predicting diffraction patterns which are in good agreement with those measured from some disordered polycrystalline fibres (Stroud & Millane, 1995*a*).

We consider now the case of correlated packing disorder. As a result of intermolecular contacts within a polycrystalline specimen, it is possible that distortions at one lattice site will affect the degree of distortion at neighbouring sites. Coupling between distortions at different lattice sites can be included in the model of disorder by allowing the distortions at different lattice sites to be correlated. The effect of correlated distortions on diffraction patterns is that the diffracted intensity does not separate into Bragg and diffuse components as it does in the case of uncorrelated distortions [equation (4.5.2.33)]. The intensity can be described as being diffuse on the whole diffraction pattern, with (often broad) maxima occurring at some of the reciprocal-lattice points, but with no significant maxima at other reciprocal-lattice points. The widths of the profiles of the maxima generally increase with increasing resolution, whereas the widths of the Bragg maxima resulting from uncorrelated disorder as described above are independent of resolution. A broadening of diffraction maxima with increasing resolution and blending into continuous diffraction is sometimes seen on diffraction patterns from polycrystalline fibres, indicating the presence of correlated disorder (Stroud & Millane, 1996*b*).

Correlated lattice disorder consists of correlated distortions of the two-dimensional lattice into three-dimensional space. A flexible model of crystalline disorder is that based on the perturbed lattice approach (Welberry *et al.*, 1980). While formulating perturbed lattices with only nearest-neighbour interactions is complicated, a more tractable approach is to base the statistics on an imposed correlation field (de Graaf, 1989; Stroud & Millane, 1996*a*). This approach has been used to describe cylindrically averaged diffraction from polycrystalline fibres that contain correlated lattice disorder and uncorrelated substitution disorder (Stroud & Millane, 1996*a*,*b*), and is presented here.

To develop a flexible and tractable theory for diffraction from crystallites with correlated disorder, it is necessary to formulate the problem in real space. The size and shape of a crystallite in the xy (lateral) plane is described by a *shape function* $s_{\rm lat}(\mathbf{r})$, where $\mathbf{r}$ denotes the position vector in real space, which is equal to unity inside the crystallite and zero outside. The autocorrelation of the shape function, $t(\mathbf{r})$, is given by

$$t(\mathbf{r}) = \int s(\mathbf{r}') s(\mathbf{r} + \mathbf{r}') \, {\rm d}\mathbf{r}'. \qquad (4.5.2.40)$$

The correlations between the x components, and between the y components, of the distortions at any two lattice sites are taken to be identical. The correlations between distortion vectors are defined in terms of lateral, $\rho_{\rm lat}(\mathbf{r})$, and axial, $\rho_{\rm axial}(\mathbf{r})$, correlation fields such that the correlation coefficients between components of the distortions in the x (or y) and z directions, respectively, are equal to the correlation field evaluated for $\mathbf{r}$ equal to the inter-site vector. Various functional forms for the correlation fields are possible, but exponential correlation functions are usually used (Stroud & Millane, 1996*a*). If $t(\mathbf{r})$ and the correlation fields are circularly symmetric, then cylindrical averaging of the diffracted intensity can be performed analytically.

For a polycrystalline fibre with correlated lattice disorder and uncorrelated substitution disorder, the diffracted intensity is given by (Stroud & Millane, 1996*b*)

$$\begin{aligned} I_l(R) = {} & \sum_{j,k} t(r_{jk}) w_{\rm lat}(R, r_{jk}) w_{\rm axial}(l/c, r_{jk}) \\ & \times \sum_{m,n} J_{n-m}(2\pi R r_{jk}) \Re\{w_{ml} w_{nl}^* G_{ml}(R) G_{nl}^*(R) \\ & \times \exp[i(m-n)\varphi_{jk}]\} \end{aligned} \qquad (4.5.2.41)$$

where $r = |\mathbf{r}|$, the sum over (j, k) is over all the sites of the undistorted lattice within the region occupied by the autocorrelation function, (r_{jk}, φ_{jk}) are the polar coordinates of the

lattice sites, and the lateral and axial lattice disorder weights are given by

$$w_{\rm lat}(R, r) = \exp\left(-4\pi^2 R^2 \sigma_{\rm lat}^2 [1 - \rho_{\rm lat}(r)]\right) \qquad (4.5.2.42)$$

and

$$w_{\rm axial}(Z, r) = \exp\left(-4\pi^2 Z^2 \sigma_{\rm axial}^2 [1 - \rho_{\rm axial}(r)]\right). \qquad (4.5.2.43)$$

Equation (4.5.2.41) is an expression for the continuous intensity distribution along the layer lines and does not separate into Bragg and continuous components as in the case of uncorrelated disorder. However, calculations using these expressions show that the continuous intensity is sharply peaked around the projected reciprocal-lattice points at low resolution, the peaks broadening with increasing resolution until they have the character of continuous diffraction at high resolution (Stroud & Millane, 1996*a*). This is consistent with the character of diffraction patterns from some disordered polycrystalline fibres. A detailed study of the effects of correlated disorder on fibre diffraction patterns, and analysis of such disorder, can be found in Stroud & Millane (1996*a*) and Stroud & Millane (1996*b*).

4.5.2.5. Processing diffraction data

Since the diffraction pattern from a fibre is two-dimensional, it can be collected with a single exposure of a stationary specimen. Diffraction data are collected either on film, which is subsequently scanned by a two-dimensional microdensitometer to obtain a digitized representation of the diffracted intensity, or using an electronic area detector (imaging plate, CCD camera, wire detector *etc.*) (Fraser *et al.*, 1976; Namba, Yamashita & Vonderviszt, 1989; Lorenz & Holmes, 1993). We assume here that the diffraction pattern is recorded on a flat film (or detector) that is normal to the incident X-ray beam, although other film geometries are easily accommodated (Fraser *et al.*, 1976). The fibre specimen is usually oriented with its axis normal to the incident X-ray beam, although, as is described below, it is sometimes tilted by a small angle to the normal in order to better access reciprocal space close to the meridian. The diffraction and camera geometry are shown in Fig. 4.5.2.1. Referring to this figure, P and S denote the intersections of the diffracted beam with the sphere of reflection and the film, respectively. The fibre, and therefore reciprocal space, is tilted by an angle β to the normal to the incident beam. The angles μ and χ define the direction of the diffracted beam and θ is the Bragg angle. Cartesian and polar coordinates on the film are denoted by (u, v) and (r, φ), respectively, and D denotes the film-to-specimen distance.

Inspection of Fig. 4.5.2.1 shows that the cylindrical (R, ψ, Z) and spherical (ρ, ψ, σ) polar coordinates in reciprocal space are related to μ and χ by

$$\rho = (1/\lambda)[2(1 - \cos\mu - \cos\chi)]^{1/2}, \qquad (4.5.2.44)$$

$$Z = (1/\lambda)[\sin\beta(1 - \cos\mu\cos\chi) + \cos\beta\sin\chi]^{1/2}, \qquad (4.5.2.45)$$

$$R = (\rho^2 - Z^2)^{1/2}, \qquad (4.5.2.46)$$

$$\sin\psi = \frac{\sin\mu\cos\chi}{R\lambda} \qquad (4.5.2.47)$$

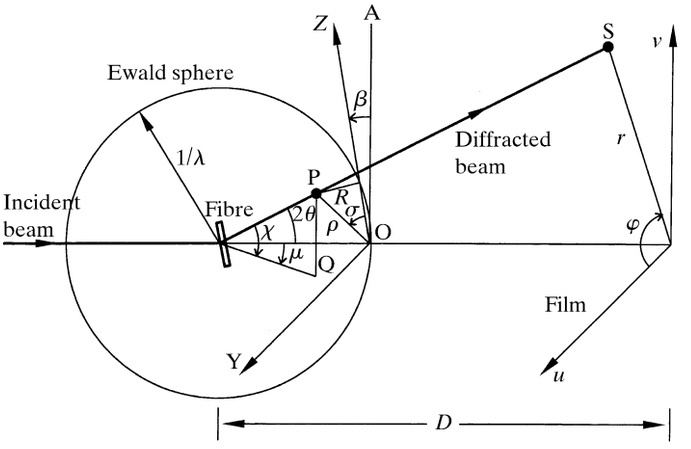

Fig. 4.5.2.1. Fibre diffraction geometry (see text). O is the origin of reciprocal space and **OA** is normal to the incident X-ray beam. Reciprocal space is rotated about **OY** so that the Z axis is inclined at an angle β to **OA**. Q is the projection of P onto the plane containing the incident beam and **OY**.

and

$$\tan\sigma = R/Z. \qquad (4.5.2.48)$$

The coordinates on the film are related to μ and χ by

$$u = D\tan\mu \qquad (4.5.2.49)$$

and

$$v = D\cos\mu\tan\chi, \qquad (4.5.2.50)$$

and we also have that

$$r = D\tan 2\theta. \qquad (4.5.2.51)$$

Use of the above equations allows the reciprocal-space coordinates to be calculated from film-space coordinates, and *vice versa.* The film coordinates (u, v) represent a relatively undistorted map of reciprocal space (R, Z), except near the v (vertical) axis of the diffraction pattern. The meridian of reciprocal space does not map onto the film. Inspection of Fig. 4.5.2.1 shows that the only point on the meridian that does appear on the film is at $Z = \lambda^{-1}\sin\beta$. The region *close* to the meridian that appears on the film can therefore be manipulated by adjusting the fibre tilt.

The film-to-specimen distance can be determined by including with the specimen a crystalline power that gives a diffraction ring of known spacing and adjusting the film-to-specimen distance so that the calculated and observed rings coincide. A nonzero fibre tilt leads to differences between the upper and lower halves of the diffraction pattern, and these differences can be used to determine the tilt. This can be done by either calculating the ρ and χ values for several sets of the same reflection above and below the equator and using the relationship

$$\tan\beta = \frac{\sin\chi_{\rm U} + \sin\chi_{\rm L}}{\lambda^2\rho^2}, \qquad (4.5.2.52)$$

where $\chi_{\rm U}$ and $\chi_{\rm L}$ refer to the upper and lower ($\chi < 0$) reflections (Millane & Arnott, 1986; Lorenz & Holmes, 1993), or by finding the tilt that minimizes the differences between optical densities at the same reciprocal-space coordinates above and below the

equator (Fraser *et al.*, 1976). The optical densities may also be corrected for the effects of film (or detector) nonlinearity (Fraser *et al.*, 1976) and the effects of variable absorption owing to the oblique passage of the beam through the film using expressions given by Fraser *et al.* (1976) and Lorenz & Holmes (1993).

Accurate subtraction of background diffraction is important in order to obtain accurate intensity measurements. One approach to estimating background diffraction is to fit a global background function, usually expanded as a polynomial (Lorenz & Holmes, 1993) or a Fourier–Bessel (Millane & Arnott, 1985) series, to optical densities at a set of points on the diffraction pattern that represent background alone. The background function may or may not be circularly symmetric. The background function is subtracted from the whole diffraction pattern. Another approach, suitable only for Bragg diffraction patterns, is to fit a plane under each reflection, either to the peripheral regions of the reflection or as part of a profile-fitting procedure (Fraser *et al.*, 1976). A different plane is required for each reflection. A third approach, more suitable for continuous diffraction patterns, is to fit a one-dimensional polynomial in angle, for each value of r on the film, possibly as part of a deconvolution procedure (Makowski, 1978). Recently, Ivanova & Makowski (1998) have described an iterative low-pass filtering technique for estimating the background on diffraction patterns from poorly oriented specimens in which there is little space between the layer lines for sampling the background.

A polarization correction is applied to the diffraction pattern, where for unpolarized X-rays (laboratory sources) the polarization factor p is given by (Fraser *et al.*, 1976)

$$p = (1 + \cos^2 2\theta)/2. \tag{4.5.2.53}$$

The diffraction pattern is usually mapped into reciprocal space (R, Z) for subsequent analysis. The mapping is performed by assigning to the intensity $I(R, Z)$ at position (R, Z) in reciprocal space the value given by (Fraser *et al.*, 1976)

$$I(R, Z) = \frac{I(u(R, Z); v(R, Z))}{\cos^3 \mu \cos^3 \chi}, \tag{4.5.2.54}$$

where $I(u; v)$ denotes the intensity on the film. The functions $u(R, Z)$ and $v(R, Z)$ can be derived from the equations given above. Note that equation (4.5.2.54) includes, implicitly, the Lorentz factor.

Subsequent processing depends on whether the diffraction pattern is continuous (*i.e.* from a noncrystalline specimen) or Bragg (*i.e.* from a polycrystalline specimen). Diffraction patterns from partially crystalline specimens that contain both components have been analysed using a combination of both approaches (Arnott *et al.*, 1986; Park *et al.*, 1987).

For a diffraction pattern containing continuous diffraction on layer lines, one usually extracts the cylindrically averaged transform $I_l(R)$ from the intensity $I(R, Z)$ on the diffraction pattern mapped into reciprocal space. This involves correcting for the effects of coherence length and disorientation expressed by equation (4.5.2.19), and for the overlap of the smeared layer lines that results from their increasing width with increasing R. The diffracted intensity $I(\rho, \sigma)$ in polar coordinates in reciprocal space is equal to the sum of the diffraction $I_l(\rho, \sigma)$ due to each (overlapping) layer line so that

$$I(\rho, \sigma) = \sum_l I_l(\rho, \sigma). \tag{4.5.2.55}$$

Referring to equations (4.5.2.55), (4.5.2.19) and (4.5.2.20) shows that if the smearing due to disorientation dominates over that due to coherence length, then for fixed ρ, equation (4.5.2.55) represents a convolution along σ of the layer-line intensities $I_l(\rho \sin \sigma_l)$ with the Gaussian angular profile in equation (4.5.2.19). By mapping the intensity $I(R, Z)$ into polar coordinates as $I(\rho, \sigma)$, or by simply sampling $I(R, Z)$ for fixed ρ and equally spaced samples of σ, $I_l(R)$ can be calculated from $I(\rho, \sigma)$ by deconvolution, usually by some appropriate solution of the resulting system of linear equations (Makowski, 1978). If the effects of coherence length are significant, as they often are, then equation (4.5.2.55) does not represent a convolution since the width of the Gaussian smearing function depends on σ through equation (4.5.2.20). However, the problem can still be posed as the solution of a system of linear equations and becomes one of profile fitting rather than deconvolution (Millane & Arnott, 1986). This allows the layer-line intensities to be extracted from the data beyond the resolution where they overlap, although there is a limiting resolution, owing to excessive overlap, beyond which reliable data cannot be obtained (Makowski, 1978; Millane & Arnott, 1986). This procedure requires that α_0 and l_c be known; these parameters can be estimated from the angular profiles at low resolution where there is no overlap, or they can be determined as part of the profile-fitting procedure.

For a diffraction pattern from a polycrystalline specimen containing Bragg reflections, the intensities $I_l(R_{hk})$ given by equation (4.5.2.24) need to be extracted from the intensity $I(R, Z)$ on the diffraction pattern mapped into reciprocal space. Each composite reflection $I_l(R_{hk})$ is smeared into a spot whose intensity profile is given by equation (4.5.2.27), and adjacent reflections may overlap. The intensity $I_l(R_{hk})$ is equal to the intensity $I(R, Z)$ integrated over the region of the spot, and the intensity at the centre of a spot is reduced, relative to $I_l(R_{hk})$, by a factor that increases with the degree of smearing.

The c repeat can be obtained immediately from the layer-line spacing. Initial estimates of the remaining cell constants can be made from inspection of the (R, Z) coordinates of low-order reflections. These values are refined by minimizing the difference between the calculated and measured (R, Z) coordinates of all the sharp reflections on the pattern.

One approach to measuring the intensities of Bragg reflections is to estimate the boundary of each spot (or a fixed proportion of the region occupied by each spot) and integrate the intensity over that region (Millane & Arnott, 1986; Hall *et al.*, 1987). For spots that overlap, an integration region that is the union of the region occupied by each contributing spot can be used, allowing the intensities for composite spots to be calculated (Millane & Arnott, 1986). This is more accurate than methods based on the measurement of the peak intensity followed by a correction for smearing. Integration methods suffer from problems associated with determining accurate spot boundaries and they are not capable of separating weakly overlapping spots. A more effective approach is one based on profile fitting. The intensity distribution on the diffraction pattern can be written as

$$I(R, Z) = \sum_l \sum_{h,k} I_l(R_{hk}, R, Z), \tag{4.5.2.56}$$

where $I_l(R_{hk}, R, Z)$ denotes the intensity distribution of the spot $I_l(R_{hk})$, and the sums are over all spots on the diffraction pattern. Using equation (4.5.2.27) shows that equation (4.5.2.56) can be written as

$$I(R, Z) = \sum_l \sum_{h,k} I_l(R_{hk}) S(R_{hk}; l/c; R; Z), \tag{4.5.2.57}$$

where $S(R_{hk}; l/c; R; Z)$ denotes the profile of the spot centred at $(R_{hk}, l/c)$ [which can be derived from equation (4.5.2.27)]. Given estimates of the parameters $l_{\rm lat}$, $l_{\rm axial}$ and α_0, equation (4.5.2.57) can be written as a system of linear equations that can be solved

for the intensities $I_l(R_{hk})$ from the data $I(R, Z)$ on the diffraction pattern. The parameters $l_{\rm lat}$, $l_{\rm axial}$ and α_0, as well as the cell constants and possibly other parameters, can also be refined as part of the profile-fitting procedure using nonlinear optimization.

A suite of programs for processing fibre diffraction data is distributed (and often developed) by the Collaborative Computational Project for Fibre and Polymer Diffraction (CCP13) in the UK (http://www.ccp13.ac.uk/) (Shotton *et al.*, 1998).

4.5.2.6. Structure determination

4.5.2.6.1. Overview

Structure determination in fibre diffraction is concerned with determining atomic coordinates or some other structural parameters, from the measured cylindrically averaged diffraction data. Fibre diffraction analysis suffers from the phase problem and low resolution (diffraction data rarely extend beyond 3 Å resolution), but this is no worse than in protein crystallography where phases derived from, say, isomorphous replacement or molecular replacement, coupled with the considerable stereochemical information usually available on the molecule under study, together contribute enough information to lead to precise structures. What makes structure determination by fibre diffraction more difficult is the loss of information owing to the cylindrical averaging of the diffraction data. However, in spite of these difficulties, fibre diffraction has been used to determine, with high precision, the structures of a wide variety of biological and synthetic polymers, and other macromolecular assemblies. Because of the size of the repeating unit and the resolution of the diffraction data, methods for structure determination in fibre diffraction tend to mimic those of macromolecular (protein) crystallography, rather than small-molecule crystallography (direct methods).

For a noncrystalline fibre one can determine only the molecular structure from the continuous diffraction data, whereas for a polycrystalline fibre one can determine crystal structures from the Bragg diffraction data. However, there is little fundamental difference between methods used for structure determination with noncrystalline and polycrystalline fibres. For partially crystalline fibres, little has so far been attempted with regard to rigorous structure determination.

As is the case with protein crystallography, the precise methods used for structure determination by fibre diffraction depend on the particular problem at hand. A variety of tools are available and one selects from these those that are appropriate given the data available in a particular case. For example, the structure of a polycrystalline polynucleotide might be determined by using Patterson functions to determine possible packing arrangements, molecular model building to define, refine and arbitrate between structures, difference Fourier synthesis to locate ions or solvent molecules, and finally assessment of the reliability of the structure. As a second example, to determine the structure of a helical virus, one might use isomorphous replacement to obtain phase estimates, calculate an electron-density map, fit a preliminary model and refine it using simulated annealing alternating with difference Fourier analysis, and assess the results. The various tools available, together with indications of where and how they are used, are described in the following sections.

Although a variety of techniques are used to solve structures using fibre diffraction, most of the methods do fall broadly into one of three classes that depend primarily on the size of the helical repeat unit. The first class applies to molecules whose repeating units are small, *i.e.* are represented by a relatively small number of independent parameters or degrees of freedom (after all stereochemical constraints have been incorporated). The structure can then be determined by an exhaustive exploration of the parameter space using molecular model building. The first example above would belong to this class. The second class of methods is appropriate when the size of the helical repeating unit is such that its structure is described by too many variable parameters for the parameter space to be explored *a priori*. It is then necessary to phase the fibre diffraction data and construct an electron-density map into which the molecular structure can be fitted and then refined. The second example above would belong to this class. The second class of methods therefore mimics conventional protein crystallography quite closely. The third class of problems applies when the structure is large, but there are too few diffraction data to attempt phasing and the usual determination of atomic coordinates. The solution to such problems varies from case to case and usually involves modelling and optimization of some kind.

An important parameter in structure determination by fibre diffraction is the degree of overlap (that results from the cylindrical averaging) in the data. This parameter is equal to the number of significant terms in equation (4.5.2.17) or the number of independent terms in equation (4.5.2.24), and depends on the position in reciprocal space and, for a polycrystalline fibre, the space-group symmetry. The number of degrees of freedom in a particular datum is equal to twice this number (since each structure factor generally has real and imaginary parts), and is denoted in this section by m. Determination of the $G_{nl}(R)$ from the cylindrically averaged data $I_l(R)$ therefore involves separating the $m/2$ amplitudes $|G_{nl}(R)|$ and assigning phases to each. The electron density can be calculated from the $G_{nl}(R)$ using equations (4.5.2.7) and (4.5.2.11).

4.5.2.6.2. Helix symmetry, cell constants and space-group symmetry

The first step in analysis of any fibre diffraction pattern is determination of the molecular helix symmetry u_v. Only the zero-order Bessel term contributes diffracted intensity on the meridian, and referring to equation (4.5.2.6) shows that the zero-order term occurs only on layer lines for which l is a multiple of u. Therefore, inspection of the distribution of diffraction along the meridian allows the value of u to be inferred. This procedure is usually effective, but can be difficult if u is large, because the first meridional maximum may be on a layer line that is difficult to measure. This difficulty was overcome in one case by Franklin & Holmes (1958) by noting that the second Bessel term on the equator is $n = u$, estimating $G_{00}(R)$ using data from a heavy-atom derivative (see Section 4.5.2.6.6), subtracting this from $I_0(R)$, and using the behaviour of the remaining intensity for small R to infer the order of the next Bessel term [using equation (4.5.2.14)] and thence u.

Referring to equations (4.5.2.6) and (4.5.2.14) shows that the distribution of $R_{\rm min}$ for $0 < l < u$ depends on the value of v. Therefore, inspection of the intensity distribution close to the meridian often allows v to be inferred. Note, however, that the distribution of $R_{\rm min}$ does not distinguish between the helix symmetries u_v and u_{u-v}. Any remaining ambiguities in the helix symmetry need to be resolved by steric considerations, or by detailed testing of models with the different symmetries against the available data.

For a polycrystalline system, the cell constants are determined from the (R, Z) coordinates of the spots on the diffraction pattern as described in Section 4.5.2.6.4. Space-group assignment is based on analysis of systematic absences, as in conventional crystallography. However, in some cases, because of possible overlap of systematic absences with other reflections, there may be some ambiguity in space-group assignment. However, the space group can always be limited to one of a few possibilities, and ambiguities can usually be resolved during structure determination (Section 4.5.2.6.4).

4.5.2.6.3. Patterson functions

In fibre diffraction, the conventional Patterson function cannot be calculated since the individual structure-factor intensities are not available. However, MacGillavry & Bruins (1948) showed that the *cylindrically averaged Patterson function* can be calculated from fibre diffraction data. Consider the function $\hat{Q}(r, z)$ defined by

$$\hat{Q}(r, z) = \sum_{l=0}^{\infty} \int_0^{\infty} \varepsilon_l I_l(R) J_0(2\pi Rr) \cos(2\pi lz/c) 2\pi R \, \mathrm{d}R, \quad (4.5.2.58)$$

where $\varepsilon_l = 1$ for $l = 0$ and 2 for $l > 0$, which can be calculated from the intensity distribution on a continuous fibre diffraction pattern. Using equations (4.5.2.7), (4.5.2.10), (4.5.2.17) and (4.5.2.58) shows that $\hat{Q}(r, z)$ is the cylindrical average of the Patterson function, $\hat{P}(r, \varphi, z)$, of one molecule, *i.e.*

$$\hat{Q}(r, z) = (1/2\pi) \int_0^{2\pi} \hat{P}(r, \varphi, z) \, \mathrm{d}\varphi. \quad (4.5.2.59)$$

The $\hat{}$ symbols on $\hat{P}(r, \varphi, z)$ and $\hat{Q}(r, z)$ indicate that these are Patterson functions of a single molecule, as distinct from the usual Patterson function of a crystal, which contains intermolecular interatomic vectors and is periodic with the same periodicity as the crystal. $\hat{P}(r, \varphi, z)$ is periodic only along z and is therefore, strictly, a Patterson function along z and an autocorrelation function along x and y (Millane, 1990*b*). The cylindrically averaged Patterson contains information on interatomic separations along the axial direction and in the lateral plane, but no information on orientations of the vectors in the lateral plane.

For a polycrystalline system; consider the function $Q(r, z)$ given by

$$Q(r, z) = \sum_l \sum_{h,k} R_{hk} I_l(R_{hk}) J_0(2\pi R_{hk} r) \cos(2\pi lz/c), \quad (4.5.2.60)$$

where the sums are over all the overlapped reflections $I_l(R_{hk})$ on the diffraction pattern, given by equation (4.5.2.24). It is easily shown that $Q(r, z)$ is related to the Patterson function $P(r, \varphi, z)$ by

$$Q(r, z) = (1/2\pi) \int_0^{2\pi} P(r, \varphi, z) \, \mathrm{d}\varphi, \quad (4.5.2.61)$$

where, in this case, $P(r, \varphi, z)$ is the usual Patterson function (expressed in cylindrical polar coordinates), *i.e.* it contains all intermolecular (both intra- and inter-unit cell) interatomic vectors and has the same translational symmetry as the unit cell. The cylindrically averaged Patterson function for polycrystalline fibres therefore contains the same information as it does for noncrystalline fibres (*i.e.* no angular information in the lateral plane), except that it also contains information on intermolecular separations.

Low resolution and cylindrical averaging, in addition to the usual difficulties with interpretation of Patterson functions, has resulted in the cylindrically averaged Patterson function not playing a major role in structure determination by fibre diffraction. However, information provided by the cylindrically averaged Patterson function has, in a number of instances, been a useful component in fibre diffraction analyses. A good review of the application of Patterson functions in fibre diffraction is given by Stubbs (1987). Removing data from the low-resolution part (or all) of the equator when calculating the cylindrically averaged Patterson function removes the strong vectors related to axially invariant (or cylindrically symmetric) parts of the map, and can aid interpretation (Namba *et al.*, 1980; Stubbs, 1987). It is also important when calculating cylindrically averaged Patterson functions to use data only at a resolution that is appropriate to the size and spacings of features one is looking for (Stubbs, 1987).

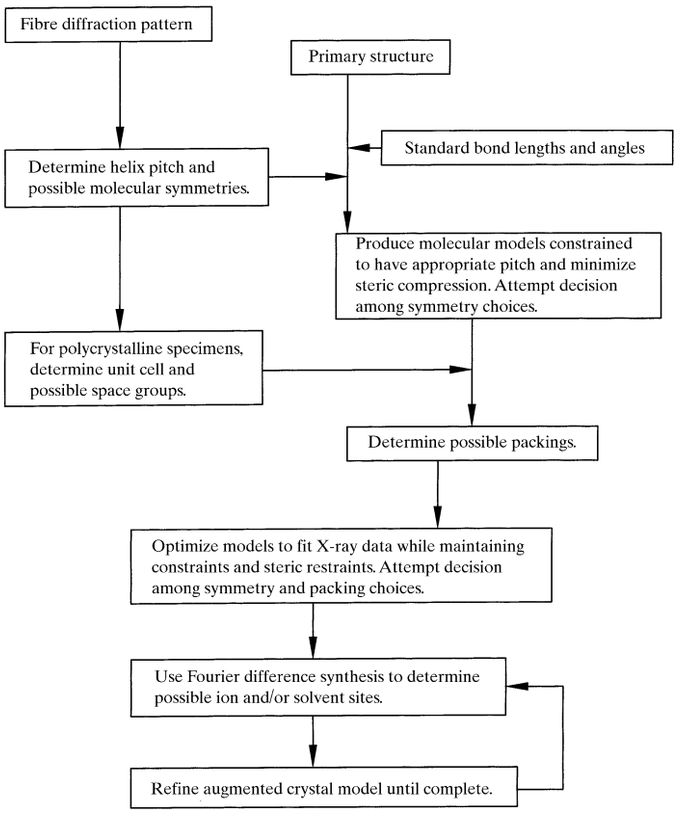
Cylindrically averaged Patterson functions were used in early applications of fibre diffraction analysis (Franklin & Gosling, 1953; Franklin & Klug, 1955). The intermolecular peaks that usually dominate in a cylindrically averaged Patterson function can help to define the locations of multiple molecules in the unit cell. Depending on the space-group symmetry, it is sometimes possible to calculate the complete three-dimensional Patterson function (or certain projections of it). This comes about because of the equivalence of the amplitudes of overlapping reflections in some high-symmetry space groups. The intensity of each reflection can then be determined and a full three-dimensional Patterson map calculated (Alexeev *et al.*, 1992). The only difficulty is that nonsystematic overlaps are often present, although these are usually relatively few in number and the intensity can be apportioned equally amongst them, the resulting errors usually being small relative to the level of detail present in the Patterson map. For lower space-group symmetries, it may not be possible to calculate a three-dimensional Patterson map, but it may be possible to calculate certain projections of the map. For example, if the overlapped $hk0$ reflections have the same intensities, a projection of the Patterson map down the c axis can be calculated. Since such a projection is along the polymer axes, it gives the relative positions of the molecules in the ab plane. If the combined helix and space-group symmetry is high, an estimate of the electron density can be obtained by averaging appropriate copies of the three-dimensional Patterson function (Alexeev *et al.*, 1992).

4.5.2.6.4. Molecular model building

The majority of the structures determined by X-ray fibre diffraction analysis have been determined by molecular model building (Campbell Smith & Arnott, 1978; Arnott, 1980; Millane, 1988). Most applications of molecular model building have been to polycrystalline systems, although there have been a number of applications to noncrystalline systems (Park *et al.*, 1987; Millane *et al.*, 1988). The approach is to use spacings and symmetry information derived directly from the diffraction pattern, coupled with the primary structure and stereochemical information on the molecule under study, to construct models of all *kinds* of possible molecular or crystal structure. These models are each refined (optimized) against the diffraction data, as well as stereochemical restraints, to produce the best model of each kind. The optimized models can be compared using various figures of merit, and in favourable cases one model will be sufficiently superior to the remainder for it to represent unequivocally the correct structure. The principle of this approach is that by making use of stereochemical constraints, the molecular and crystal structure have few enough degrees of freedom that the parameter space has a sufficiently small number of local minima for these to be identified and individually examined to find the global minimum. The X-ray phases are therefore not determined explicitly.

There are three steps involved in structure determination by molecular model building: (1) construction of all possible molecular and crystal structure models, (2) refinement of each model against the X-ray data and stereochemical restraints, and (3) adjudication among the refined models. The overall procedure for determining polymer structures using molecular model building is summarized by the flow chart in Fig. 4.5.2.2, and is described below.

The helix symmetry of the molecule, or one of a few helix symmetries, can be determined as described in Section 4.5.2.6.2. Different kinds of molecular model may correspond to one of a few different helix symmetries, usually corresponding to different



Fibre diffraction pattern
Primary structure
Standard bond lengths and angles
Determine helix pitch and possible molecular symmetries.
Produce molecular models constrained to have appropriate pitch and minimize steric compression. Attempt decision among symmetry choices.
For polycrystalline specimens, determine unit cell and possible space groups.
Determine possible packings.
Optimize models to fit X-ray data while maintaining constraints and steric restraints. Attempt decision among symmetry and packing choices.
Use Fourier difference synthesis to determine possible ion and/or solvent sites.
Refine augmented crystal model until complete.

values of v. For example, helix symmetries u_v and u_{u-v}, which correspond to the left- and right-handed helices, cannot be distinguished on the basis of the overall intensity distribution alone. Other examples of different kinds of molecular model may include single, double or multiple helices, parallel or antiparallel double helices, different juxtapositions of chains within multiple helices and different conformational domains within the molecule. For polycrystalline systems, in addition to different kinds of molecular structures, there are often different kinds of possible packing arrangements within the unit cell. There may be a number of possible packings which correspond to different arrangements within the crystallographic asymmetric unit, and there may be more than one space group that needs to be considered.

Despite the apparent large number of potential starting models implied by the above discussion, in practice the number of feasible models is usually quite small, and many of these are often eliminated at an early stage. Definition and refinement of helical polymers [steps (1) and (2) above] are carried out using computer programs, the most popular and versatile being the *linked-atom least-squares* (*LALS*) system (Campbell Smith & Arnott, 1978; Millane *et al.*, 1985), originally developed by Arnott and co-workers in the early 1960s (Arnott & Wonacott, 1966). This system has been used to determine the structures of a wide variety of polynucleotides, polysaccharides, polyesters and polypeptides (Arnott, 1980; Arnott & Mitra, 1984; Chandrasekaran & Arnott, 1989; Millane, 1990*c*). Other refinement systems exist (Zugenmaier & Sarko, 1980; Iannelli, 1994), but the principles are essentially the same and the following discussion is in terms of the *LALS* system. The atomic coordinates are defined, using a linked-atom description, in terms of bond lengths, bond angles and conformation (torsion) angles (Campbell Smith & Arnott, 1978). Stereochemical constraints are imposed, and the number of parameters reduced, by fixing the bond lengths, often (but not always) the bond angles, and possibly some of the conformation angles. The molecular conformation is then defined by the remaining parameters. For polycrystalline systems, there are usually additional variable parameters that define the packing of the molecule(s) in the unit cell. A further source of stereochemical data is the requirement that a model exhibit no overshort nonbonded interatomic distances. These are incorporated by a quadratic nonbonded potential that is matched to a Buckingham potential (Campbell Smith & Arnott, 1978). A variety of other restraints can also be incorporated.

In the *LALS* system, the quantity Ω given by

$$\Omega = \sum_m \omega_m \Delta F_m^2 + \sum_m k_m \Delta d_m^2 + \sum_m \lambda_m G_m = X + C + L \qquad (4.5.2.62)$$

is minimized by varying a set of chosen parameters consisting of conformation angles, possibly bond angles, and packing parameters. The term X involves the differences ΔF_m between the model and experimental X-ray amplitudes – Bragg and/or continuous. The term C involves restraints to ensure that overshort nonbonded interatomic distances are driven beyond acceptable minimum values, that conformations are within desired domains, that hydrogen-bond and coordination geometries are close to the expected configurations, and a variety of other relationships are satisfied (Campbell Smith & Arnott, 1978). The ω_m and k_m are weights that are inversely proportional to the estimated variances of the data. The term L involves constraints which are relationships that are to be satisfied exactly ($G_m = 0$) and the λ_m are Lagrange multipliers. Constraints are used, for example, to ensure connectivity from one helix pitch to the next and to ensure that chemical ring systems are closed. The cost function Ω is minimized using full-matrix nonlinear least squares and singular value decomposition (Campbell Smith & Arnott, 1978).

Structure determination usually involves first using equation (4.5.2.62) with the terms C and L only, to establish the stereochemical viability of each kind of possible molecular model and packing arrangement. It is worth emphasizing that it is usually advantageous if the specimen is polycrystalline, even though the continuous diffraction contains, in principle, more information than the Bragg reflections (since the latter are sampled). This is because the molecule in a noncrystalline specimen must be refined in steric isolation, whereas for a polycrystalline specimen it is refined while packed in the crystal lattice. The extra information provided by the intermolecular contacts can often help to eliminate incorrect models. This can be particularly significant if the molecule has flexible sidechains. The initial models that survive the steric optimization are then optimized also against the X-ray data, by further refinement with X included in equation (4.5.2.62). The ratios $(\Omega_P/\Omega_Q)^{1/2}$ and $(X_P/X_Q)^{1/2}$ can be used in Hamilton's test (Hamilton, 1965) to evaluate the differences between models P and Q. On the basis of these statistical tests, one can decide if one model is superior to the others at an acceptable confidence level. In the final stages of refinement, bond angles may be varied in a 'stiffly elastic' fashion from their mean values if there are sufficient data to justify the increase in the number of degrees of freedom.

If sufficient X-ray data are available, it is sometimes possible to locate additional ordered molecules such as counterions or solvent molecules by difference Fourier synthesis as described in Section 4.5.2.6.5. Their positions can then be co-refined with the polymer structure while hydrogen bonds and coordination geometries are optimized. The resulting structure can then be used to compute improved phases to search for additional molecules. Since the signal-to-noise ratio in fibre difference syntheses is usually low, difference maps must be interpreted with caution. The assignment of counterions or solvent molecules to peaks in the difference synthesis must be supported by plausible

interactions with the rest of the structure and, following refinement of the structure, by elimination of the peak in the difference map and by a significant improvement in the agreement between the calculated and measured X-ray amplitudes.

4.5.2.6.5. Difference Fourier synthesis

Difference Fourier syntheses are widely used in both protein and small-molecule crystallography to detect structural errors or to complete partial structures (Drenth, 1994). The difficulty in applying difference Fourier techniques in fibre diffraction is that the individual observed amplitudes $|F_o|$ are not available. However, difference syntheses have found wide use in fibre diffraction analysis, one of the earliest applications being to polycrystalline fibres of polynucleotides (*e.g.* Arnott *et al.*, 1967). Calculation of a three-dimensional difference map (for the unit cell) from Bragg fibre diffraction data requires that the observed intensity $I_l(R_{hk}) = I_o$ be apportioned among the contributing intensities $|F_{hkl}|^2 = |F_o|^2$. There are two ways of doing this. The intensities may be divided equally among the contributing $(m/2)$ reflections [*i.e.* $|F_o| = (2I_o/m)^{1/2}$], or they may be divided in the same proportions as those in the model, *i.e.*

$$|F_o| = \left(\frac{I_o}{\sum|F_c|^2}\right)^{1/2} |F_c|. \qquad (4.5.2.63)$$

The advantage of the former is that it is unbiased, and the advantage of the latter is that it may be more accurate but is biased towards the model. Equal division of the intensities is often (but not always) used to minimize model bias. Once the observed amplitudes have been apportioned, an $|F_o| - |F_c|$ map can be calculated as in conventional crystallography, although noise levels will be higher owing to errors in apportioning the amplitudes. As a result of overlapping of the reflections, a synthesis based on coefficients $m|F_o| - (m-1)|F_c|$ gives a more accurate estimate of the true density than does one based on $2|F_o| - |F_c|$, as is described below. Difference syntheses for polycrystalline specimens calculated in this way have been used, for example, to locate cations and water molecules in polynucleotide and polysaccharide structures (*e.g.* Cael *et al.*, 1978), to help position molecules in the unit cell (*e.g.* Chandrasekaran *et al.*, 1994) and to help position side chains, and have also been applied in neutron fibre diffraction studies of polynucleotides (Forsyth *et al.*, 1989).

Sim (1960) has shown that the mean-squared error in difference syntheses can be minimized by weighting the coefficients based on the agreement between the calculated and observed structure amplitudes. Such an analysis has recently been conducted for fibre diffraction, and shows that the optimum difference synthesis is obtained by using coefficients (Millane & Baskaran, 1997; Baskaran & Millane, 1999*a*)

$$\left[w_m \frac{|F_c|(I_o)^{1/2}}{(\sum|F_c|^2)^{1/2}} - |F_c|\right] \exp(i\alpha_c), \qquad (4.5.2.64)$$

where m is the number of degrees of freedom as defined in Section 4.5.2.6.1. If the reflections contributing to I_o are either all centric or all acentric, then the weights are given by

$$w_m = \frac{I_{m/2}(X)}{I_{m/2-1}(X)}, \qquad (4.5.2.65)$$

where $I_m(\cdot)$ denotes the modified Bessel function of the first kind of order m, and X is given by

$$X = \frac{\kappa(I_o)^{1/2}(\sum|F_c|^2)^{1/2}}{\sum_j f_j^2}, \qquad (4.5.2.66)$$

where $\kappa = 1$ for centric reflections and 2 for acentric reflections. The form of the weighting function is more complicated if both centric and acentric reflections contribute, but it can be approximated as w' given by

$$w' = (w_{2N_a} + w_{N_c})/2, \qquad (4.5.2.67)$$

where N_a and N_c are the number of acentric and centric reflections, respectively, contributing. Use of the weighted maps reduces bias towards the model (Baskaran & Millane, 1999*b*).

For continuous diffraction data from noncrystalline specimens, the situation is essentially identical except that one works in cylindrical coordinates. Referring to equations (4.5.2.7) and (4.5.2.10), the desired difference synthesis, $\Delta g(r, \varphi, z)$, is the Fourier–Bessel transform of $G_o - G_c$ where G_o and G_c denote the observed and calculated, respectively, Fourier–Bessel structure factors $G_{nl}(R)$. Since G_o is not known, the synthesis is based on the Fourier–Bessel transform of $(|G_o| - |G_c|)\exp(i\alpha_c)$, where α_c is the phase of G_c. As in the polycrystalline case, the individual $|G_o|$ need to be estimated from the data $I_o^{1/2}$ given by equation (4.5.2.17), and can be based on either equal division of the data, or division in the same proportion as the amplitudes from the model.

Namba & Stubbs (1987*a*) have shown that the peak heights in a difference synthesis are $1/m$ times their true value, as opposed to half their true value in a conventional difference synthesis. The best estimate of the true map is therefore provided by a synthesis based on the coefficients $[m|F_o| - (m-1)|F_c|]\exp(i\alpha_c)$, rather than on $(2|F_o| - |F_c|)\exp(i\alpha_c)$. Test examples showed that the noise in the synthesis can be reduced by using a value for m that is fixed over the diffraction pattern and approximately equal to the average value of m over the pattern (Namba & Stubbs, 1987*a*). Difference Fourier maps for noncrystalline systems have been used in studies of helical viruses to locate heavy atoms, to correct errors in atomic models and to locate water molecules (Mandelkow *et al.*, 1981; Lobert *et al.*, 1987; Namba, Pattanayek & Stubbs, 1989; Wang & Stubbs, 1994).

4.5.2.6.6. Multidimensional isomorphous replacement

At low enough resolution, only one Fourier–Bessel structure factor contributes on each layer line of a fibre diffraction pattern, so that only the phase needs to be determined and the situation is no different to that in protein crystallography. If heavy-atom-derivative specimens can be prepared, the usual method of multiple isomorphous replacement (MIR) (Drenth, 1994) can be applied, which in principle requires only two heavy-atom derivatives. At higher resolution, however, more than one Fourier–Bessel structure factor contributes on each layer line. A generalized form of isomorphous replacement which involves using diffraction data from several heavy-atom derivatives to determine the real and imaginary components of each contributing $G_{nl}(R)$ is referred to as *multidimensional isomorphous replacement* (MDIR) (Namba & Stubbs, 1985). MDIR was first described and used to determine the structure of TMV at 6.7 Å resolution (Stubbs & Diamond, 1975; Holmes *et al.*, 1975), and has since been used to extend the resolution to 2.9 Å (Namba, Pattanayek & Stubbs, 1989). A consequence of cylindrical averaging is that large numbers of heavy-atom derivatives are required: at least two for each Bessel term to be separated. The theory of MDIR is outlined here.

The first step in MDIR is location of the heavy atoms in the derivative structures. The radial coordinate of a heavy atom can be determined by analysis of the intensity distribution in the low-

resolution region of the equator where only the $G_{00}(R)$ Bessel term contributes. Since $G_{00}(R)$ is real, and $I_l(R)$ can be measured continuously in R, inspection of the positions of the minima and maxima in the low-resolution region of the equator generally allows the sign of $G_{00}(R)$ to be assigned to $I_0^{1/2}(R)$, *i.e.* $G_{00}(R)$ can be determined from $I_0(R)$. If the sign is determined for both the native and a heavy-atom derivative, referring to equation (4.5.2.13) shows that

$$G_{00}^{\rm D}(R) - G_{00}(R) = o_h f_h J_0(2\pi R r_h), \tag{4.5.2.68}$$

where $G_{00}^{\rm D}(R)$ is the value derived from the derivative data, o denotes the occupancy and the subscript h denotes values for the heavy atom. The parameters o_h and r_h on the right-hand side of equation (4.5.2.68) can be searched in a trial-and-error fashion to obtain the best agreement with the left-hand side (calculated from the data) to determine the radial coordinate r_h of the heavy atom (Mandelkow & Holmes, 1974). Lobert *et al.* (1987) applied the same method to cucumber green mottle mosaic virus (CGMMV), except that the sign of $G_{00}(R)$ was taken from that of TMV.

Two approaches have been used to determine the angular and axial coordinates of the heavy atom. Mandelkow & Holmes (1974) and Holmes *et al.* (1975) used a search procedure in which the quantity $\Phi = -n\varphi_h + 2\pi l z_h/c$ is varied and used to calculate the intensity of the Fourier–Bessel structure factor for the heavy atom alone. This is compared to $I_l^{\rm D}(R) - I_l(R)$ on each layer line, where only one Bessel order contributes, and Φ chosen to minimize the mean-square difference. The values of Φ found for each layer line can then be combined to determine φ_h and z_h. In the case of CGMMV, Lobert *et al.* (1987) used the phases and Bessel-order separations from TMV to calculate Fourier–Bessel difference maps between the native and derivative data to determine the heavy-atom coordinates (r_h, φ_h, z_h).

Consider a set of isomorphous heavy-atom derivatives indexed by j. Since the analysis is applied at any point (l, R) on the fibre diffraction pattern, the symbol G_n will be used for $G_{nl}(R)$ where no confusion arises. Denote by $G_{n,j}$ the value of G_n for the jth derivative, so that

$$G_{n,j} = G_n + g_{n,j}, \tag{4.5.2.69}$$

where $g_{n,j}$ denotes the Fourier–Bessel structure factor of a structure containing the heavy atom only. Denote by A_n and B_n the real and imaginary parts, respectively, of G_n (for the native structure), and by $a_{n,j}$ and $b_{n,j}$ the real and imaginary parts of $g_{n,j}$, *i.e.* for the jth heavy-atom structure alone. Equation (4.5.2.17) can then be written as

$$I = \sum_n (A_n^2 + B_n^2) \tag{4.5.2.70}$$

for the native and

$$I_j = \sum_n [(A_n + a_{n,j})^2 + (B_n + b_{n,j})^2] \tag{4.5.2.71}$$

for the jth derivative. If intensity data are available from J heavy-atom derivatives, $a_{n,j}$ and $b_{n,j}$ can be calculated from the heavy-atom positions, and equations (4.5.2.70) and (4.5.2.71) represent a system of $J+1$ second-order equations for the m unknowns A_n and B_n. If $J+1 > m$, then the system of equations is over-determined and can be solved for the A_n and B_n. The solution of this nonlinear system can be eased by deriving a system of linear equations by substituting from (4.5.2.70) into (4.5.2.71), giving

$$\sum_n (A_n a_{n,j} + B_n b_{n,j}) = (1/2)\left[I_j - I - \sum_n (a_{n,j}^2 + b_{n,j}^2)\right]. \tag{4.5.2.72}$$

Equation (4.5.2.72) is a system of linear equations for the unknowns A_n and B_n, the solution being subject to the constraint equation (4.5.2.70). However, since the original problem is second-order, there may be up to m local minima. Stubbs & Diamond (1975) describe a numerical procedure for locating *all* the local minima and selecting the best of these based on 'continuity' of the $G_{nl}(R)$. This method was used to determine the structure of TMV at 6.7 Å resolution (Holmes *et al.*, 1975) and 4 Å resolution (Stubbs *et al.*, 1977). In current applications of MDIR a more direct solution technique is used in which the phase-determining equations (4.5.2.70) and (4.5.2.71) are solved by first solving the linear equations (4.5.2.72) by linear least squares to obtain an approximate solution, which is then refined by solving the quadratic equations (4.5.2.70) and (4.5.2.71) directly using nonlinear least squares (Namba & Stubbs, 1985).

The number of heavy-atom derivatives required can be quite demanding experimentally, although phasing with fewer heavy-atom derivatives is possible, particularly if additional information is available, such as from a related structure. The different Bessel terms may be assumed to contribute the same amplitude each, or, if the structure of a related molecule is known, the ratios of the amplitudes can be taken as being the same as those for the related molecule. Using the amplitude estimates derived using either of these two approaches, applied to both native and derivative data, the phases of the Bessel terms can be estimated using conventional MIR and data from at least two heavy-atom derivatives, allowing an initial electron-density map to be calculated. If only one heavy-atom derivative is available then two phase solutions are obtained, but the method of conventional single isomorphous replacement (SIR) (Drenth, 1994) can be used to obtain an estimate of the electron density. The electron density obtained by MIR, and particularly by SIR, in this way tends to be noisy and low contrast as a result of inaccurate division of the intensities, as well as the usual sources of errors in MIR. The electron density can, however, be improved using solvent levelling. If *no* heavy-atom derivatives are available, both the relative amplitudes *and* the phases can be based on those of a related structure. Model bias can, however, be more serious than in conventional crystallography since both the phases and the relative amplitudes are based on the model.

The feasibility of structure determination with a limited number of heavy-atom derivatives was first demonstrated by Namba & Stubbs (1987*b*) using data from TMV at 4 Å resolution. The structure of CGMMV has been determined at 5 Å resolution using data from two heavy-atom derivatives and the techniques described above (Lobert *et al.*, 1987; Lobert & Stubbs, 1990). Structure determination at this resolution using MDIR would theoretically require six heavy-atom derivatives. Initial separation of the Bessel-term amplitudes was based on the equal-amplitude assumption and also on the relative amplitudes for (homologous) TMV.

In general, the equal-amplitude assumption appears to produce reliable electron-density maps where only two or three Bessel terms contribute. The corresponding resolution depends on the helix symmetry and the molecular diameter, but can be relatively high for molecules with high helix symmetry. At higher resolution where more Bessel terms contribute, use of related or partial structures can be used to calculate initial Bessel-term amplitudes and can lead to successful phasing.

If the molecule has only approximate helix symmetry, then layer-line splitting (Section 4.5.2.3.3) can provide additional information which reduces the number of heavy-atom derivatives required. The degree of splitting is usually significantly less than

the breadth of the layer lines so that the different Bessel terms within a (split) layer line overlap. The effect of splitting can be observed, however, since the centre of a layer line, at a particular value of R, is shifted towards the position of the stronger Bessel term contributing at that radius. The shift depends on the relative magnitudes of the contributing Bessel terms, and can be measured and used in phase determination as detailed by Stubbs & Makowski (1982). If P of the heavy-atom derivatives (in addition to the native) give accurate splitting information, then an additional P linear equations [analogous to equation (4.5.2.72)] and one quadratic equation [analogous to equation (4.5.2.70)] are available for solution of the phase problem, and the number of heavy-atom derivatives required is reduced by a factor of up to two. The value of layer-line splitting was first demonstrated by recalculating an electron-density map of TMV at 6.7 Å resolution using only two derivatives, rather than using six derivatives without the use of splitting data (Stubbs & Makowski, 1982). Layer-line splitting was subsequently used in a structure determination of TMV at 3.6 Å resolution (Namba & Stubbs, 1985).

Macromolecular fibre structures that have been built into an electron-density map have been refined using both restrained least-squares (RLS) and molecular-dynamics (MD) refinements. Restrained least squares has been used to refine the structure of TMV at 2.9 Å resolution (Namba, Pattanayek & Stubbs, 1989); however, Wang & Stubbs (1993) have shown that a larger radius of convergence is obtained using MD refinement (as in protein crystallography).

Molecular-dynamics refinement in fibre diffraction has been implemented by adding a fibre diffraction option (Wang & Stubbs, 1993) to the *X-PLOR* program (Brünger, 1992). This involves including the cylindrically averaged fibre diffraction intensities in the energy term and taking account of the inter-helical subunit contacts and covalent connections in the same way as described above for RLS refinement. The effective potential-energy function E used is

$$E = E_{\rm e} + S\sum_l \sum_i w_{li}\{[I_l^{\rm o}(R_i)]^{1/2} - k[I_l^{\rm c}(R_i)]^{1/2}\}^2, \qquad (4.5.2.73)$$

where $E_{\rm e}$ is the empirical energy function (which typically includes bond-length, bond-angle and torsion-angle distortions, van der Waals and electrostatic interactions, and other terms such as ring planarity), $I_l^{\rm o}(R_i)$ and $I_l^{\rm c}(R_i)$ are the observed and calculated, respectively, cylindrically averaged diffraction intensities sampled at $R = R_i$, the w_{li} are weights for the observed intensities $I_l^{\rm o}(R_i)$ and k is a scale factor between the calculated and observed data. The quantity S is a weight to make the gradients of the two terms in equation (4.5.2.73) comparable (Wang & Stubbs, 1993), and can be estimated using the method of Brünger (1992). Molecular-dynamics refinement has been successfully used to refine the structure of CGMMV at 3.4 Å resolution (Wang & Stubbs, 1994). In the case of ribgrass mosaic virus (RMV), the close isomorphism with TMV (identical helix symmetry, similar repeat distance, significant sequence homology and similar diffraction pattern) allowed an initial model to be built based on the TMV structure, and a solution obtained at 2.9 Å by alternating molecular-dynamics refinement with difference-map and omit-map calculations (Wang *et al.*, 1997).

4.5.2.6.7. Other techniques

Aside from the techniques for structure determination described in the previous sections, a variety of other techniques have been applied to specific problems where the methods described above are not suitable. This situation usually arises where the diffraction data available are far too few, by themselves, to determine the individual atomic coordinates of a structure, even with the usual stereochemical constraints. Often only relatively low-resolution data are available, but they can be supplemented by either a low-resolution or high-resolution model of either a whole molecule or relatively large subunits. Structure determination often amounts to positioning the molecules or subunits within a larger assembly. The results can be quite precise, depending on the information available. The problem is almost always one of refinement or optimization, since it invariably involves optimizing some kind of model directly against the fibre diffraction data. The problem is usually twofold: (1) parameterizing the model with few enough parameters to obtain a usable data-to-parameter ratio, but retaining enough degrees of freedom to represent the important structural features; and (2) devising an optimization procedure that will locate the global minimum of the resulting complicated cost function. There have been numerous such applications in fibre diffraction, and rather than attempt to be exhaustive or detailed, I will briefly mention a few of the more prominent applications and techniques.

The structure of the bacteriophage Pf1 was determined at 7 Å resolution using a model in which the α-helical segments of the structure were represented by rods of electron density of appropriate dimensions and spacings (Makowski *et al.*, 1980). The positions and orientations of the rods were refined in an iterative procedure that alternated between real space and reciprocal space and also incorporated solvent levelling. Neutron fibre diffraction data have been collected from specifically deuterated phages and, starting with a model of the kind described above, iterative application of difference maps (between the deuterated and native data) was used to locate 15 (of the 46) residues, allowing construction of a model of the coat protein (Stark *et al.*, 1988; Nambudripad *et al.*, 1991).

Pf1 undergoes a temperature-induced structural transition that involves a small change in the helix symmetry. The low-temperature form has 71_{13} helix symmetry with a c repeat of 216.5 Å, and the high-temperature form (that discussed in the previous paragraph) has 27_5 helix symmetry and a c repeat of 78.3 Å. These two symmetries are very similar since $71/3 \simeq 27/5$ and $216.5/71 \simeq 78.3/27$, *i.e.* the rotations and translations from one subunit to the next are very similar in both structures.

The structure of the low-temperature form of Pf1 has been determined at 3.3 Å resolution by starting with an α-helical polyalanine model (Marvin *et al.*, 1987) and alternating rounds of molecular-dynamics refinement and model rebuilding based on $(2F_{\rm o} - F_{\rm c})$ maps and omit maps (Gonzalez *et al.*, 1995). The structure of the high-temperature form of Pf1 was determined using data to 3 Å resolution, starting with a model based on the low-temperature form, making small adjustments to satisfy the slightly different helix symmetry, and refining the model using molecular dynamics (Welsh *et al.*, 2000).

The bacteriophage Pf3 is related to Pf1 but does not undergo a structural transition, and fibre diffraction patterns are similar to those from the high-temperature form of Pf1. An α-helical polyalanine model of Pf3 based on the Pf1 structure was used to separate and phase the Bessel terms, which were then used to calculate $(5F_{\rm o} - 4F_{\rm c})$ maps. These maps were used to align and position the polypeptide chain, and the resulting model was refined by molecular dynamics (Welsh *et al.*, 1998).

The R-type bacterial flagellar filament structure (that has a very high molecular weight subunit) has been determined at 9 Å resolution by X-ray fibre diffraction (Yamashita *et al.*, 1998). Accurate intensities were taken from high-quality X-ray diffraction patterns and combined with phases obtained from electron cryomicroscopy, and solvent levelling was used to refine the phases.

Some studies of muscle provide a good example of the use of low-resolution fibre diffraction data, coupled with high-resolution crystal structures of some of the component molecules, to determine the structure of a complex. Holmes *et al.* (1990) constructed a model of F-actin based on the crystal structure of

the monomer, G-actin, and 8 Å fibre diffraction data, by either treating the monomer as a rigid body or dividing it into four separate rigid domains, and using a search procedure followed by least-squares refinement. The results gave the orientation of the actin monomer in the actin helix. This structure has since been refined using a genetic algorithm (Lorenz *et al.*, 1993) and normal-mode analysis (Tirion *et al.*, 1995). The genetic algorithm involved a Monte Carlo method of selecting subdomains to be refined and nonlinear least squares to obtain the best fit for the selected domains. In the normal-mode analysis, the model was parameterized in terms of its low-frequency vibrational modes to allow low-energy conformational changes and reduce the number of parameters which were optimized against the fibre diffraction data using nonlinear least squares.

Squire *et al.* (1993) have refined a low-resolution model of the muscle thin-filament structure that consists of four spheres representing each of the F-actin monomer subdomains and five spheres (fixed relative to each other) representing tropomyosin. Steric restraints were placed on the actin subdomain and thin-filament structures. The positions of the actin subdomains and the orientation of the tropomyosin were refined using a search procedure against fibre diffraction data from both 'resting' and 'activated' muscle at 25 Å resolution. More recent work has used a low-resolution model of the myosin head (based on the single-crystal atomic structure), a search procedure and simulated-annealing refinements to study myosin head configuration (Hudson *et al.*, 1997) and myosin rod packing (Squire *et al.*, 1998).

4.5.2.6.8. Reliability

As with structure determination in any area of crystallography, assessment of the reliability or precision of a structure is critically important. The most commonly used measure of reliability in fibre diffraction is the *R* factor, calculated as

$$R = \frac{\sum_i ||F|_i^{\rm o} - |F|_i^{\rm c}|}{\sum_i |F|_i^{\rm o}}, \qquad (4.5.2.74)$$

where $|F|_i^{\rm o}$ and $|F|_i^{\rm c}$ denote the observed (measured) and calculated, respectively, amplitude of either the samples (along *R*) of the cylindrically averaged intensity $I_l^{1/2}(R)$ (for a noncrystalline specimen) or the cylindrically averaged structure factors $I_l^{1/2}(R_{hk})$ (for a polycrystalline specimen). One way of assessing the significance of the *R* factor obtained in a particular structure determination is by comparing it with the 'largest likely *R* factor' (Wilson, 1950), *i.e.* the expected value of the *R* factor for a random distribution of atoms. Wilson (1950) showed that the largest likely *R* factor is 0.83 for a centric crystal and 0.59 for an acentric crystal. Although it does not provide a quantitative measure of structural reliability, the largest likely *R* factor does provide a useful yardstick for evaluating the significance of *R* factors obtained in structure determinations.

The largest likely *R* factor for fibre diffraction can be calculated from the amplitude statistics, which depend on the number of degrees of freedom, *m*, in the measured intensity (Stubbs, 1989; Millane, 1990*a*). Making use of these statistics shows that the largest likely *R* factor, R_m, for *m* components is given by (Stubbs, 1989; Millane, 1989*a*)

$$R_m = 2 - 2^{2-m} m \binom{2m-1}{m} B_{1/2}\left(\frac{m+1}{2}, \frac{m}{2}\right), \qquad (4.5.2.75)$$

where $\binom{m}{n}$ is the binomial coefficient and $B_x(m, n)$ the incomplete beta function. The beta function in equation (4.5.2.75) can be replaced by a finite series that is easy to evaluate (Millane, 1989*a*). The expression in equation (4.5.2.75) for R_m can be written in various approximate forms (Millane, 1990*d*, 1992*a*), the simplest being

$$R_m \simeq (2/\pi m)^{1/2} \qquad (4.5.2.76)$$

(Millane, 1990*d*), which shows that the largest likely *R* factor falls off approximately as $m^{-1/2}$ with increasing *m*. This is because it is easier to match the sum of a number of structure amplitudes than to match each of them individually. The important conclusion is that the largest likely *R* factor is smaller in fibre diffraction than in conventional crystallography (where $m = 1$ or 2), and it is smaller when there are more overlapping reflections. This means that for equivalent precision, the *R* factor must be smaller for a structure determined by fibre diffraction than for one determined by conventional crystallography. How much smaller depends on the number of overlapping reflections on the diffraction pattern.

In a structure determination, the data have different values of *m* at different positions on the diffraction pattern. Using the definition of the *R* factor, equation (4.5.2.74), shows that the largest likely *R* factor for a structure determination is given by (Millane, 1989*b*)

$$R = \frac{\sum_m N_m R_m S_m}{\sum_m N_m S_m}, \qquad (4.5.2.77)$$

where the sums are over the values of *m* on the diffraction pattern, N_m is the number of data that have *m* components, R_m is given by equation (4.5.2.75) and S_m is given by

$$S_m = \frac{\Gamma\big((m/2) + (1/2)\big)}{\Gamma(m/2)}, \qquad (4.5.2.78)$$

where $\Gamma(\cdot)$ is the gamma function. The quantities on the right-hand side of equation (4.5.2.77) are easily determined for a particular data set. The largest likely *R* factor decreases (since *m* increases) with increasing resolution of the data, increasing diameter of the molecule and decreasing order *u* of the helix symmetry. For example, for TMV at 5 Å resolution the largest likely *R* factor is 0.37, and at 3 Å resolution it is 0.31, whereas for a tenfold nucleic acid structure at 3 Å resolution it is 0.40 (Millane, 1989*b*, 1992*b*). This underlines the importance of comparing *R* factors obtained in a fibre diffraction analysis with the largest likely *R* factor; an *R* factor of 0.25 that may indicate a good protein structure may, or may not, indicate a well determined fibre structure.

Using approximations for R_m, S_m and *m* allows the following approximation for the largest likely *R* factor for a noncrystalline fibre to be derived (Millane, 1992*b*):

$$R \simeq 0.261(u d_{\rm max}/r_{\rm max})^{1/2}, \qquad (4.5.2.79)$$

where $d_{\rm max}$ is the resolution of the data. The approximation (4.5.2.79) is generally not good enough for calculating accurate largest likely *R* factors, but it does show the general behaviour with helix symmetry, molecular diameter and diffraction-data resolution. Other approximations to largest likely *R* factors have been derived that are quite accurate and also include the effect of a minimum resolution for the data (Millane, 1992*b*).

Largest likely *R* factors in fibre diffraction studies are typically between about 0.3 and 0.5, depending on the particular structure (Millane, 1989*b*, 1992*b*; Millane & Stubbs, 1992). Although the largest likely *R* factor does not give a quantitative assessment of the significance of an *R* factor obtained in a particular structure determination, it can be used as a guide to the significance. *R* factors obtained for well determined protein structures are

typically between about one-third and one-half of the corresponding largest likely R factor, depending on the resolution. It is therefore reasonable to expect the R factor for a well determined fibre structure to be between one-third and one-half of the largest likely R factor calculated for the structure. R factors should, therefore, generally be less than 0.15 to 0.25, depending on the particular structure and the resolution as illustrated by the examples presented in Millane & Stubbs (1992).

The free R factor (Brünger, 1997) has become popular in single-crystal crystallography as a tool for validation of refinements. The free R factor is more difficult to implement (but is probably even more important) in fibre diffraction studies because of the smaller data sets, but has been used to advantage in recent studies (Hudson *et al.*, 1997; Welsh *et al.*, 1998, 2000).

4.5.3. Electron crystallography of polymers

By D. L. Dorset

4.5.3.1. Is polymer electron crystallography possible?

As a crystallographic tool, the electron microscope has also made an important impact in polymer science. Historically, single-crystal electron diffraction information has been very useful for the interpretation of cylindrically averaged fibre X-ray patterns (Atkins, 1989), particularly when there is an extensive overlap of diffracted intensities. An electron diffraction pattern aids indexing of the fibre pattern and facilitates measurement of unit-cell constants, and the observation of undistorted plane-group symmetry similarly places important constraints on the identification of the space group (Geil, 1963; Wunderlich, 1973).

The concept of using electron diffraction intensities by themselves for the quantitative determination of crystal structures of polymers or other organics often has been met with scepticism (Lipson & Cochran, 1966). Difficulties experienced in the quantitative interpretation of images and diffraction intensities from 'hard' materials composed of heavy atoms (Hirsch *et al.*, 1965; Cowley, 1981), for example, has adversely affected the outlook for polymer structure analysis, irrespective of whether these reservations are important or not for 'soft' materials comprising light atoms. Despite the still commonly held opinion that no new crystal structures will be determined that are solely based on data collected in the electron microscope, it can be shown that this extremely pessimistic outlook is unwarranted. With proper control of crystallization (*i.e.* crystal thickness) and data collection, the electron microscope can be used quite productively for the direct determination of macromolecular structures at atomic resolution, not only to verify some of the previous findings of fibre X-ray diffraction analysis, but, more importantly, to determine new structures, even of crystalline forms that cannot be studied conveniently by X-rays as drawn fibres (Dorset, 1995*b*). The potential advantages of electron crystallography are therefore clear. The great advantage in scattering cross section of matter for electrons over X-rays permits much smaller samples to be examined by electron diffraction as single-crystalline preparations (Vainshtein, 1964). (Typical dimensions are given below.)

Electron crystallography can be defined as the quantitative use of electron micrographs and electron diffraction intensities for the determination of crystal structures. In the electron microscope, an electron beam illuminates a semitransparent object and the microscope objective lens produces an enlarged representation of the object as an image. If the specimen is thin enough and/or the electron energy is high enough, the weak-phase-object or 'kinematical' approximation is valid (Cowley, 1981), see Chapter 2.5. That is to say, there is an approximate one-to-one mapping of density points between the object mass distribution and the image, within the resolution limits of the instrument (as set by the objective lens aberrations and electron wavelength). The spatial relationships between diffraction and image planes of an electron microscope objective lens are reciprocal and related by Fourier transform operations (Cowley, 1988). While it is easy to transform from the image to the diffraction pattern, the reverse Fourier transform of the diffraction pattern to a high-resolution image requires solution of the famous crystallographic phase problem (as discussed for electron diffraction in Section 2.5.8).

Certainly, in electron diffraction studies, one must still be cognizant of the limitations imposed by the underlying scattering theory. An approximate 'quasi-kinematical' data set is often sufficient for the analysis (Dorset, 1995*a*). However (Dorset, 1995*b*), there are other important perturbations to diffraction intensities which should be minimized. For example, the effects of radiation damage while recording a high-resolution image are minimized by so-called 'low-dose' procedures (Tsuji, 1989).

4.5.3.2. Crystallization and data collection

The success of electron crystallographic determinations relies on the possibility of collecting data from *thin* single microcrystals. These can be grown by several methods, including self-seeding, epitaxic orientation, *in situ* polymerization on a substrate, in a Langmuir–Blodgett layer, *in situ* polymerization within a thin layer and polymerization in dilute solution. If these preparations do not provide sufficient information, then data can also be collected from microfibres. Thin cast films have also been examined after stretching.

Self-seeding (Blundell *et al.*, 1966) has been one of the most important techniques for growing single chain-folded lamellae. The technique is very simple. A dilute suspension of the polymer is made in a poor solvent. The temperature is raised to cause total solubilization of the macromolecule and then lowered to room temperature to crystallize ill-formed particles (mostly dendrites). The temperature is then elevated again until the suspension just clears, leaving small seeds of the polymer crystals behind. Upon lowering to a suitable temperature above ambience, which is then fixed, isothermal crystallization of well formed lamellae is allowed to occur over time. When the crystallization procedure is complete, the suspension can be cooled again to room temperature and the lamellae harvested. These lamellae are typically less than 10 nm thick, with lateral dimensions between 1.0 and 10.0 μm.

Epitaxic orientation techniques, to give alternative projections of the chain packing, have become increasingly important in recent years. While inorganic substrates have been described (Mauritz *et al.*, 1978), the use of organic layers for this purpose (Wittmann & Lotz, 1990; Lotz & Wittmann, 1993) has been more promising because these substrates are less easily contaminated by adsorbed gases and water vapour, and because the nucleation is anisotropic. Often the crystallization can be carried out from a cooled co-melt, *i.e.* a dilute solution of the polymer in the organic small molecule. When the liquidus curve of the eutectic phase diagram is crossed, the diluent crystals form first. Since these have a surface lattice spacing closely resembling that of the polymer-chain packing, the polymer chains can be directed to lie *along* the substrate surface, rather than normal to it, as the solidus line of the phase diagram is crossed. The substrate can then be removed by some suitable technique (sublimation, selective solvation) to permit the investigation of the oriented film. Variations of this procedure include crystallization of polymer-chain segments from the vapour phase onto a substrate (Wittmann & Lotz, 1985) and *in situ* crystallization of monomers that have first been epitaxically oriented on a suitable substrate (Rickert *et al.*, 1979).

A number of other possibilities for crystal growth also exist. Langmuir troughs have been used to orient monomers that may have hydrophilic moieties. If the monomers contain triple bonds that can be cross-linked, then a polymer film can be formed, *e.g.*,

if the condensed monomer film is exposed to ultraviolet light (Day & Lando, 1980). It may be possible to carry out the polymerization within a confined space (Rybnikar *et al.*, 1994) or in dilute solution (Liu & Geil, 1993) to form crystals suitable for electron diffraction data collection. In the latter case, whisker formation with the chain axis parallel to the lath plane has been observed. Films can be cast on a water surface by evaporation of an organic solvent from a polymer solution. The film can then be stretched to give a suitably oriented specimen for data collection (Vainshtein & Tatarinova, 1967). In addition, it may just be possible to obtain suitable data from drawn microfibres to supplement the single-crystal diffraction information from other preparations.

Data collection from these thin microcrystals often employs the selected-area diffraction technique in the electron microscope that is described in detail elsewhere (Dorset, 1995*b*). Using an approximately eucentric goniometric tilting device in the electron microscope, the sampling of three-dimensional reciprocal space is tomographic, *i.e.* the tilts of a nearly planar Ewald sphere surface (owing to the very small electron wavelength) are always referred to a set of reciprocal axes that intersect (0, 0, 0). For any given crystal habit, there is always a missing set of data owing to the physical limitation to the tilt imposed by the finite thickness of the specimen holder within the pole-piece gap of the electron microscope objective lens (Vainshtein, 1964). For this reason, it is desirable to crystallize two orthogonal orientations of the chain packing (using the above-mentioned approaches), if possible, so that all of the reciprocal lattice can be sampled. If electron micrographs are to be used as an additional source of crystallographic phases then 'low-dose' techniques for recording such images should be employed to reduce the deleterious effects of radiation damage caused by the inelastic interactions of the electron beam with the crystalline sample (Tsuji, 1989).

When the diffraction patterns are recorded on photographic film and these are then measured with a densitometer, relative reflection intensities can often be expressed simply as the integrated peak area without need for a Lorentz correction (Dorset, 1995*b*). Only if the diffraction maxima are extensively arced (*e.g.* in patterns from epitaxic films) is such a correction required. That is to say, $|\Phi_{\rm obs}| \propto KI_{\rm obs}^{1/2}$ where $|\Phi_{\rm obs}|$ is the observed structure-factor magnitude. Assuming the kinematical approximation holds, the calculated value is

$$\Phi_h^{\rm calc} = \sum_i f_i \exp 2\pi i(\mathbf{h}\cdot\mathbf{r}),$$

where f_i are the electron scattering factors (Doyle & Turner, 1968), *e.g.* as tabulated in Table 4.3.1.1 in *IT* C. By analogy with X-ray crystallography (see Chapter 2.2), normalized values can be found from

$$|E_h|^2 = I_h^{\rm obs}/\varepsilon\sum_i f_i^2,$$

with the usual scaling condition that $\langle E_h^2\rangle = 1.000$. [Note, however, that these intensities only describe the chain monomer packing in the 'stem' region of the lamellar microcrystal. Details owing to the surface chain folds are lost (even if they are strictly periodic), because of reasons similar to those described by Cowley (1961) for the electron scattering from elastically bent silicate crystals.]

4.5.3.3. Crystal structure analysis

Two approaches to crystal structure analysis are generally employed in polymer electron crystallography. As already mentioned, the procedure adapted from fibre X-ray crystallography relies on the construction of a model (Brisse, 1989; Perez & Chanzy, 1989). Conformational searches (Campbell Smith & Arnott, 1978) simultaneously minimize the fit of observed diffraction data to calculated values (the *R* factor based on structure factors computed *via* known atomic scattering factors) and a nonbonded atom–atom potential function (Tadokoro, 1979). Reviews of structures solved by this approach have been published (Dorset, 1989, 1995*b*).

Recently, direct phasing methods of the kind used in X-ray crystallography (Chapter 2.2 and, applied to electron diffraction, Section 2.5.8) have also been found to be particularly effective for electron crystallographic structure analyses (Dorset, 1995*b*). While the Fourier transform of an electron micrograph would be the most easily imagined direct method, yielding crystallographic phases after image analysis (see Section 2.5.5), this use of micrographs has been of less importance to polymer crystallography than it has been in the study of globular proteins, even though there is at least one notable example where it has been helpful (Isoda *et al.*, 1983*a*) for the determination of a structure from X-ray fibre data. On the other hand, high-resolution images of polymer crystals are of considerable use for the characterization of packing defects (Isoda *et al.*, 1983*b*).

In polymer electron crystallography, the sole reliance on the diffraction intensities for structure analysis has proven, in recent years, to be quite effective. Several direct-methods approaches have been pursued, including the use of probabilistic techniques, either in the symbolic addition procedure, or in more automated procedures involving the tangent formula (see Chapter 2.2). The Sayre (1952) equation has been found to be particularly effective, where the correct structure is identified *via* some figure of merit after algebraic phase values are used to generate multiple solutions (Stanley, 1986). More recently, maximum-entropy and likelihood methods (Gilmore *et al.*, 1993) have also been effective for solving such structures. After the initial atomic model is found, it can be improved by refinement, generally using Fourier techniques. Least-squares refinement can be carried out under most favourable circumstances (Dorset, 1995*a*), but requires the availability of a sufficient number of diffraction data. Even so, the refinement of thermal parameters must be uncoupled from that of the atomic positions. Also, positional shifts must be dampened (if X-ray crystallographic software is used) to prevent finding a false minimum, especially if the kinematical *R* factor is used as a figure of merit.

4.5.3.4. Examples of crystal structure analyses

At least four kinds of electron diffraction intensity data sets have been used as tests for direct phase determination *via* the approaches mentioned above.

Case 1: Zonal data sets – view down the chain axis. Such data are from the least optimal projection of the polymer packing, because of extensive atomic overlap along the chain axis. Initially, symbolic addition was used to find phase values for *hk*0 data sets from six representative polymers, including three complicated saccharide structures (Dorset, 1992). Most of the determinations were strikingly successful. Later, an unknown data set from the polysaccharide chitosan was obtained from Grenoble (Mazeau *et al.*, 1994) and direct phase determination was able to find a correct model (Dorset, 1995*b*). More recently, other polymers have been tested [including one case where an electron micrograph provided many of the starting phase terms (Dorset, 1995*b*)] also comparing favourably with the solution found by energy minimization of a linkage model. For all examples considered so far, the projected symmetry was centrosymmetric.

Later, it was found that a partial phase set provided by symbolic addition could be expanded to the complete zone by the Sayre equation (Dorset *et al.*, 1995). In all of these tests (Dorset, 1995*b*), there were only one or two examples where there were serious deviations from the phase terms found by other methods. Even in these instances, the potential maps could still be used as

envelopes for the actual projection of the chain structure (Dorset, 1992).

Case 2: Zonal data set – view onto the chain axes. Electron diffraction data from a projection onto the polymer chain axes would be more useful if individual atomic positions were to be resolved. An interesting example where such a view can be obtained is an *h0l* data set from the polypeptide poly-γ-methyl-L-glutamate. Electron diffraction data were collected from stretched films by Vainshtein & Tatarinova (1967). In projection, the cell constants are $a = 4.72$, $c = 6.83$ Å with plane-group symmetry *pg*. As shown in Table 4.5.3.1, there were 19 unique intensity data used for the analysis. After initial phase assignment by symbolic addition, a correct solution could be visualized which, after Fourier refinement (Dorset, 1995*b*), differed from the original one by a mean phase difference of only 6°.

The progress of this structure analysis can be reviewed to give a representative example. Since the *h*00 reflections have centrosymmetric phases, the value $\varphi_{100} = 0$ was chosen as a single origin-defining point. From high-probability Σ_1 three-phase invariants (assessed after calculation of normalized structure factors $|E_h|$), one could assign $\varphi_{200} = \varphi_{400} = 0$. Symbolic values were then given to three other phases, *viz.* $\varphi_{106} = a$; $\varphi_{103} = b$; $\varphi_{101} = c$. From this entire basis, other values could be found from highly probable Σ_2 three-phase invariants, as follows:

$$\begin{aligned}
\varphi_{006} &= \varphi_{106} + \varphi_{\bar{1}00} \;\;\therefore\;\; \varphi_{006} = a \\
\varphi_{105} &= \varphi_{006} + \varphi_{10\bar{1}} \;\;\therefore\;\; \varphi_{105} = a - c + \pi \\
\varphi_{203} &= \varphi_{106} + \varphi_{10\bar{3}} \;\;\therefore\;\; \varphi_{203} = a - b + \pi \\
\varphi_{300} &= \varphi_{100} + \varphi_{200} \;\;\therefore\;\; \varphi_{300} = 0 \\
\varphi_{002} &= \varphi_{103} + \varphi_{\bar{1}01} \;\;\therefore\;\; \varphi_{002} = b - c \\
\varphi_{004} &= \varphi_{006} + \varphi_{00\bar{2}} \;\;\therefore\;\; \varphi_{004} = a - b + c.
\end{aligned}$$

(These invariant relationships include phase interactions among symmetry-related Miller indices characteristic of the plane group.) Additionally $c = \pi$ could be specified to complete origin definition for the zone. It was then possible to permute values of *a* and *b* to arrive at test phase values for this subset, *i.e.* to generate a multiple set of solutions. When $a = 0$, $b = \pi/2$, the map in Fig. 4.5.3.1 was observed. After finding trial atomic positions for Fourier refinement (assuming that two carbon-atom positions were eclipsed in this projection), the final phase set was found as shown in Table 4.5.3.1. Although the crystallographic residual to the observed data, calculated with the model coordinates, was rather large (0.32), there was a close agreement with the earlier determination.

More recently a similar data set, collected from oriented crystal 'whiskers' of poly(*p*-oxybenzoate) in plane group *pg* was analysed. Again the Sayre equation, *via* a multisolution approach, was used to produce a map that contained 13 of 18 possible atomic positions for the two subunits in the asymmetric unit. The complete structure was observed after the remaining five atom sites were identified in two subsequent cycles of Fourier refinement (Liu *et al.*, 1997) and the average atomic positions were found to be within 0.2 Å of the model derived from an energy minimization.

Case 3: Three-dimensional data – single crystal orientation. The first data set from a chain-folded lamella for a direct structure analysis was a centrosymmetric set (space group $P2_1/n$) from poly(1,4-*trans*-cyclohexanediyl dimethylene succinate), composed of 87 reflections (Brisse *et al.*, 1984). The phase determination was quite successful and atomic positions could be found as somewhat blurred density maxima in the three-dimensional maps (Dorset, 1991*a*). A model was constructed from these positions and the bonding parameters optimized to give the best fit to the data ($R = 0.29$).

Noncentrosymmetric three-dimensional intensity sets (orthorhombic space group $P2_12_12_1$) from the polysaccharides mannan (form I) (Chanzy *et al.*, 1987) and chitosan (Mazeau *et al.*, 1994) were also collected from tilted crystals. In both cases, direct phase determination by symbolic addition *via* an algebraic unknown was successful, even though the data were not sampled along the chain repeat. For the former polymer, a monomer model could be fitted to the blurred density profile, much as one would fit a polypeptide sequence to a continuous electron-density map (Dorset & McCourt, 1993; Dorset, 1995*c*). If the Sayre equation were used to predict phases and amplitudes within the 'missing cone' of unsampled data, then the fit of the monomer could be much more highly constrained.

Case 4: Three-dimensional data – two crystal orientations. The optimal case for collection of diffraction data is when two

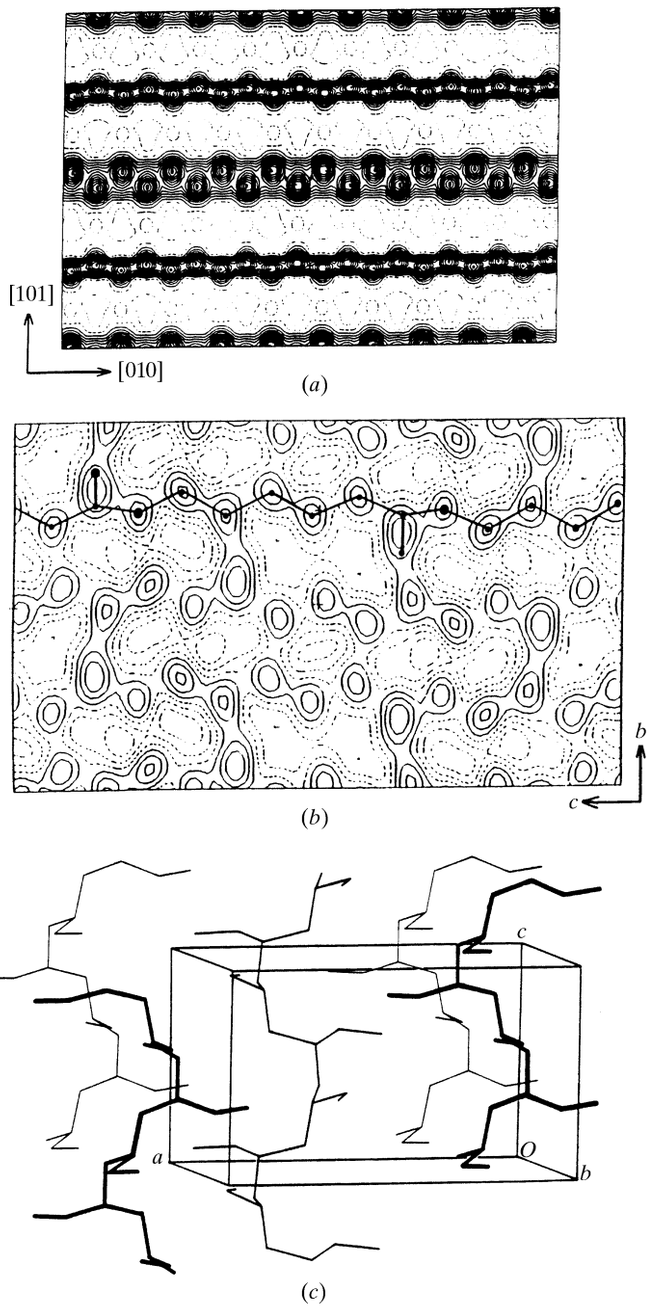

Fig. 4.5.3.2. Crystal structures of linear polymers determined from three-dimensional data. (*a*) Polyethylene; (*b*) poly(ε-caprolactone); (*c*) poly(1-butene), form (III).

orthogonal projections of the same polymer polymorph can be obtained, respectively, by self-seeding and epitaxic orientation. While tilting these specimens, all of reciprocal space can be sampled for intensity data collection.

Polyethylene crystals were used to collect 50 unique maxima (Hu & Dorset, 1989) and, *via* symbolic addition, the centrosymmetric phases of 40 reflections (space group *Pnma*) could be readily determined (Dorset, 1991*b*). The structural features were readily observed in the three-dimensional potential maps (Fig. 4.5.3.2*a*), and atomic coordinates (with estimated values for hydrogen-atom positions) could be refined by least squares (Dorset, 1995*b*) to give a final R value of 0.19.

Poly(ε-caprolactone) was epitaxically crystallized on benzoic acid and, with *hk*0 data from solution-crystallized samples, a unique set of 47 intensities was collected for the noncentrosymmetric orthorhombic unit cell (space group $P2_12_12_1$) (Hu & Dorset, 1990). Direct phase determination was achieved *via* symbolic addition, using one algebraic unknown to assign values to 30 reflections (Dorset, 1991*c*). Atomic positions along the chain repeat, including the carbonyl position, were clearly discerned in the [100] projection (Fig. 4.5.3.2*b*) and the three-dimensional model was constructed to fit to the map calculated from all phased data, yielding a final crystallographic residual R = 0.21. This independent determination was able to distinguish between two rival fibre X-ray structures, in favour of the one that predicted a nonplanar chain conformation. Because of the methylene repeat, this is actually a difficult structure to solve by automated techniques. For example, the tangent formula and *SnB* (Miller *et al.*, 1993) could only find chain zigzag positions and not the position of the carbonyl oxygen atom (Dorset, 1995*b*).

The most complicated complete polymer crystal structure solved so far by direct methods using electron diffraction data (Dorset *et al.*, 1994) was based on 125 unique data (space group $P2_12_12_1$) from isotactic poly(1-butene), form (III), using orthogonal molecular orientations crystallized in Strasbourg (Kopp *et al.*, 1994). Initially, the standard NQEST figure of merit (FOM) (De Titta *et al.*, 1975) was not suitable for identifying the correct solution among the multiple sets generated with the tangent formula. A solution could only be found when a separate phase determination was carried out with the *hk*0 data to compare with the multiple solutions generated. More recently, the minimal principle (Hauptman, 1993), used as a FOM with the tangent formula or with a multiple random structure generator, *SnB*, correctly identified the structure on the first try (Dorset, 1995*b*). The maps clearly show individual carbon-atom positions in a 4_1 helix that parallels 2_1 helices of the space group (Fig. 4.5.3.2*c*). After Fourier refinement, the crystallographic residual was R = 0.26. The previous powder X-ray diffraction determination was based on only 21 diffraction maxima, some of which had as many as 15 individual contributors.

The work of both RPM and DLD was supported by the US National Science Foundation (grant DBI-9722862 for RPM).

4.6. Reciprocal-space images of aperiodic crystals

By W. Steurer‡ and T. Haibach

4.6.1. Introduction

The discovery of materials with icosahedral diffraction symmetry (Shechtman *et al.*, 1984) was the main reason for the reassessment of the definition of *crystallinity* and for the introduction of the concept of *aperiodic crystals*. The first aperiodic crystal, *i.e.* a material with Bragg reflections not located only at reciprocal-lattice nodes, was identified long before (Dehlinger, 1927). In the following decades a wealth of incommensurately modulated phases and composite crystals were discovered. Nevertheless, only a few attempts have been made to develop a crystallography of aperiodic crystals; the most powerful of these was the higher-dimensional approach (see de Wolff, 1974, 1977; Janner & Janssen, 1979, 1980*a*,*b*; de Wolff *et al.*, 1981). In fact, incommensurate structures can be easily described using the higher-dimensional approach and also, fully equivalently, in a dual way: as a three-dimensional (3D) combination of one or more periodic basic structures and one or several modulation waves (de Wolff, 1984). However, with the discovery of quasicrystals and their noncrystalline symmetries, the latter approach failed and geometrical crystallography including the higher-dimensional approach received new attention. For more recent reviews of the crystallography of all three types of aperiodic crystals see van Smaalen (1995), of incommensurately modulated structures see Cummins (1990), of quasicrystals see Steurer (1990, 1996), of quasicrystals and their crystalline approximants see Goldman & Kelton (1993) and Kelton (1995). Textbooks on quasicrystals have been written by Janot (1994) and Senechal (1995).

According to the traditional crystallographic definition, an *ideal crystal* corresponds to an infinite 3D periodic arrangement of identical structure motifs. Its symmetry can be described by one of the 230 3D space groups. Mathematically, a periodic structure can be generated by the convolution of a function representing the structure motif with a lattice function. The structure motif can be given, for instance, by the electron-density distribution $\rho(\mathbf{r})$ of one primitive unit cell of the structure. The lattice function $g(\mathbf{r})$ is represented by a set of δ functions at the nodes $\mathbf{r} = \sum_{i=1}^{3} k_i \mathbf{a}_i$ of a 3D lattice Λ with basis $\mathbf{a}_i$, $i = 1, \ldots, 3$, and $k_i \in \mathbb{Z}$ ($\mathbb{Z}$ is the set of integer numbers). In reciprocal space, this convolution corresponds to the product of the Fourier transform $G(\mathbf{H})$ of the lattice function $g(\mathbf{r})$ and the Fourier transform $F(\mathbf{H}) = \int_v \rho(\mathbf{r}) \exp(2\pi i \mathbf{H} \cdot \mathbf{r})\, \mathrm{d}\mathbf{r}$ of the structure motif $\rho(\mathbf{r})$. $G(\mathbf{H})$ is represented by the reciprocal lattice Λ^* decorated with δ functions on the reciprocal-lattice nodes $\mathbf{H} = \sum_{i=1}^{3} h_i \mathbf{a}_i^*$, with the reciprocal-basis vectors $\mathbf{a}_i^*$, $i = 1, \ldots, 3$, defined by $\mathbf{a}_i \cdot \mathbf{a}_j^* = \delta_{ij}$ and $h_i \in \mathbb{Z}$. The product $G(\mathbf{H}) \times F(\mathbf{H})$ is called the weighted reciprocal lattice; the weights are given by the structure factors $F(\mathbf{H})$. Thus, the characteristic feature of an ideal crystal in direct and reciprocal space is the existence of a lattice. In direct space, this lattice is decorated with identical structure motifs preserving translational and point symmetry in the framework of *space-group symmetry*. In reciprocal space, only the point symmetry between structure factors is maintained. The *Fourier spectrum* (or *Fourier image*, *i.e.* the Fourier transform) of the electron-density distribution of an ideal crystal consists of a countably infinite set of discrete Bragg peaks with a strictly defined minimum distance.

This crystal definition can be generalized to $n > 3$ dimensions. A d-dimensional (dD) *ideal aperiodic crystal* can be defined as a dD irrational section of an n-dimensional (nD, $n > d$) crystal with nD lattice symmetry. The intersection of the nD *hypercrystal* with the dD physical space is equivalent to a projection of the weighted nD reciprocal lattice $\Sigma^* = \left\{\mathbf{H} = \sum_{i=1}^{n} h_i \mathbf{d}_i^* | h_i \in \mathbb{Z}\right\}$ onto the dD physical space. The resulting set (Fourier module) $M^* = \left\{\mathbf{H}^{\parallel} = \sum_{i=1}^{n} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\right\}$ is countably dense. *Countably dense* means that the dense set of Bragg peaks can be mapped one-to-one onto the set of natural numbers. Hence, the Bragg reflections can be indexed with integer indices on an appropriate basis. The Fourier module of the projected reciprocal-lattice vectors $\mathbf{H}^{\parallel}$ has the structure of a $\mathbb{Z}$ module of rank n. A $\mathbb{Z}$ module is a free Abelian group, its rank n is given by the number of free generators (rationally independent vectors). The dimension of a $\mathbb{Z}$ module is that of the vector space spanned by it. The vectors $\mathbf{a}_i^*$ are the images of the vectors $\mathbf{d}_i^*$ projected onto the physical space $\mathbf{V}^{\parallel}$. Thus, by definition, the 3D reciprocal space of an ideal *aperiodic crystal* consists of a countably dense set of Bragg reflections only. Contrary to an ideal *crystal*, a minimum distance between Bragg reflections does not exist in an aperiodic one. In summary, it may be stressed that the terms *aperiodic* and *periodic* refer to properties of crystal structures in dD space. In nD space, as considered here, lattice symmetry is always present and, therefore, the term *crystal* is used.

Besides the *aperiodic crystals* mentioned above, other classes of *aperiodic structures* with strictly defined construction rules exist (see Axel & Gratias, 1995). Contrary to the kind of aperiodic crystals dealt with in this chapter, the Fourier spectra of aperiodic structures considered in the latter reference are continuous and contain only in a few cases additional sharp Bragg reflections (δ peaks).

Experimentally, the borderline between aperiodic crystals and their periodic approximations (*crystalline approximants*) is not sharply defined. Finite crystal size, static and dynamic disorder, chemical impurities and defects broaden Bragg peaks and cause diffuse diffraction phenomena. Furthermore, the resolution function of the diffraction equipment is limited.

However, the concept of describing an aperiodic structure as a dD physical-space section of an nD crystal (see Section 4.6.2) is only useful if it significantly simplifies the description of its structural order. Thus, depending on the shape of the *atomic surfaces*, which gives information on the atomic ordering, incommensurately modulated structures (IMSs, Sections 4.6.2.2 and 4.6.3.1), composite structures (CSs, Sections 4.6.2.3 and 4.6.3.2), or quasiperiodic structures (QSs, Sections 4.6.2.4 and 4.6.3.3) can be obtained from irrational cuts. The atomic surfaces are continuous $(n-d)$-dimensional objects for IMSs and CSs, and discrete $(n-d)$-dimensional objects for QSs. A class of aperiodic crystals with discrete fractal atomic surfaces also exists (Section 4.6.2.5). In this case the Hausdorff dimension (Hausdorff, 1919) of the atomic surface is not an integer number and smaller than $n-d$. The most outstanding characteristic feature of a fractal is its scale invariance: the object appears similar to itself 'from near as from far, that is, whatever the scale' (Gouyet, 1996).

To overcome the problems connected with experimental resolution, the translational symmetry of periodic crystals is used as a hard constraint in the course of the determination of their structures. Hence, space-group symmetry is taken for granted and only the local atomic configuration in a unit cell (actually, asymmetric unit) remains to be determined. In reciprocal space, this assumption corresponds to a condensation of Bragg reflections with finite full width at half maximum (FWHM) to δ peaks

‡ To whom correspondence should be addressed.

Copyright © 2010 International Union of Crystallography

accurately located at the reciprocal-lattice nodes. Diffuse diffraction phenomena are mostly neglected. This extrapolation to the existence of an ideal crystal is generally out of the question even if samples of very poor quality (high mosaicity, microdomain structure, defects, ...) are investigated.

The same practice is convenient for the determination of real aperiodic structures once the type of idealized aperiodic ordering is 'known'. Again, the global ordering principle is taken as a hard constraint. For instance, the question of whether a structure is commensurately or incommensurately modulated can only be answered within a given experimental resolution. Experimentally, the ratio of the wavelength of a modulation to the period of the underlying lattice can always be determined as a rational number only. Saying that a structure is incommensurately modulated, with the above ratio being an irrational number, simply means that the experimental results can be better understood, modelled and interpreted assuming an incommensurate modulation. For example, an incommensurate charge-density wave can be moved through an ideal crystal without changing the energy of the crystal. This is not so for a commensurate modulation. In some cases, the modulation period changes with temperature in discrete steps ('devil's staircase'), generating a series of commensurate superstructures ('lock-in structures'); in other cases, a continuous variation can be observed within the experimental resolution. The latter case will be described best by an incommensurately modulated structure.

However, if only the local structure of an aperiodic crystal is of interest, a structure analysis does not take much more experimental effort than for a regular crystal. In contrast, for the analysis of the global structure, *i.e.* the characterization of the type of its 'aperiodicity', diffraction experiments with the highest possible resolution are essential. Some problems connected with the structure analysis of aperiodic crystals are dealt with in Section 4.6.4.

To determine the long-range order – whether a real 'quasicrystal' is perfectly quasiperiodic, on average quasiperiodic, a crystalline approximant or a nanodomain structure – requires information from experiments that are sensitive to changes of the global structure. Hence, one needs diffraction experiments that allow the accurate determination of the spatial intensity distribution. Consequently, the limiting factors for such experiments are the maximum spatial and intensity resolution of the diffraction and detection equipment, as well as the size and quality of the sample. Nevertheless, the resolution available on state-of-the-art standard synchrotron-beamline equipment is sufficient to test whether the ordering of atoms in an aperiodic crystal reaches the same degree of perfection as found in high-quality silicon. Of course, the higher the sample quality the more necessary it is to account for dynamical diffraction effects such as reflection broadening and displacement. Otherwise, a misinterpretation may bias the global structure modelling.

The following sections present an aid to the characterization of aperiodic crystals based on information from diffraction experiments and give a survey of aperiodic crystals from the viewpoint of the experimentally accessible reciprocal space. Characteristic features of the diffraction patterns of the different types of aperiodic crystals are shown. A standard way of determining the metrics and finding the optimum nD embedding is described. Structure-factor formulae for general and special cases are given.

4.6.2. The n-dimensional description of aperiodic crystals

4.6.2.1. Basic concepts

An incommensurate modulation of a lattice-periodic structure destroys its translational symmetry in direct and reciprocal space. In the early seventies, a method was suggested by de Wolff (1974) for restoring the lost lattice symmetry by considering the diffraction pattern of an *incommensurately modulated structure* (IMS) as a projection of an nD reciprocal lattice upon the physical space. n, the dimension of the superspace, is always larger than or equal to d, the dimension of the physical space. This leads to a simple method for the description and characterization of IMSs as well as a variety of new possibilities in their structure analysis. The nD *embedding method* is well established today and can be applied to all aperiodic crystals with reciprocal-space structure equivalent to a $\mathbb{Z}$ module with finite rank n (Janssen, 1988). The dimension of the embedding space is determined by the rank of the $\mathbb{Z}$ module, *i.e.* by the number of reciprocal-basis vectors necessary to allow for indexing all Bragg reflections with integer numbers. The point symmetry of the 3D reciprocal space (Fourier spectrum) constrains the point symmetry of the nD reciprocal lattice and restricts the number of possible nD symmetry groups.

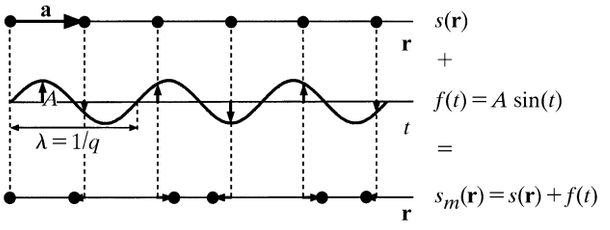

Fig. 4.6.2.1. The combination of a basic structure $s(\mathbf{r})$, with period a, and a sinusoidal modulation function $f(t)$, with amplitude A, period λ and $t = \mathbf{q} \cdot \mathbf{r}$, gives a modulated structure (MS) $s_m(\mathbf{r})$. The MS is aperiodic if a and λ are on incommensurate length scales. The filled circles represent atoms.

In the following sections, the nD descriptions of the four main classes of aperiodic crystals are demonstrated on simple 1D examples of incommensurately modulated phases, composite crystals, quasicrystals and structures with fractally shaped atomic surfaces. The main emphasis is placed on quasicrystals that show scaling symmetry, a new and unusual property in structural crystallography. A detailed discussion of the different types of 3D aperiodic crystals follows in Section 4.6.3.

4.6.2.2. 1D incommensurately modulated structures

A periodic deviation of atomic parameters from a reference structure (*basic structure*, BS) is called a *modulated structure* (MS). In the case of mutual incommensurability of the basic structure and the modulation period, the structure is called incommensurately modulated. Otherwise, it is called commensurately modulated. The modulated atomic parameters may be one or several of the following:

(a) coordinates,
(b) occupancy factors,
(c) thermal displacement parameters,
(d) orientation of the magnetic moment.

An incommensurately modulated structure can be described in a dual way by its *basic structure* $s(\mathbf{r})$ and a *modulation function* $f(t)$. This allows the structure-factor formula to be calculated and a full symmetry characterization employing representation theory to be performed (de Wolff, 1984). A more general method is the nD description: it relates the dD aperiodic incommensurately modulated structure to a periodic structure in nD space. This simplifies the symmetry analysis and structure-factor calculation, and allows more powerful structure-determination techniques.

The nD embedding method is demonstrated in the following 1D example of a displacively modulated structure. A basic structure $s(\mathbf{r}) = s(\mathbf{r} + n\mathbf{a})$, with period a and $n \in \mathbb{Z}$, is modulated by a function $f(t) = f(\mathbf{q} \cdot \mathbf{r}) = f(\alpha r) = f[\alpha r + (n a/\alpha)]$, with the satellite vector $\mathbf{q} = \alpha \mathbf{a}^*$, period $\lambda = 1/q = a/\alpha$, and α a rational or irrational number yielding a commensurately or incommensurately modulated structure $s_m(\mathbf{r})$ (Fig. 4.6.2.1).

If the 1D IMS and its 1D modulation function are properly combined in a 2D parameter space $\mathbf{V} = (\mathbf{V}^{\parallel}, \mathbf{V}^{\perp})$, a 2D lattice-

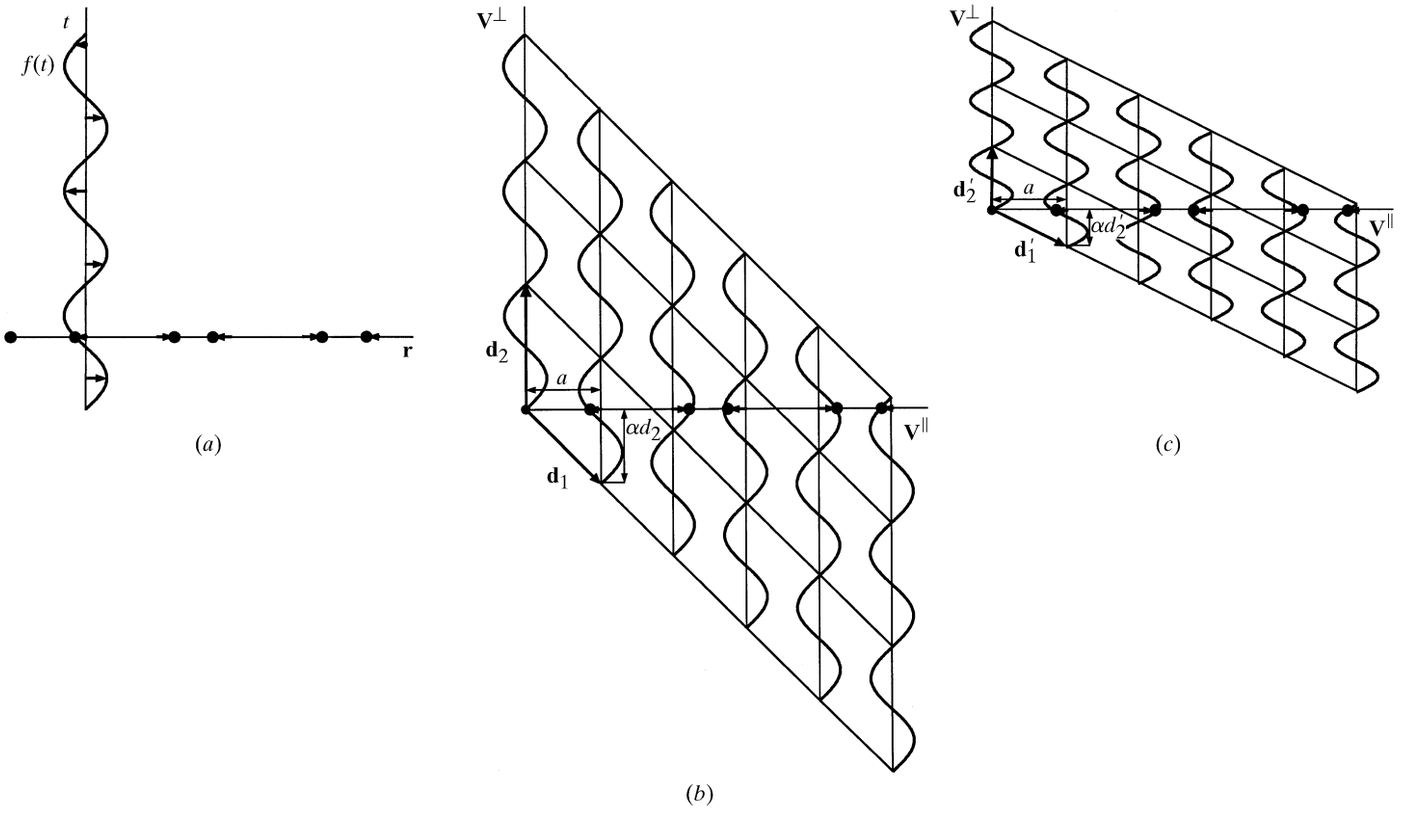

Fig. 4.6.2.2. 2D embedding of the sinusoidally modulated structure illustrated in Fig. 4.6.2.1. The correspondence between the actual displacement of an atom in the 1D structure and the modulation function defined in one additional dimension is illustrated in part (*a*). Adding to each atom its modulation function in this orthogonal dimension (perpendicular space $\mathbf{V}^{\perp}$) yields a periodic arrangement in 2D space $\mathbf{V}$, part (*b*). The MS results as a special section of the 2D periodic structure along the parallel space $\mathbf{V}^{\parallel}$. It is obvious from a comparison of (*b*) and (*c*) that the actual MS is independent of the perpendicular-space scale.

periodic structure results (Fig. 4.6.2.2). The actual atoms are generated by the intersection of the 1D physical (external, parallel) space $\mathbf{V}^{\parallel}$ with the continuous *hyperatoms*. The hyperatoms have the shape of the modulation function along the perpendicular (internal, complementary) space $\mathbf{V}^{\perp}$. They result from a convolution of the physical-space atoms with their modulation functions.

A basis $\mathbf{d}_1, \mathbf{d}_2$ (D basis) of the 2D hyperlattice $\Sigma = \{\mathbf{r} = \sum_{i=1}^{2} n_i \mathbf{d}_i | n_i \in \mathbb{Z}\}$ is given by

$$\mathbf{d}_1 = \begin{pmatrix} a \\ -\alpha/c \end{pmatrix}_V, \mathbf{d}_2 = \begin{pmatrix} 0 \\ 1/c \end{pmatrix}_V,$$

where a is the translation period of the BS and c is an arbitrary constant. The components of the basis vectors are given on a 2D orthogonal coordinate system (V basis). The components of the basis vector $\mathbf{d}_1$ are simply the parallel-space period a of the BS and α times the perpendicular-space component of the basis vector $\mathbf{d}_2$. The vector $\mathbf{d}_2$ is always parallel to the perpendicular space and its length is one period of the modulation function in arbitrary units (this is expressed by the arbitrary factor $1/c$). An atom at position $\mathbf{r}$ of the BS is displaced by an amount given by the modulation function $f(t)$, with $f(t) = f(\mathbf{q} \cdot \mathbf{r})$. Hence, the perpendicular-space variable t has to adopt the value $\mathbf{q} \cdot \mathbf{r} = \alpha \mathbf{a}^* \cdot r\mathbf{a} = \alpha r$ for the physical-space variable $\mathbf{r}$. This can be achieved by assigning the slope α to the basis vector $\mathbf{d}_1$. The choice of the parameter c has no influence on the actual MS, *i.e.* the way in which the 2D structure is cut by the parallel space (Fig. 4.6.2.2*c*).

The basis of the lattice $\Sigma^* = \{\mathbf{H} = \sum_{i=1}^{2} h_i \mathbf{d}_i^* | h_i \in \mathbb{Z}\}$, reciprocal to Σ, can be obtained from the condition $\mathbf{d}_i \cdot \mathbf{d}_j^* = \delta_{ij}$:

$$\mathbf{d}_1^* = \begin{pmatrix} a^* \\ 0 \end{pmatrix}_V, \mathbf{d}_2^* = \begin{pmatrix} \alpha a^* \\ c \end{pmatrix}_V,$$

with $a^* = 1/a$. The metric tensors for the reciprocal and direct 2D lattices for $c = 1$ are

$$G^* = \begin{pmatrix} a^{*2} & \alpha a^{*2} \\ \alpha a^{*2} & 1 + \alpha^2 a^{*2} \end{pmatrix} \quad \text{and} \quad G = \begin{pmatrix} a^2 + \alpha^2 & -\alpha \\ -\alpha & 1 \end{pmatrix}.$$

The choice of an arbitrary number for c has no influence on the metrics of the physical-space components of the IMS in direct or reciprocal space.

The Fourier transform of the *hypercrystal* depicted in Fig. 4.6.2.2 gives the weighted reciprocal lattice shown in Fig. 4.6.2.3. The 1D diffraction pattern $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{2} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ in physical space is obtained by a projection of the weighted 2D reciprocal lattice Σ^* along $\mathbf{V}^{\perp}$ as the Fourier transform of a section in direct space corresponds to a projection in reciprocal space and *vice versa*:

$$M^* = \{\mathbf{H}^{\parallel}\} \xleftarrow{\text{projection } \pi^{\parallel} \text{ onto } \mathbf{V}^{\parallel}} \Sigma^* = \{\mathbf{H} = (\mathbf{H}^{\parallel}, \mathbf{H}^{\perp})\}.$$

Reciprocal-lattice points lying in physical space are referred to as *main reflections*, all others as *satellite reflections*. All Bragg reflections can be indexed with integer numbers h_1, h_2 in the 2D description $\mathbf{H} = h_1 \mathbf{d}_1^* + h_2 \mathbf{d}_2^*$. In the physical-space description, the diffraction vector can be written as $\mathbf{H}^{\parallel} = h\mathbf{a}^* + m\mathbf{q} = \mathbf{a}^*(h_1 + \alpha h_2)$, with $\mathbf{q} = \alpha \mathbf{a}^*$ for the satellite vector and $m \in \mathbb{Z}$ the order of the satellite reflection. For a detailed discussion of the

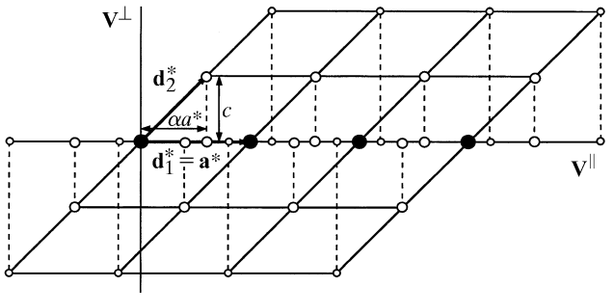

Fig. 4.6.2.3. Schematic representation of the 2D reciprocal-space embedding of the 1D sinusoidally modulated structure depicted in Figs. 4.6.2.1 and 4.6.2.2. Main reflections are marked by filled circles and satellite reflections by open circles. The sizes of the circles are roughly related to the reflection intensities. The actual 1D diffraction pattern of the 1D MS results from a projection of the 2D reciprocal space onto the parallel space. The correspondence between 2D reciprocal-lattice positions and their projected images is indicated by dashed lines.

embedding and symmetry description of IMSs see, for example, Janssen *et al.* (2004).

A commensurately modulated structure with $\alpha' = m/n$ and $\lambda = (n/m)a$, $m, n \in \mathbb{Z}$, and with $c = 1$, can be generated by shearing the 2D lattice Σ with a shear matrix S_m:

$$\mathbf{d}_i' = \sum_{j=1}^{2} S_{mij}\mathbf{d}_j, \text{ with } S_m = \begin{pmatrix} 1 & -x \\ 0 & 1 \end{pmatrix}_D \text{ and } x = \alpha' - \alpha,$$

$$\mathbf{d}_1' = \mathbf{d}_1 - x\mathbf{d}_2 = \begin{pmatrix} a \\ -\alpha \end{pmatrix}_V - (\alpha' - \alpha)\begin{pmatrix} 0 \\ 1 \end{pmatrix}_V = \begin{pmatrix} a \\ -\alpha' \end{pmatrix}_V,$$

$$\mathbf{d}_2' = \mathbf{d}_2 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}_V.$$

The subscript D (V) following the shear matrix indicates that it is acting on the D (V) basis. The shear matrix does not change the distances between the atoms in the basic structure. In reciprocal space, using the inverted and transposed shear matrix, one obtains

$$\mathbf{d}_i^{*\prime} = \sum_{j=1}^{2} (S_m^{-1})_{ij}^T \mathbf{d}_j^*, \text{ with } (S_m^{-1})^T = \begin{pmatrix} 1 & 0 \\ x & 1 \end{pmatrix}_D \text{ and } x = \alpha' - \alpha,$$

$$\mathbf{d}_1^{*\prime} = \mathbf{d}_1^* = \begin{pmatrix} a^* \\ 0 \end{pmatrix}_V,$$

$$\mathbf{d}_2^{*\prime} = x\mathbf{d}_1^* + \mathbf{d}_2^* = (\alpha' - \alpha)\begin{pmatrix} a^* \\ 0 \end{pmatrix}_V + \begin{pmatrix} \alpha a^* \\ 1 \end{pmatrix}_V = \begin{pmatrix} \alpha' a^* \\ 1 \end{pmatrix}_V.$$

4.6.2.3. 1D composite structures

In the simplest case, a *composite structure* (CS) consists of two intergrown periodic structures with mutually incommensurate lattices. Owing to mutual interactions, each subsystem may be modulated with the period of the other. Consequently, CSs can be considered as coherent intergrowths of two or more incommensurately modulated substructures. The substructures have at least the origin of their reciprocal lattices in common. However, in all known cases, at least one common reciprocal-lattice plane exists. This means that at least one particular projection of the composite structure exhibits full lattice periodicity.

The unmodulated (basic) 1D subsystems of a 1D incommensurate intergrowth structure can be related to each other in a 2D parameter space $\mathbf{V} = (\mathbf{V}^{\parallel}, \mathbf{V}^{\perp})$ (Fig. 4.6.2.4). The actual atoms result from the intersection of the physical space $\mathbf{V}^{\parallel}$ with the hypercrystal. The hyperatoms correspond to a convolution of the

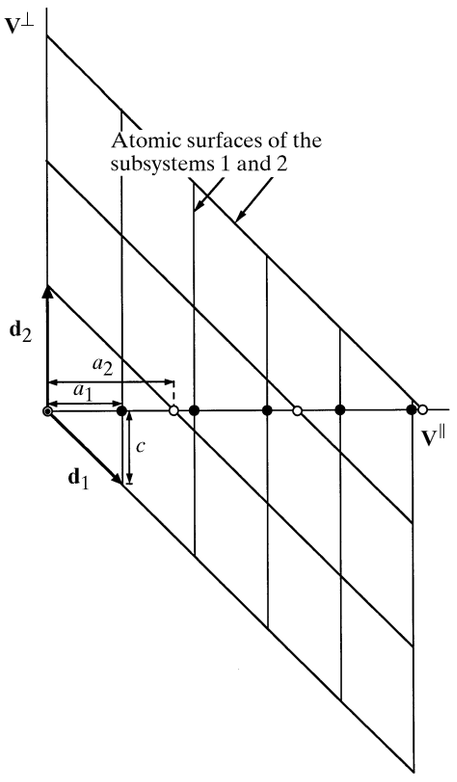

Fig. 4.6.2.4. 2D embedding of a 1D composite structure without mutual interaction of the subsystems. Filled and empty circles represent the atoms of the unmodulated substructures with periods a_1 and a_2, respectively. The atoms result from the parallel-space cut of the linear atomic surfaces parallel to $\mathbf{d}_1$ and $\mathbf{d}_2$.

real atoms with infinite lines parallel to the basis vectors $\mathbf{d}_1$ and $\mathbf{d}_2$ of the 2D hyperlattice $\Sigma = \{\mathbf{r} = \sum_{i=1}^{2} n_i\mathbf{d}_i | n_i \in \mathbb{Z}\}$.

An appropriate basis is given by

$$\mathbf{d}_1 = \begin{pmatrix} a_1 \\ -c \end{pmatrix}_V, \mathbf{d}_2 = \begin{pmatrix} 0 \\ c(a_2/a_1) \end{pmatrix}_V,$$

where a_1 and a_2 are the lattice parameters of the two substructures and c is an arbitrary constant. Taking into account the interactions between the subsystems, each one becomes modulated with the period of the other. Consequently, in the 2D description, the shape of the hyperatoms is determined by their modulation functions (Fig. 4.6.2.5).

A basis of the reciprocal lattice $\Sigma^* = \{\mathbf{H} = \sum_{i=1}^{2} h_i\mathbf{d}_i^* | h_i \in \mathbb{Z}\}$ can be obtained from the condition $\mathbf{d}_i \cdot \mathbf{d}_j^* = \delta_{ij}$:

$$\mathbf{d}_1^* = \begin{pmatrix} a_1^* \\ 0 \end{pmatrix}_V, \mathbf{d}_2^* = \begin{pmatrix} a_2^* \\ (a_2^*/ca_1^*) \end{pmatrix}_V.$$

The metric tensors for the reciprocal and the direct 2D lattices for $c = 1$ are

$$G^* = \begin{pmatrix} a_1^{*2} & a_1^* a_2^* \\ a_1^* a_2^* & (1 + a_1^{*2})(a_2^*/a_1^*)^2 \end{pmatrix} \text{ and } G = \begin{pmatrix} 1 + a_1^2 & -a_2/a_1 \\ -a_2/a_1 & (a_2/a_1)^2 \end{pmatrix}.$$

The Fourier transforms of the hypercrystals depicted in Figs. 4.6.2.4 and 4.6.2.5 correspond to the weighted reciprocal lattices illustrated in Figs. 4.6.2.6 and 4.6.2.7. The 1D diffraction patterns $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{2} h_i\mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ in physical space are obtained by a projection of the weighted 2D reciprocal lattices Σ^* upon $\mathbf{V}^{\parallel}$. All Bragg reflections can be indexed with integer numbers h_1, h_2

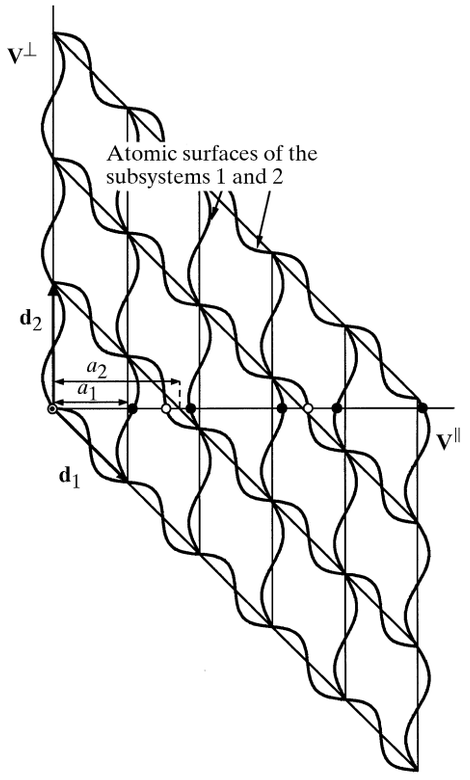

Fig. 4.6.2.5. 2D embedding of a 1D composite structure with mutual interaction of the subsystems causing modulations. Filled and empty circles represent the modulated substructures with periods a_1 and a_2 of the basic substructures, respectively. The atoms result from the parallel-space cut of the sinusoidal atomic surfaces running parallel to $\mathbf{d}_1$ and $\mathbf{d}_2$.

in both the 2D description $\mathbf{H} = h_1\mathbf{d}_1^* + h_2\mathbf{d}_2^*$ and in the 1D physical-space description with two parallel basis vectors $\mathbf{H}^{\parallel} = h_1\mathbf{a}_1^* + h_2\mathbf{a}_2^*$.

The reciprocal-lattice points $\mathbf{H} = h_1\mathbf{d}_1^*$ and $\mathbf{H} = h_2\mathbf{d}_2^*$, h_1, $h_2 \in \mathbb{Z}$, on the main axes $\mathbf{d}_1^*$ and $\mathbf{d}_2^*$ are the main reflections of the two substructures. All other reflections are referred to as satellite reflections. Their intensities differ from zero only in the case of modulated substructures. Each reflection of one subsystem coincides with exactly one reflection of the other subsystem.

4.6.2.4. 1D quasiperiodic structures

The Fibonacci sequence, the best investigated example of a 1D quasiperiodic structure, can be obtained from the substitution rule σ: S $\rightarrow$ L, L $\rightarrow$ LS, replacing the letter S by L and the letter L by the word LS (see *e.g.* Luck *et al.*, 1993). Applying the substitution matrix

$$S = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}$$

associated with σ, this rule can be written in the form

$$\begin{pmatrix} \mathrm{S} \\ \mathrm{L} \end{pmatrix} \rightarrow \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} \mathrm{S} \\ \mathrm{L} \end{pmatrix} = \begin{pmatrix} \mathrm{L} \\ \mathrm{L}+\mathrm{S} \end{pmatrix}.$$

S gives the sum of letters, L + S = S + L, and not their order. Consequently, the same substitution matrix can also be applied, for instance, to the substitution σ': S $\rightarrow$ L, L $\rightarrow$ SL. The repeated action of S on the alphabet $A = \{\mathrm{S}, \mathrm{L}\}$ yields the words $A_n = \sigma^n(\mathrm{S})$ and $B_n = \sigma^n(\mathrm{L}) = A_{n+1}$ as illustrated in Table 4.6.2.1. The frequencies of letters contained in the words A_n and B_n can

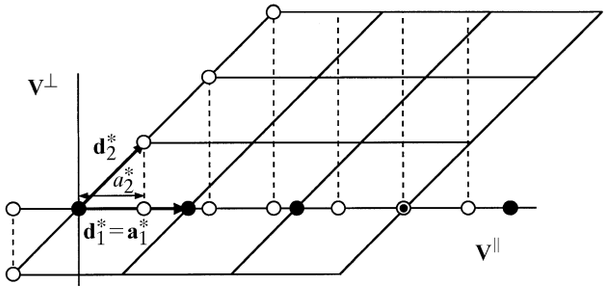

Fig. 4.6.2.6. Schematic representation of the reciprocal space of the embedded 1D composite structure depicted in Fig. 4.6.2.4. Filled and empty circles represent the reflections generated by the substructures with periods a_1 and a_2, respectively. The actual 1D diffraction pattern of the 1D CS results from a projection of the 2D reciprocal space onto the parallel space. The correspondence between 2D reciprocal-lattice positions and their projected images is indicated by dashed lines.

be calculated by applying the nth power of the transposed substitution matrix on the unit vector. From

$$\begin{pmatrix} \nu_{n+1}^A \\ \nu_{n+1}^B \end{pmatrix} = S^T \begin{pmatrix} \nu_n^A \\ \nu_n^B \end{pmatrix}$$

it follows that

$$\begin{pmatrix} \nu_n^A \\ \nu_n^B \end{pmatrix} = (S^T)^n \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

In the case of the Fibonacci sequence, ν_n^B gives the total number of letters S and L, and ν_n^A the number of letters L.

An infinite Fibonacci sequence, *i.e.* a word B_n with $n \rightarrow \infty$, remains invariant under inflation (deflation). Inflation (deflation) means that the number of letters L, S increases (decreases) under the action of the (inverted) substitution matrix S. Inflation and deflation represent self-similarity (scaling) symmetry operations on the infinite Fibonacci sequence. A more detailed discussion of the scaling properties of the Fibonacci chain in direct and reciprocal space will be given later.

The Fibonacci numbers $F_n = F_{n-1} + F_{n-2}$ form a series with $\lim_{n\rightarrow\infty}(F_{n+1}/F_n) = \tau$ {the golden mean $\tau = [1 + (5)^{1/2}]/2 = 2\cos(\pi/5) = 1.618\ldots$}. The ratio of the frequencies of L and S

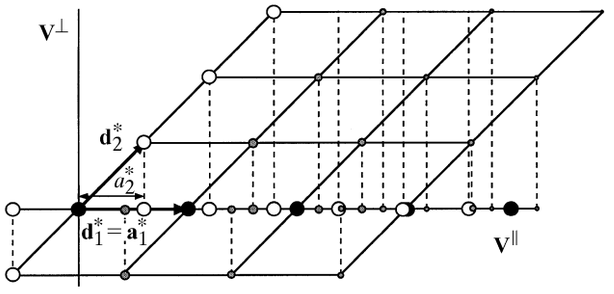

Fig. 4.6.2.7. Schematic representation of the reciprocal space of the embedded 1D composite structure depicted in Fig. 4.6.2.5. Filled and empty circles represent the main reflections of the two subsystems. The satellite reflections generated by the modulated substructures are shown as grey circles. The diameters of the circles are roughly proportional to the intensities of the reflections. The actual 1D diffraction pattern of the 1D CS results from a projection of the 2D reciprocal space onto the parallel space. The correspondence between 2D reciprocal-lattice positions and their projected images is indicated by dashed lines.

in the Fibonacci sequence converges to τ if the sequence goes to infinity. The continued fraction expansion of the golden mean τ,

$$\tau = 1 + \cfrac{1}{1 + \cfrac{1}{1 + \cfrac{1}{1 + \ldots}}},$$

contains only the number 1. This means that τ is the 'most irrational' number, *i.e.* the irrational number with the worst truncated continued fraction approximation to it. This might be one of the reasons for the stability of quasiperiodic systems, where τ plays a role. The strong irrationality may impede the lock-in into commensurate systems (*rational approximants*).

By associating intervals (*e.g.* atomic distances) with length ratio τ to 1 to the letters L and S, a quasiperiodic structure $s(\mathbf{r})$ (*Fibonacci chain*) can be obtained. The invariance of the ratio of lengths $\mathrm{L/S} = (\mathrm{L} + \mathrm{S})/\mathrm{L} = \tau$ is responsible for the invariance of the Fibonacci chain under scaling by a factor τ^n, $n \in \mathbb{Z}$. Owing to a minimum atomic distance S in real crystal structures, the full set of inverse symmetry operators τ^{-n} does not exist. Consequently, the set of scaling operators $s = \{\tau^0 = 1, \tau^1, \ldots\}$ forms only a semi-group, *i.e.* an associative groupoid. Groupoids are the most general algebraic sets satisfying only one of the group axioms: the associative law. The scaling properties of the Fibonacci sequence can be derived from the eigenvalues of the scaling matrix S. For this purpose the equation

$$\det|S - \lambda I| = 0$$

with eigenvalue λ and unit matrix I has to be solved. The evaluation of the determinant yields the characteristic polynomial

$$\lambda^2 - \lambda - 1 = 0,$$

yielding in turn the eigenvalues $\lambda_1 = [1 + (5)^{1/2}]/2 = \tau$, $\lambda_2 = [1 - (5)^{1/2}]/2 = -1/\tau$ and the eigenvectors

$$\mathbf{w}_1 = \begin{pmatrix} 1 \\ \tau \end{pmatrix}, \quad \mathbf{w}_2 = \begin{pmatrix} 1 \\ -1/\tau \end{pmatrix}.$$

Rewriting the eigenvalue equation gives for the first (*i.e.* the largest) eigenvalue

$$\begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} 1 \\ \tau \end{pmatrix} = \begin{pmatrix} \tau \\ 1 + \tau \end{pmatrix} = \begin{pmatrix} \tau \\ \tau^2 \end{pmatrix} = \tau\begin{pmatrix} 1 \\ \tau \end{pmatrix}.$$

Identifying the eigenvector

$$\begin{pmatrix} 1 \\ \tau \end{pmatrix}$$

with

$$\begin{pmatrix} \mathrm{S} \\ \mathrm{L} \end{pmatrix}$$

shows that an infinite Fibonacci sequence $s(\mathbf{r})$ remains invariant under scaling by a factor τ. This scaling operation maps each new lattice vector $\tau\mathbf{r}$ upon a vector $\mathbf{r}$ of the original lattice:

$$s(\tau\mathbf{r}) = s(\mathbf{r}).$$

Considering periodic lattices, these eigenvalues are integer numbers. For quasiperiodic 'lattices' (*quasilattices*) they always correspond to *algebraic numbers* (*Pisot numbers*). A Pisot number is the solution of a polynomial equation with integer coefficients. It is larger than one, whereas the modulus of its conjugate is smaller than unity: $\lambda_1 > 1$ and $|\lambda_2| < 1$ (Luck *et al.*, 1993). The total lengths l_n^A and l_n^B of the words A_n, B_n can be determined from the equations $l_n^A = \lambda_1^n l^A$ and $l_n^B = \lambda_1^n l^B$ with the eigenvalue λ_1. The left Perron–Frobenius eigenvector $\mathbf{w}_1$ of S, *i.e.* the left eigenvector associated with λ_1, determines the ratio S:L to 1:τ. The right Perron–Frobenius eigenvector $\mathbf{w}_1$ of S associated with λ_1 gives the relative frequencies, 1 and τ, for the letters S and L (for a definition of the Perron–Frobenius theorem see Luck *et al.*, 1993, and references therein).

The general case of an alphabet $A = \{\mathrm{L}_1 \ldots \mathrm{L}_k\}$ with k letters (intervals) L_i, of which at least two are on incommensurate length scales and which transform with the substitution matrix S,

$$\mathrm{L}_i' \rightarrow \sum_{j=1}^{k} S_{ij}\mathrm{L}_j,$$

can be treated analogously. S is a $k \times k$ matrix with non-negative integer coefficients. Its eigenvalues are solutions of a polynomial equation of rank k with integer coefficients (algebraic or Pisot numbers). The dimension n of the embedding space is generically equal to the number of letters (intervals) k involved by the substitution rule. From substitution rules, infinitely many different 1D quasiperiodic sequences can be generated. However, their atomic surfaces in the nD description are generically of fractal shape (see Section 4.6.2.5).

The quasiperiodic 1D density distribution $\rho(\mathbf{r})$ of the Fibonacci chain can be represented by the Fourier series

$$\rho(\mathbf{r}) = (1/V)\sum_{\mathbf{H}^\parallel} F(\mathbf{H}^\parallel)\exp(-2\pi i\mathbf{H}^\parallel \cdot \mathbf{r}),$$

with $\mathbf{H}^\parallel \in \mathbb{R}$ (the set of real numbers). The Fourier coefficients $F(\mathbf{H}^\parallel)$ form a Fourier module $M^* = \{\mathbf{H}^\parallel = \sum_{i=1}^{2} h_i\mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ equivalent to a $\mathbb{Z}$ module of rank 2. Thus a periodic function in 2D space can be defined by

$$\rho(\mathbf{r}^\parallel, \mathbf{r}^\perp) = (1/V)\sum_{\mathbf{H}} F(\mathbf{H})\exp[-2\pi i(\mathbf{H}^\parallel \cdot \mathbf{r}^\parallel + \mathbf{H}^\perp \cdot \mathbf{r}^\perp)],$$

where $\mathbf{r} = (\mathbf{r}^\parallel, \mathbf{r}^\perp) \in \Sigma$ and $\mathbf{H} = (\mathbf{H}^\parallel, \mathbf{H}^\perp) \in \Sigma^*$ are, by construction, direct- and reciprocal-lattice vectors (Figs. 4.6.2.8 and 4.6.2.9):

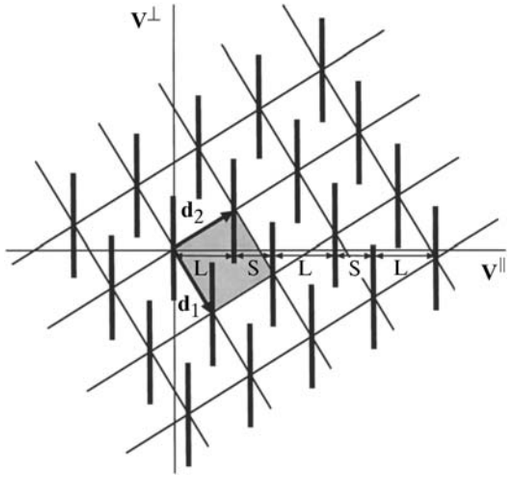

Fig. 4.6.2.8. 2D embedding of the Fibonacci chain. The short and long distances S and L, generated by the intersection of the atomic surfaces with the physical space $\mathbf{V}^\parallel$, are indicated. The atomic surfaces are represented by bars parallel to $\mathbf{V}^\perp$. Their lengths correspond to the projection of one unit cell (shaded) upon $\mathbf{V}^\perp$.

$$\mathbf{r} = n_1\mathbf{d}_1 + n_2\mathbf{d}_2, \text{ with } \mathbf{d}_1 = \frac{1}{a^*(2+\tau)}\begin{pmatrix}1\\-\tau\end{pmatrix}_V,$$

$$\mathbf{d}_2 = \frac{1}{a^*(2+\tau)}\begin{pmatrix}\tau\\1\end{pmatrix}_V;$$

$$\mathbf{H} = h_1\mathbf{d}_1^* + h_2\mathbf{d}_2^*, \text{ with } \mathbf{d}_1^* = a^*\begin{pmatrix}1\\-\tau\end{pmatrix}_V, \mathbf{d}_2^* = a^*\begin{pmatrix}\tau\\1\end{pmatrix}_V.$$

The 1D Fibonacci chain results from the cut of the parallel (physical) space with the 2D lattice Σ decorated with line elements for the *atomic surfaces* (*acceptance domains*). In this description, the atomic surfaces correspond simply to the projection of one 2D unit cell upon the perpendicular-space coordinate. This satisfies the condition that each unit cell contributes exactly to one point of the Fibonacci chain (*primitive unit cell*). The physical space $\mathbf{V}^\parallel$ is related to the eigenspace of the substitution matrix S associated with its eigenvalue $\lambda_1 = \tau$. The perpendicular space $\mathbf{V}^\perp$ corresponds to the eigenspace of the substitution matrix S associated with its eigenvalue $\lambda_2 = -1/\tau$. Thus, the physical space scales to powers of τ and the perpendicular space to powers of $-1/\tau$.

By block-diagonalization, the reducible substitution (scaling) matrix S can be decomposed into two non-equivalent irreducible representations. These can be assigned to the two 1D orthogonal subspaces $\mathbf{V}^\parallel$ and $\mathbf{V}^\perp$ forming the 2D embedding space $\mathbf{V} = \mathbf{V}^\parallel \oplus \mathbf{V}^\perp$. Thus, using $WSW^{-1} = S_V = S_V^\parallel \oplus S_V^\perp$, where

$$W = \begin{pmatrix}1 & \tau\\ -\tau & 1\end{pmatrix} = \begin{pmatrix}\mathbf{d}_1^* & \mathbf{d}_2^*\end{pmatrix},$$

one obtains

$$\begin{pmatrix}1 & \tau\\ -\tau & 1\end{pmatrix}\begin{pmatrix}0 & 1\\ 1 & 1\end{pmatrix}_D\begin{pmatrix}1 & \tau\\ -\tau & 1\end{pmatrix}^{-1} = \left(\begin{array}{c|c}\tau & 0\\ \hline 0 & -1/\tau\end{array}\right)_V = \left(\begin{array}{c|c}S^\parallel & 0\\ \hline 0 & S^\perp\end{array}\right)_V,$$

the scaling operations $S^\parallel$ and $S^\perp$ in parallel and in perpendicular space as indicated by the partition lines.

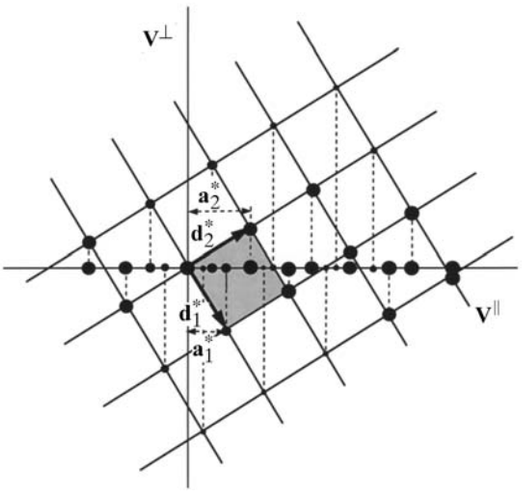

Fig. 4.6.2.9. Schematic representation of the reciprocal space of the embedded Fibonacci chain depicted in Fig. 4.6.2.8. The physical-space reciprocal basis $\mathbf{a}_1^*$ and $\mathbf{a}_2^*$ is marked. The diameters of the filled circles are roughly proportional to the reflection intensities. One 2D reciprocal-lattice unit cell is shadowed. The actual 1D diffraction pattern of the 1D Fibonacci chain results from a projection of the 2D reciprocal space onto the parallel space. The correspondence between 2D reciprocal-lattice positions and their projected images is indicated by dashed lines.

The metric tensors for the reciprocal and the direct 2D square lattices read

$$G^* = |a^*|^2(2+\tau)\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix} \text{ and } G = \frac{1}{|a^*|^2(2+\tau)}\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix}.$$

The short distance S of the Fibonacci sequence is related to a^* by

$$\begin{aligned} S &= 1/[a^*(2+\tau)]\\ &= \min\left\{\left|\pi^\parallel(\mathbf{d}_i - \mathbf{d}_j)\right| \,\middle|\, \left|\pi^\perp(\mathbf{d}_i - \mathbf{d}_j)\right| < \Omega_{\rm AS} \wedge i, j \in \mathbb{Z}\right\}, \end{aligned}$$

with the projectors $\pi^\parallel$ and $\pi^\perp$ onto $\mathbf{V}^\parallel$ and $\mathbf{V}^\perp$. The *point density* $\rho_{\rm p}$ of the Fibonacci chain, *i.e.* the number of vertices per unit length, can be calculated using the formula

$$\rho_{\rm p} = \frac{\Omega_{\rm AS}}{\Omega_{\rm UC}} = \frac{(1+\tau)/[a^*(2+\tau)]}{1/[|a^*|^2(2+\tau)]} = a^*\tau^2,$$

where $\Omega_{\rm AS}$ and $\Omega_{\rm UC}$ are the areas of the atomic surface and of the 2D unit cell, respectively.

For an infinite Fibonacci sequence generated from the intervals S and L an average distance d can be calculated:

$$d = \lim_{n\to\infty}\frac{F_n\mathrm{S} + F_{n+1}\mathrm{L}}{F_n + F_{n+1}} = \lim_{n\to\infty}\frac{F_n(\mathrm{S}+\tau\mathrm{L})}{F_n(1+\tau)} = \frac{\mathrm{S}(1+\tau^2)}{(1+\tau)} = (3-\tau)\mathrm{S}.$$

Therefrom, the point density can also be calculated:

$$\rho_{\rm p} = 1/d = 1/[(3-\tau)\mathrm{S}] = [a^*(2+\tau)]/(3-\tau) = a^*\tau^2.$$

An approximant structure of the Fibonacci sequence with a unit cell containing m intervals L and n intervals S can be generated by shearing the 2D lattice Σ by the shear matrix S_m,

$$S_m = \frac{1}{2+\tau}\begin{pmatrix} \tau^2 + x\tau + 1 & -x \\ x\tau^2 & \tau^2 - x\tau + 1 \end{pmatrix}_D,$$

where $x = (n\tau - m)/(m\tau + n)$:

$$\begin{aligned}
\mathbf{d}_i' &= \sum_{j=1}^{2} S_{mij}\mathbf{d}_j; \\
\mathbf{d}_1' &= \frac{1}{2+\tau}\left[(\tau^2 + x\tau + 1)\mathbf{d}_1 - x\mathbf{d}_2\right] \\
&= \frac{1}{(2+\tau)a^*}\begin{pmatrix} 1 \\ -\tau - x \end{pmatrix}_V \\
&= \frac{1}{(2+\tau)a^*}\begin{pmatrix} 1 \\ -\dfrac{2n\tau + m\tau}{m\tau + n} \end{pmatrix}_V, \\
\mathbf{d}_2' &= \frac{1}{2+\tau}\left[x\tau^2\mathbf{d}_1 + (\tau^2 - x\tau + 1)\mathbf{d}_2\right] \\
&= \frac{1}{(2+\tau)a^*}\begin{pmatrix} \tau \\ -x\tau + 1 \end{pmatrix}_V \\
&= \frac{1}{(2+\tau)a^*}\begin{pmatrix} \tau \\ \dfrac{2m\tau - n\tau}{m\tau + n} \end{pmatrix}_V.
\end{aligned}$$

This shear matrix does not change the magnitudes of the intervals L and S. In reciprocal space the inverted and transposed shear matrix is applied on the reciprocal basis,

$$(S_m^{-1})^T = \frac{1}{2+\tau}\begin{pmatrix} \tau^2 - x\tau + 1 & -x\tau^2 \\ x & \tau^2 + x\tau + 1 \end{pmatrix}_D,$$

where $x = (n\tau - m)/(m\tau + n)$:

$$\begin{aligned}
\mathbf{d}_i^{*'} &= \sum_{j=1}^{2} (S_m^{-1})_{ij}^T \mathbf{d}_j^*; \\
\mathbf{d}_1^{*'} &= \frac{1}{2+\tau}\left[(\tau^2 - x\tau + 1)\mathbf{d}_1^* - x\tau^2\mathbf{d}_2^*\right] \\
&= a^*\begin{pmatrix} 1 - x\tau \\ -\tau \end{pmatrix}_V \\
&= a^*\begin{pmatrix} \dfrac{2m\tau - n\tau}{m\tau + n} \\ -\tau \end{pmatrix}_V, \\
\mathbf{d}_2^{*'} &= \frac{1}{2+\tau}\left[x\mathbf{d}_1^* + (\tau^2 + x\tau + 1)\mathbf{d}_2^*\right] \\
&= a^*\begin{pmatrix} \tau + x \\ 1 \end{pmatrix}_V \\
&= a^*\begin{pmatrix} \dfrac{2n\tau + m\tau}{m\tau + n} \\ 1 \end{pmatrix}_V.
\end{aligned}$$

The point $x_n(t)$ of the nth interval L or S of an infinite Fibonacci sequence is given by

$$x_n(t) = \{x_0 + n(3 - \tau) - (\tau - 1)[\mathrm{frac}(n\tau + t) - (1/2)]\}\mathrm{S},$$

where t is the phase of the modulation function $y(t) = (\tau - 1)[\mathrm{frac}(n\tau + t) - (1/2)]$ (Janssen, 1986). Thus, the Fibonacci sequence can also be dealt with as an incommensurately modulated structure. This is a consequence of the fact that for 1D structures only the crystallographic point symmetries 1 and $\bar{1}$ allow the existence of a periodic average structure.

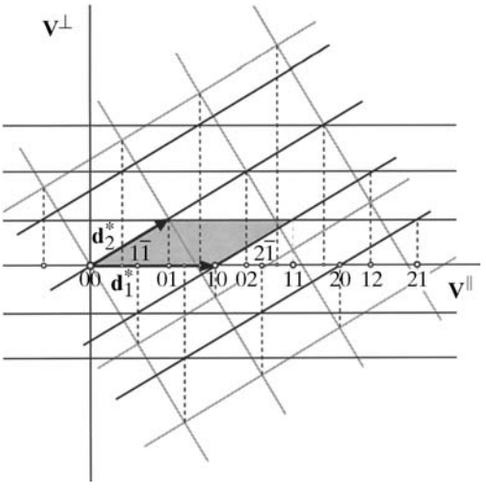

Fig. 4.6.2.10. Reciprocal space of the embedded Fibonacci chain as a modulated structure. Several main and satellite reflections are indexed. The square reciprocal lattice of the quasicrystal description illustrated in Fig. 4.6.2.9 is indicated by grey lines. The reflections located on $\mathbf{V}^\parallel$ can be considered to be projected either from the 2D square lattice of the embedding as for a QS or from the 2D oblique lattice of the embedding as for an IMS.

The embedding of the Fibonacci chain as an incommensurately modulated structure can be performed as follows:

(1) select a subset $\Lambda^* \subset M^*$ of strong reflections for main reflections $\mathbf{H} = h\mathbf{a}^*, h \in \mathbb{Z}$;

(2) define a satellite vector $\mathbf{q} = \alpha\mathbf{a}^*$ pointing from each main reflection to the next satellite reflection.

One possible way of indexing based on the same $\mathbf{a}^*$ as defined above is illustrated in Fig. 4.6.2.10. The scattering vector is given by $\mathbf{H}^\parallel = h(\tau + 1)\mathbf{a}^* + mq$, where $\mathbf{q} = \tau\mathbf{a}^*$, or, in the 2D representation, $\mathbf{H} = h_1\mathbf{d}_1^* + h_2\mathbf{d}_2^*$, where

$$\mathbf{d}_1^* = a^*\begin{pmatrix} 1 + \tau \\ 0 \end{pmatrix}_V$$

and

$$\mathbf{d}_2^* = a^*\begin{pmatrix} \tau \\ 1 \end{pmatrix}_V,$$

with the direct basis

$$\mathbf{d}_1 = \frac{1}{a^*(1+\tau)}\begin{pmatrix} 1 \\ -\tau \end{pmatrix}_V, \quad \mathbf{d}_2 = \frac{1}{a^*}\begin{pmatrix} 0 \\ 1 \end{pmatrix}_V.$$

The modulation function is saw-tooth-like (Fig. 4.6.2.11).

4.6.2.5. 1D structures with fractal atomic surfaces

A 1D structure with a *fractal atomic surface* (Hausdorff dimension 0.9157...) can be derived from the Fibonacci sequence by squaring its substitution matrix S:

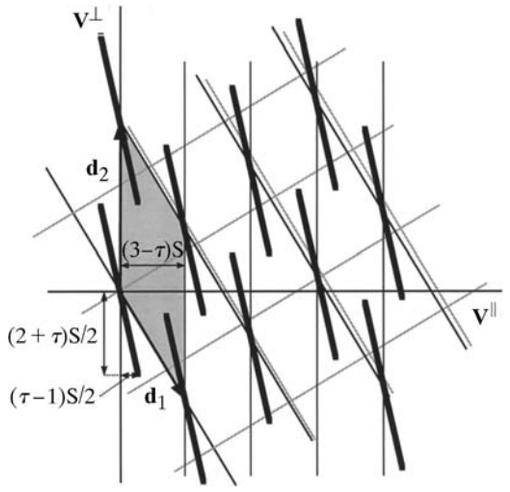

Fig. 4.6.2.11. 2D direct-space embedding of the Fibonacci chain as a modulated structure. The average period is $(3-\tau)$S. The square lattice in the quasicrystal description shown in Fig. 4.6.2.8 is indicated by grey lines. The rod-like atomic surfaces are now inclined relative to $\mathbf{V}^{\parallel}$ and arranged so as to give a saw-tooth modulation wave.

$$\begin{pmatrix} \mathrm{S} \\ \mathrm{L} \end{pmatrix} \rightarrow \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} \begin{pmatrix} \mathrm{S} \\ \mathrm{L} \end{pmatrix} = \begin{pmatrix} \mathrm{S}+\mathrm{L} \\ \mathrm{S}+2\mathrm{L} \end{pmatrix}$$
$$\text{with } S^2 = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix},$$

corresponding to the substitution rule S $\rightarrow$ SL, L $\rightarrow$ LLS as well as two other non-equivalent ones (see Janssen, 1995). The eigenvalues λ_i are obtained by calculating

$$\det |S - \lambda I| = 0.$$

The evaluation of the determinant gives the characteristic polynomial

$$\lambda^2 - 3\lambda + 1 = 0,$$

with the solutions $\lambda_{1,2} = [3 \pm (5)^{1/2}]/2$, with $\lambda_1 = \tau^2$ and $\lambda_2 = 1/\tau^2 = 2 - \tau$, and the same eigenvectors

$$\mathbf{w}_1 = \begin{pmatrix} 1 \\ \tau \end{pmatrix}, \quad \mathbf{w}_2 = \begin{pmatrix} 1 \\ -1/\tau \end{pmatrix}$$

as for the Fibonacci sequence. Rewriting the eigenvalue equation gives

$$\begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} \begin{pmatrix} 1 \\ \tau \end{pmatrix} = \begin{pmatrix} \tau+1 \\ 2\tau+1 \end{pmatrix} = \begin{pmatrix} \tau^2 \\ \tau^3 \end{pmatrix} = \tau^2 \begin{pmatrix} 1 \\ \tau \end{pmatrix}.$$

Identifying the eigenvector

$$\begin{pmatrix} 1 \\ \tau \end{pmatrix}$$

with

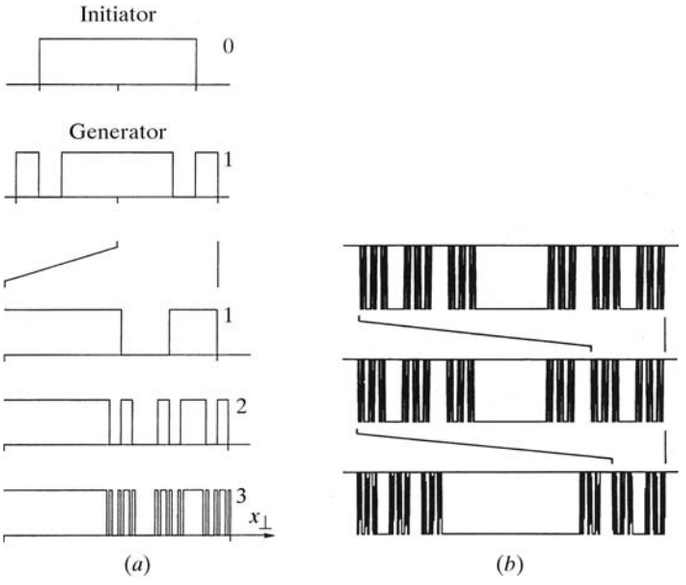

Fig. 4.6.2.12. (*a*) Three steps in the development of the fractal atomic surface of the squared Fibonacci sequence starting from an initiator and a generator. The action of the generator is to cut a piece from each side of the initiator and to add it where the initiator originally ended. This is repeated, cutting thinner and thinner pieces each time from the generated structures. (*b*) Magnification sequence of the fractal atomic surface illustrating its self-similarity. Each successive figure represents a magnification of a selected portion of the previous figure (from Zobetz, 1993).

$$\begin{pmatrix} \mathrm{S} \\ \mathrm{L} \end{pmatrix}$$

shows that the infinite 1D sequence $s(\mathbf{r})$ multiplied by powers of its eigenvalue τ^2 (scaling operation) remains invariant (each new lattice point coincides with one of the original lattice):

$$s(\tau^2\mathbf{r}) = s(\mathbf{r}).$$

The fractal sequence can be described on the same reciprocal and direct bases as the Fibonacci sequence. The only difference in the 2D direct-space description is the fractal character of the perpendicular-space component of the hyperatoms (Fig. 4.6.2.12) (see Zobetz, 1993).

4.6.3. Reciprocal-space images

4.6.3.1. Incommensurately modulated structures (IMSs)

One-dimensionally modulated structures are the simplest representatives of IMSs. The vast majority of the one hundred or so IMSs known so far belong to this class (Cummins, 1990). However, there is also an increasing number of IMSs with 2D or 3D modulation. The dimension d of the modulation is defined by the number of rationally independent modulation wavevectors (satellite vectors) $\mathbf{q}_i$ (Fig. 4.6.3.1). The electron-density function of a dD modulated 3D crystal can be represented by the Fourier series

$$\rho(\mathbf{r}) = (1/V)\sum_{\mathbf{H}} F(\mathbf{H}) \exp(-2\pi i \mathbf{H} \cdot \mathbf{r}).$$

The Fourier coefficients (*structure factors*) $F(\mathbf{H})$ differ from zero only for reciprocal-space vectors $\mathbf{H} = \sum_{i=1}^{3} h_i \mathbf{a}_i^* + \sum_{j=1}^{d} m_j \mathbf{q}_j = \sum_{i=1}^{3+d} h_i \mathbf{a}_i^*$ with $h_i, m_j \in \mathbb{Z}$. The d satellite vectors are given by $\mathbf{q}_j = \mathbf{a}_{3+j}^* = \sum_{i=1}^{3} \alpha_{ij} \mathbf{a}_i^*$, with α_{ij} a $3 \times d$ matrix σ. In the case of an

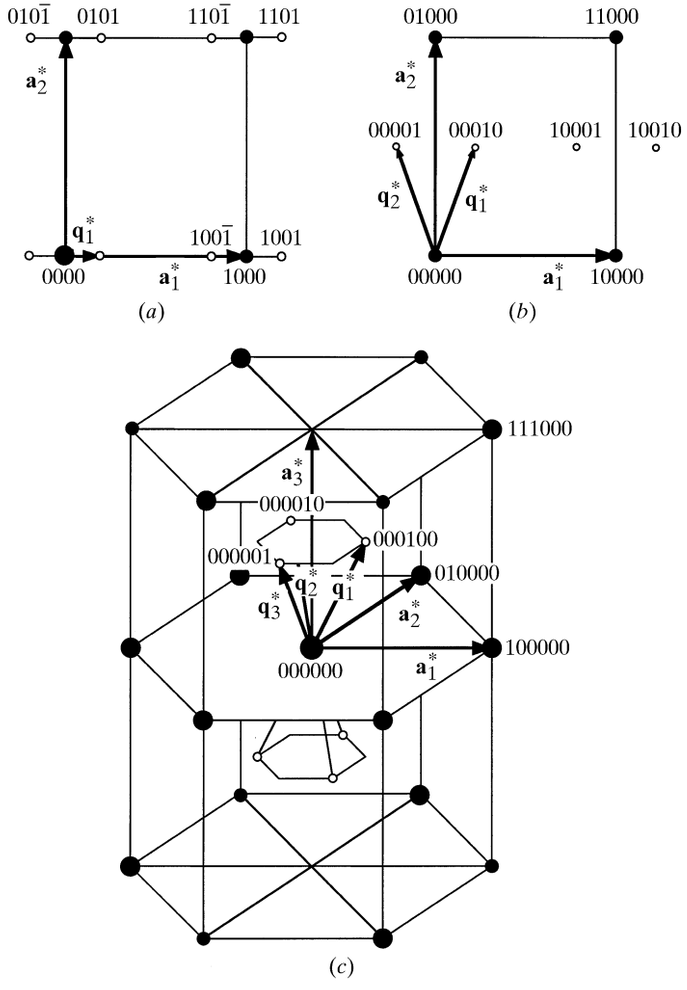

Fig. 4.6.3.1. Schematic diffraction patterns for IMSs with (*a*) 1D, (*b*) 2D and (*c*) 3D modulation. The satellite vectors correspond to $\mathbf{q} = \alpha_1\mathbf{a}_1^*$ in (*a*), $\mathbf{q}_1 = \alpha_{11}\mathbf{a}_1^* + (1/2)\mathbf{a}_2^*$ and $\mathbf{q}_2 = -\alpha_{12}\mathbf{a}_1^* + (1/2)\mathbf{a}_2^*$, where $\alpha_{11} = \alpha_{12}$, in (*b*), and $\mathbf{q}_1 = \alpha_{11}\mathbf{a}_1^* + \alpha_{31}\mathbf{a}_3^*$, $\mathbf{q}_2 = \alpha_{12}(-\mathbf{a}_1^* + \mathbf{a}_2^*) + \alpha_{32}\mathbf{a}_3^*$, $\mathbf{q}_3 = -\alpha_{13}\mathbf{a}_2^* + \alpha_{33}\mathbf{a}_3^*$, where $\alpha_{11} = \alpha_{12} = \alpha_{13}$ and $\alpha_{31} = \alpha_{32} = \alpha_{33}$, in (*c*). The areas of the circles are proportional to the reflection intensities. Main (filled circles) and satellite (open circles) reflections are indexed (after Janner *et al.*, 1983*b*).

IMS, at least one entry to σ has to be irrational. The wavelength of the modulation function is $\lambda_j = 1/q_j$. The set of vectors $\mathbf{H}$ forms a Fourier module $M^* = \{\mathbf{H} = \sum_{i=1}^{3+d} h_i\mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ of rank $n = 3 + d$, which can be decomposed into a rank 3 and a rank d submodule $M^* = M_1^* \oplus M_2^*$. $M_1^* = \{h_1\mathbf{a}_1^* + h_2\mathbf{a}_2^* + h_3\mathbf{a}_3^*\}$ corresponds to a $\mathbb{Z}$ module of rank 3 in a 3D subspace (the physical space), $M_2^* = \{h_4\mathbf{a}_4^* + \ldots + h_{3+d}\mathbf{a}_{3+d}^*\}$ corresponds to a $\mathbb{Z}$ module of rank d in a dD subspace (perpendicular space). The submodule M_1 is identical to the 3D reciprocal lattice Λ^* of the average structure. M_2 results from the projection of the perpendicular-space component of the $(3 + d)$D reciprocal lattice Σ^* upon the physical space. Owing to the coincidence of one subspace with the physical space, the dimension of the embedding space is given as $(3 + d)$D and not as nD. This terminology points out the special role of the physical space.

Hence the reciprocal-basis vectors $\mathbf{a}_i^*, i = 1, \ldots, 3 + d$, can be considered to be physical-space projections of reciprocal-basis vectors $\mathbf{d}_i^*, i = 1, \ldots, 3 + d$, spanning a $(3 + d)$D reciprocal lattice Σ^*:

$$\Sigma^* = \left\{\mathbf{H} = \sum_{i=1}^{3+d} h_i\mathbf{d}_i^* \Big| h_i \in \mathbb{Z}\right\},$$

$$\mathbf{d}_i^* = (\mathbf{a}_i^*, \mathbf{0}),\ i = 1, \ldots, 3 \text{ and } \mathbf{d}_{3+j}^* = (\mathbf{a}_{3+j}^*, c\mathbf{e}_j^*),\ j = 1, \ldots, d.$$

The first vector component of $\mathbf{d}_i^*$ refers to the physical space, the second to the perpendicular space spanned by the mutually orthogonal unit vectors $\mathbf{e}_j$. c is an arbitrary constant which can be set to 1 without loss of generality.

A direct lattice Σ with basis $\mathbf{d}_i$, $i = 1, \ldots, 3 + d$ and $\mathbf{d}_i \cdot \mathbf{d}_j^* = \delta_{ij}$, can be constructed according to

$$\Sigma = \left\{\mathbf{r} = \sum_{i=1}^{3+d} m_i\mathbf{d}_i \Big| m_i \in \mathbb{Z}\right\},$$

$$\mathbf{d}_i = \left(\mathbf{a}_i, -\sum_{j=1}^{d} \alpha_{ij}(1/c)\mathbf{e}_j\right),\ i = 1, \ldots, 3$$

$$\text{and } \mathbf{d}_{3+j} = \left(\mathbf{0}, (1/c)\mathbf{e}_j^*\right),\ j = 1, \ldots, d.$$

Consequently, the aperiodic structure in physical space $\mathbf{V}^{\parallel}$ is equivalent to a 3D section of the $(3 + d)$D hypercrystal.

4.6.3.1.1. Indexing

The 3D reciprocal space M^* of a $(3 + d)$D IMS consists of two separable contributions,

$$M^* = \left\{\mathbf{H} = \sum_{i=1}^{3} h_i\mathbf{a}_i^* + \sum_{j=1}^{d} m_j\mathbf{q}_j\right\},$$

the set of main reflections ($m_j = 0$) and the set of satellite reflections ($m_j \neq 0$) (Fig. 4.6.3.1). In most cases, the modulation is only a weak perturbation of the crystal structure. The main reflections are related to the average structure, the satellites to the difference between the average and actual structure. Consequently, the satellite reflections are generally much weaker than the main reflections and can be easily identified. Once the set of main reflections has been separated, a conventional basis $\mathbf{a}_i^*, i = 1, \ldots, 3$, for Λ^* is chosen.

The only ambiguity is in the assignment of rationally independent satellite vectors $\mathbf{q}_i$. They should be chosen inside the reciprocal-space unit cell (Brillouin zone) of Λ^* in such a way as to give a minimal number d of additional dimensions. If satellite vectors reach the Brillouin-zone boundary, centred $(3 + d)$D Bravais lattices are obtained. The star of satellite vectors has to be invariant under the point-symmetry group of the diffraction pattern. There should be no contradiction to a reasonable physical modulation model concerning period or propagation direction of the modulation wave. More detailed information on how to find the optimum basis and the correct setting is given by Janssen *et al.* (2004) and Janner *et al.* (1983*a*,*b*).

4.6.3.1.2. Diffraction symmetry

The Laue symmetry group $K^{\mathrm{L}} = \{R\}$ of the Fourier module M^*,

$$M^* = \left\{\mathbf{H} = \sum_{i=1}^{3} h_i\mathbf{a}_i^* + \sum_{j=1}^{d} m_j\mathbf{q}_j = \sum_{i=1}^{3+d} h_i\mathbf{a}_i^*\right\},\ \Lambda^* = \left\{\mathbf{H} = \sum_{i=1}^{3} h_i\mathbf{a}_i^*\right\},$$

is isomorphous to or a subgroup of one of the 11 3D crystallographic Laue groups leaving Λ^* invariant. The action of the point-group symmetry operators R on the reciprocal basis $\mathbf{a}_i^*, i = 1, \ldots, 3 + d$, can be written as

$$R\mathbf{a}_i^* = \sum_{j=1}^{3+d} \Gamma_{ij}^T(R)\mathbf{a}_j^*,\ i = 1, \ldots, 3 + d.$$

The $(3+d)\times(3+d)$ matrices $\Gamma^T(R)$ form a finite group of integral matrices which are reducible, since R is already an orthogonal transformation in 3D physical space. Consequently, R can be expressed as pair of orthogonal transformations $(R^{\parallel}, R^{\perp})$ in 3D physical and dD perpendicular space, respectively. Owing to their mutual orthogonality, no symmetry relationship exists between the set of main reflections and the set of satellite reflections. $\Gamma^T(R)$ is the transpose of $\Gamma(R)$ which acts on vector components in direct space.

For the $(3+d)$D direct-space (*superspace*) symmetry operator $(R_s, \mathbf{t}_s)$ and its matrix representation $\Gamma(R_s, \mathbf{t}_s)$ on Σ, the following decomposition can be performed:

$$\Gamma(R_s) = \begin{pmatrix} \Gamma^{\parallel}(R) & 0 \\ \Gamma^{M}(R) & \Gamma^{\perp}(R) \end{pmatrix} \text{ and } \mathbf{t}_s = (\mathbf{t}_3, \mathbf{t}_d).$$

$\Gamma^{\parallel}(R)$ is a 3×3 matrix, $\Gamma^{\perp}(R)$ is a $d\times d$ matrix and $\Gamma^{M}(R)$ is a $d\times 3$ matrix. The translation operator $\mathbf{t}_s$ consists of a 3D vector $\mathbf{t}_3$ and a dD vector $\mathbf{t}_d$. According to Janner & Janssen (1979), $\Gamma^{M}(R)$ can be derived from $\Gamma^{M}(R) = \sigma\Gamma^{\parallel}(R) - \Gamma^{\perp}(R)\sigma$. $\Gamma^{M}(R)$ has integer elements only as it contains components of primitive-lattice vectors of Λ^*, whereas σ in general consists of a rational and an irrational part: $\sigma = \sigma^{i} + \sigma^{r}$. Thus, only the rational part gives rise to nonzero entries in $\Gamma^{M}(R)$. With the order of the Laue group denoted by N, one obtains $\sigma^{i} \equiv (1/N)\sum_R \Gamma^{\perp}(R)\sigma\Gamma^{\parallel}(R)^{-1}$, where $\Gamma^{\perp}(R)\sigma^{i}\Gamma^{\parallel}(R)^{-1} = \sigma^{i}$, implying that $\Gamma^{M}(R) = \sigma^{r}\Gamma^{\parallel}(R) - \Gamma^{\perp}(R)\sigma^{r}$ and $0 = \sigma^{i}\Gamma^{\parallel}(R) - \Gamma^{\perp}(R)\sigma^{i}$.

Example

In the case of a 3D IMS with 1D modulation ($d = 1$) the $3\times d$ matrix

$$\sigma = \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

has the components of the wavevector $\mathbf{q} = \sum_{i=1}^{3}\alpha_i \mathbf{a}_i^* = \mathbf{q}^{i} + \mathbf{q}^{r}$. $\Gamma^{\perp}(R) = \varepsilon = \pm 1$ because for $d = 1$, $\mathbf{q}$ can only be transformed into $\pm\mathbf{q}$. Corresponding to $\mathbf{q}^{i} \equiv (1/N)\sum_R \varepsilon R\mathbf{q}$, one obtains $R^T\mathbf{q}^{i} \equiv \varepsilon\mathbf{q}^{i}$ (modulo Λ^*). The 3×1 row matrix $\Gamma^{M}(R)$ is equivalent to the difference vector between $R^T\mathbf{q}$ and $\varepsilon\mathbf{q}$ (Janssen *et al.*, 2004).

For a monoclinic modulated structure with point group $2/m$ for M^* (unique axis $\mathbf{a}_3$) and satellite vector $\mathbf{q} = (1/2)\mathbf{a}_1^* + \alpha_3\mathbf{a}_3^*$, with α_3 an irrational number, one obtains

$$\begin{aligned}\mathbf{q}^{i} &\equiv (1/N)\sum_R \varepsilon R\mathbf{q} \\ &= \tfrac{1}{4}\left(+1\cdot\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix}\begin{pmatrix}1/2\\0\\\alpha_3\end{pmatrix} \right. \\ &\quad +1\cdot\begin{pmatrix}\bar1&0&0\\0&\bar1&0\\0&0&1\end{pmatrix}\begin{pmatrix}1/2\\0\\\alpha_3\end{pmatrix} - 1\cdot\begin{pmatrix}\bar1&0&0\\0&\bar1&0\\0&0&\bar1\end{pmatrix}\begin{pmatrix}1/2\\0\\\alpha_3\end{pmatrix} \\ &\quad \left. -1\cdot\begin{pmatrix}1&0&0\\0&1&0\\0&0&\bar1\end{pmatrix}\begin{pmatrix}1/2\\0\\\alpha_3\end{pmatrix}\right) \\ &= \begin{pmatrix}0\\0\\\alpha_3\end{pmatrix}.\end{aligned}$$

From the relations $R^T\mathbf{q}^{i} \equiv \varepsilon\mathbf{q}^{i}$ (modulo Λ^*), it can be shown that the symmetry operations 1 and 2 are associated with the perpendicular-space transformations $\varepsilon = 1$, and m and $\bar1$ with $\varepsilon = -1$. The matrix $\Gamma^{M}(R)$ is given by

$$\begin{aligned}\Gamma^{M}(2) &= \sigma^{r}\Gamma^{\parallel}(2) - \Gamma^{\perp}(2)\sigma^{r} \\ &= \begin{pmatrix}1/2\\0\\0\end{pmatrix}\begin{pmatrix}\bar1&0&0\\0&\bar1&0\\0&0&1\end{pmatrix} - (+1)\begin{pmatrix}1/2\\0\\0\end{pmatrix} = \begin{pmatrix}\bar1\\0\\0\end{pmatrix}\end{aligned}$$

for the operation 2, for instance.

The matrix representations $\Gamma^T(R_s)$ of the symmetry operators R in reciprocal $(3+d)$D superspace decompose according to

$$\Gamma^T(R_s) = \begin{pmatrix} \Gamma^{\parallel T}(R) & \Gamma^{MT}(R) \\ 0 & \Gamma^{\perp T}(R) \end{pmatrix}.$$

Phase relationships between modulation functions of symmetry-equivalent atoms can give rise to systematic extinctions of different classes of satellite reflections. The extinction rules may include indices of both main and satellite reflections. A full list of systematic absences is given in the table of $(3+1)$D superspace groups (Janssen *et al.*, 2004). Thus, once point symmetry and systematic absences are found, the superspace group can be obtained from the tables in a way analogous to that used for regular 3D crystals. A different approach for the symmetry description of IMSs from the 3D Fourier-space perspective has been given by Dräger & Mermin (1996).

4.6.3.1.3. Structure factor

The structure factor of a periodic structure is defined as the Fourier transform of the density distribution $\rho(\mathbf{r})$ of its unit cell (UC):

$$F(\mathbf{H}) = \int_{\mathrm{UC}} \rho(\mathbf{r})\exp(2\pi i\mathbf{H}\cdot\mathbf{r})\ \mathrm{d}\mathbf{r}.$$

The same is valid in the case of the $(3+d)$D description of IMSs. The parallel- and perpendicular-space components are orthogonal to each other and can be separated. The Fourier transform of the parallel-space component of the electron-density distribution of a single atom gives the usual atomic scattering factors $f_k(\mathbf{H}^{\parallel})$. For the structure-factor calculation, one does not need to use $\rho(\mathbf{r})$ explicitly. The hyperatoms correspond to the convolution of the electron-density distribution in 3D physical space with the modulation function in dD perpendicular space. Therefore, the Fourier transform of the $(3+d)$D hyperatoms is simply the product of the Fourier transform $f_k(\mathbf{H}^{\parallel})$ of the physical-space component with the Fourier transform of the perpendicular-space component, the modulation function.

For a general *displacive modulation* one obtains for the ith coordinate x_{ik} of the kth atom in 3D physical space

$$x_{ik} = \bar{x}_{ik} + u_{ik}(\bar{x}_4, \ldots, \bar{x}_{3+d}),\ \ i = 1, \ldots, 3,$$

where $\bar{x}_{ik}$ are the basic-structure coordinates and $u_{ik}(\bar{x}_4, \ldots, \bar{x}_{3+d})$ are the modulation functions with unit periods in their arguments (Fig. 4.6.3.2). The arguments are $\bar{x}_{3+j} = \alpha_{ij}\bar{x}_{ik}^0 + t_j,\ j = 1, \ldots, d$, where $\bar{x}_{ik}^0$ are the coordinates of the kth atom referred to the origin of its unit cell and t_j are the phases of the modulation functions. The modulation functions $u_{ik}(\bar{x}_4, \ldots, \bar{x}_{3+d})$ themselves can be expressed in terms of a Fourier series as

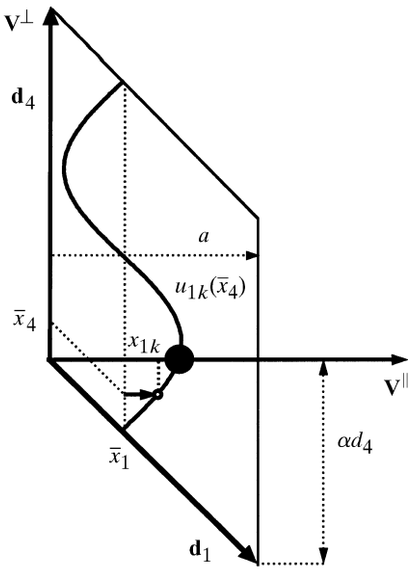

Fig. 4.6.3.2. The relationships between the coordinates $x_{1k}, x_{4k}, \bar{x}_1, \bar{x}_4$ and the modulation function u_{1k} in a special section of the $(3+d)$D space.

$$u_{ik}(\bar{x}_4, \ldots, \bar{x}_{3+d}) = \sum_{n_1=1}^{\infty} \ldots \sum_{n_d=1}^{\infty} \{{}^{u}C_{ik}^{n_1 \ldots n_d} \cos[2\pi(n_1\bar{x}_4 + \ldots + n_d\bar{x}_{3+d})] + {}^{u}S_{ik}^{n_1 \ldots n_d} \sin[2\pi(n_1\bar{x}_4 + \ldots + n_d\bar{x}_{3+d})]\},$$

where n_j are the orders of harmonics for the jth modulation wave of the ith component of the kth atom and their amplitudes are ${}^{u}C_{ik}^{n_1 \ldots n_d}$ and ${}^{u}S_{ik}^{n_1 \ldots n_d}$.

Analogous expressions can be derived for a *density modulation*, *i.e.*, the modulation of the occupation probability $p_k(\bar{x}_4, \ldots, \bar{x}_{3+d})$:

$$p_k(\bar{x}_4, \ldots, \bar{x}_{3+d}) = \sum_{n_1=1}^{\infty} \ldots \sum_{n_d=1}^{\infty} \{{}^{p}C_{k}^{n_1 \ldots n_d} \cos[2\pi(n_1\bar{x}_4 + \ldots + n_d\bar{x}_{3+d})] + {}^{p}S_{k}^{n_1 \ldots n_d} \sin[2\pi(n_1\bar{x}_4 + \ldots + n_d\bar{x}_{3+d})]\},$$

and for the modulation of the tensor of thermal parameters $B_{ijk}(\bar{x}_4, \ldots, \bar{x}_{3+d})$:

$$B_{ijk}(\bar{x}_4, \ldots, \bar{x}_{3+d}) = \sum_{n_1=1}^{\infty} \ldots \sum_{n_d=1}^{\infty} \{{}^{B}C_{ijk}^{n_1 \ldots n_d} \cos[2\pi(n_1\bar{x}_4 + \ldots + n_d\bar{x}_{3+d})] + {}^{B}S_{ijk}^{n_1 \ldots n_d} \sin[2\pi(n_1\bar{x}_4 + \ldots + n_d\bar{x}_{3+d})]\}.$$

The resulting structure-factor formula is

$$F(\mathbf{H}) = \sum_{k=1}^{N'} \sum_{(R,t)} \int_0^1 \mathrm{d}\bar{x}_{4,k} \ldots \int_0^1 \mathrm{d}\bar{x}_{3+d,k} f_k(\mathbf{H}^{\parallel}) p_k \times \exp\left(-\sum_{i,j=1}^{3+d} h_i[RB_{ijk}R^T]h_j + 2\pi i \sum_{j=1}^{3+d} h_j R x_{jk} + h_j t_j\right)$$

for summing over the set $(R, \mathbf{t})$ of superspace symmetry operations and the set of N' atoms in the asymmetric unit of the $(3+d)$D unit cell (Yamamoto, 1982). Different approaches without numerical integration based on analytical expressions including Bessel functions have also been developed. For more information see Paciorek & Chapuis (1994), Petricek, Maly & Cisarova (1991), and references therein.

For illustration, some fundamental IMSs will be discussed briefly (see Korekawa, 1967; Böhm, 1977).

Harmonic density modulation. A harmonic density modulation can result on average from an ordered distribution of vacancies on atomic positions. For an IMS with N atoms per unit cell one obtains for a harmonic modulation of the occupancy factor

$$p_k = (p_k^0/2)\{1 + \cos[2\pi(\bar{x}_{4,k} + \varphi_k)]\}, \quad 0 \le p_k^0 \le 1,$$

the structure-factor formula for the mth order satellite $(0 \le m \le 1)$

$$F_0(\mathbf{H}) = (1/2)\sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}) \exp(2\pi i \mathbf{H} \cdot \mathbf{r}_k),$$
$$F_m(\mathbf{H}) = (1/2)\sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}) (p_k^0/2)^{|m|} \exp\left[2\pi i\left(\sum_{i=1}^{3} h_i x_{ik} + m\varphi_k\right)\right].$$

Thus, a linear correspondence exists between the structure-factor magnitudes of the satellite reflections and the amplitude of the density modulation. Furthermore, only first-order satellites exist, since the modulation wave consists only of one term. An important criterion for the existence of a density modulation is that a pair of satellites around the origin of the reciprocal lattice exists (Fig. 4.6.3.3).

Symmetric rectangular density modulation. The box-function-like modulated occupancy factor can be expanded into a Fourier series,

$$p_k = p_k^0(4/\pi)\left\{\sum_{n=1}^{\infty}[(-1)^{n+1}/(2n-1)]\cos[2\pi(2n-1)(\bar{x}_{4,k} + \varphi_k)]\right\}, \quad 0 \le p_k^0 \le 1,$$

and the resulting structure factor of the mth order satellite is

$$F_0(\mathbf{H}) = (1/2)\sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}) \exp\left(2\pi i \sum_{i=1}^{3} h_i x_{ik}\right),$$
$$F_m(\mathbf{H}) = (1/\pi m)\sin(m\pi/2)\sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}) p_k^0 \times \exp\left[2\pi i\left(\sum_{i=1}^{3} h_i x_{ik} + m\varphi_k\right)\right].$$

According to this formula, only odd-order satellites occur in the diffraction pattern. Their structure-factor magnitudes decrease linearly with the order $|m|$ (Fig. 4.6.3.3*b*).

Harmonic displacive modulation. The displacement of the atomic coordinates is given by the function

$$x_{ik} = x_{ik}^0 + A_{ik}\cos[2\pi(\bar{x}_{4,k} + \varphi_k)], \quad i = 1, \ldots, 3,$$

and the structure factor by

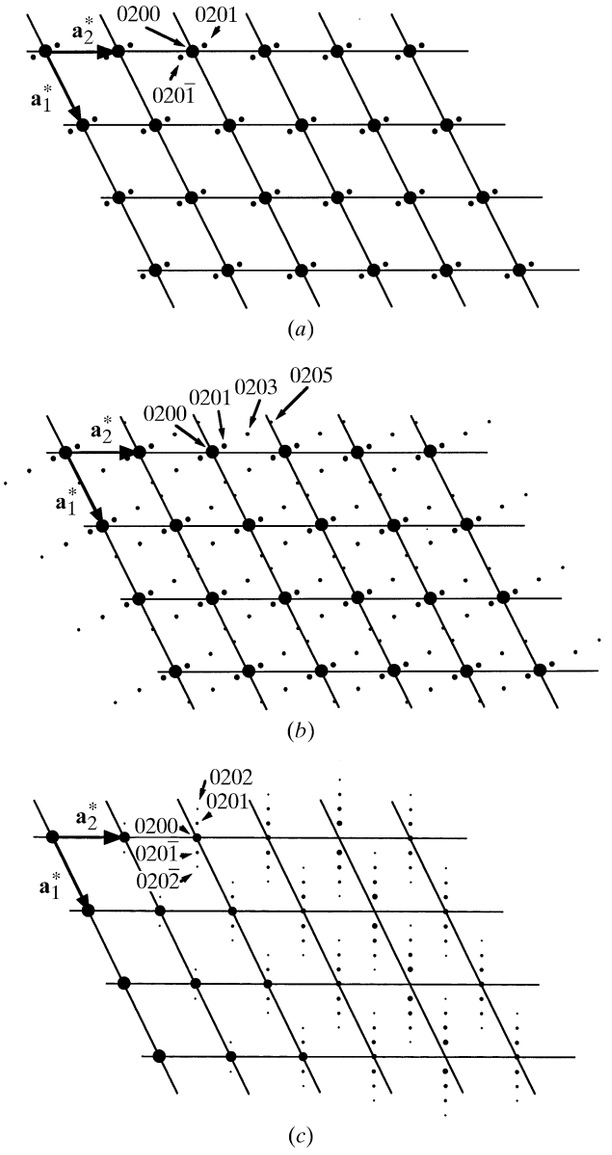

Fig. 4.6.3.3. Schematic diffraction patterns for 3D IMSs with (*a*) 1D harmonic and (*b*) rectangular density modulation. The modulation direction is parallel to $\mathbf{a}_2$. In (*a*) only first-order satellites exist; in (*b*), all odd-order satellites can be present. In (*c*), the diffraction pattern of a harmonic displacive modulation along $\mathbf{a}_1$ with amplitudes parallel to $\mathbf{a}_2^*$ is depicted. Several reflections are indexed. The areas of the circles are proportional to the reflection intensities.

$$F_0(\mathbf{H}) = \sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}) J_0(2\pi \mathbf{H}^{\parallel} \cdot \mathbf{A}_k) \exp\left(2\pi i \sum_{i=1}^{3} h_i x_{ik}\right),$$

$$F_m(\mathbf{H}) = \sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}) J_m(2\pi \mathbf{H}^{\parallel} \cdot \mathbf{A}_k) \times \exp\left[2\pi i \left(\sum_{i=1}^{3} h_i x_{ik} + m\varphi_k\right)\right].$$

The structure-factor magnitudes of the *m*th-order satellite reflections are a function of the *m*th-order Bessel functions. The arguments of the Bessel functions are proportional to the scalar products of the amplitude and the diffraction vector. Consequently, the intensity of the satellites will vary characteristically as a function of the length of the diffraction vector. Each main reflection is accompanied by an infinite number of satellite reflections (Figs. 4.6.3.3*c* and 4.6.3.4).

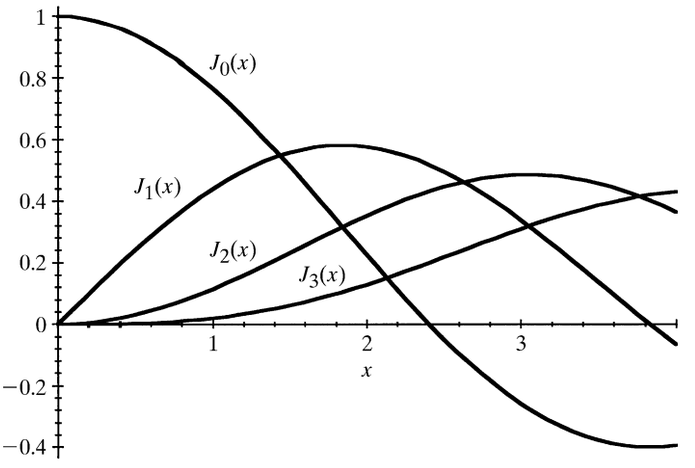

Fig. 4.6.3.4. The relative structure-factor magnitudes of *m*th-order satellite reflections for a harmonic displacive modulation are proportional to the values of the *m*th-order Bessel function $J_m(x)$.

4.6.3.2. Composite structures (CSs)

Composite structures consist of N mutually incommensurate substructures with N basic sublattices $\Lambda_\nu = \{\mathbf{a}_{1\nu}, \mathbf{a}_{2\nu}, \mathbf{a}_{3\nu}\}$, with $\nu = 1, \ldots, N$. The reciprocal sublattices $\Lambda_\nu^* = \{\mathbf{a}_{1\nu}^*, \mathbf{a}_{2\nu}^*, \mathbf{a}_{3\nu}^*\}$, with $\nu = 1, \ldots, N$, have either only the origin of the reciprocal lattice or one or two reciprocal-lattice directions in common. Thus, one needs $(3 + d) < 3N$ reciprocal-basis vectors for integer indexing of diffraction patterns that show Bragg reflections at positions given by the Fourier module M^*. The CSs discovered to date have at least one lattice direction in common and consist of a maximum number of $N = 3$ substructures. They can be divided in three main classes: channel structures, columnar packings and layer packings (see van Smaalen, 1992, 1995).

In the following, the approach of Janner & Janssen (1980*b*) and van Smaalen (1992, 1995, and references therein) for the description of CSs is used. The set of diffraction vectors of a CS, *i.e.* its Fourier module $M^* = \{\sum_{i=1}^{3+d} h_i \mathbf{a}_i^*\}$, can be split into the contributions of the ν subsystems by employing $3 \times (3 + d)$ matrices $Z_{ik\nu}$ with integer coefficients $\mathbf{a}_{i\nu}^* = \sum_{k=1}^{3+d} Z_{ik\nu} \mathbf{a}_k^*$, $i = 1, \ldots, 3$. In the general case, each subsystem will be modulated with the periods of the others due to their mutual interactions. Thus, in general, CSs consist of several intergrown incommensurately modulated substructures. The satellite vectors $\mathbf{q}_{j\nu}$, $j = 1, \ldots, d$, referred to the νth subsystem can be obtained from M^* by applying the $d \times (3 + d)$ integer matrices $V_{jk\nu}$: $\mathbf{q}_{j\nu} = \sum_{k=1}^{3+d} V_{jk\nu} \mathbf{a}_k^*$, $j = 1, \ldots, d$. The matrices consisting of the components σ_ν of the satellite vectors $\mathbf{q}_{j\nu}$ with regard to the reciprocal sublattices Λ_ν^* can be calculated by $\sigma_\nu = (V_{3\nu} + V_{d\nu}\sigma)(Z_{3\nu} + Z_{d\nu}\sigma)^{-1}$, where the subscript 3 refers to the 3×3 submatrix of physical space and the subscript d to the $d \times d$ matrix of the internal space. The juxtaposition of the $3 \times (3 + d)$ matrix Z_ν and the $d \times (3 + d)$ matrix V_ν defines the non-singular $(3 + d) \times (3 + d)$ matrix W_ν,

$$W_\nu = \begin{pmatrix} Z_\nu \\ V_\nu \end{pmatrix}.$$

This matrix allows the reinterpretation of the Fourier module M^* as the Fourier module $M_\nu^* = M^* W_\nu$ of a d-dimensionally modulated subsystem ν. It also describes the coordinate transformation between the superspace basis Σ and Σ_ν.

The superspace description is obtained analogously to that for IMSs (see Section 4.6.3.1) by considering the 3D Fourier module M^* of rank $3 + d$ as the projection of a $(3 + d)$D reciprocal lattice Σ^* upon the physical space. Thus, one obtains for the definition

of the direct and reciprocal $(3+d)$ lattices (Janner & Janssen, 1980*b*)

$$\Sigma^*: \begin{cases} \mathbf{a}_i^* & = (\mathbf{a}_i^*, \mathbf{0}) & i = 1, \ldots, 3 \\ \mathbf{a}_{3+j}^* & = (\mathbf{a}_{3+j}^*, \mathbf{e}_j^*) & j = 1, \ldots, d \end{cases}$$

$$\Sigma: \begin{cases} \mathbf{a}_i & = (\mathbf{a}_i, -\sum_{j=1}^{d} \sigma_{ji} \mathbf{e}_j) & i = 1, \ldots, 3 \\ \mathbf{a}_{3+j} & = (\mathbf{0}, \mathbf{e}_j) & j = 1, \ldots, d. \end{cases}$$

4.6.3.2.1. Indexing

The indexing of diffraction patterns of composite structures can be performed in the following way:

(1) find the minimum number of reciprocal lattices Λ_ν^* necessary to index the diffraction pattern;

(2) find a basis for M^*, the union of sublattices Λ_ν^*;

(3) find the appropriate superspace embedding.

The $(3+d)$ vectors $\mathbf{a}_i^*$ forming a basis for the 3D Fourier module $M^* = \{\sum_{i=1}^{3+d} h_i \mathbf{a}_i^*\}$ can be chosen such that $\mathbf{a}_1^*$, $\mathbf{a}_2^*$ and $\mathbf{a}_3^*$ are linearly independent. Then the remaining d vectors can be described as a linear combination of the first three, defining the $d \times 3$ matrix σ: $\mathbf{a}_{3+j}^* = \sum_{i=1}^{3+d} \sigma_{ji} \mathbf{a}_i^*$, $j = 1, \ldots, d$. This is formally equivalent to the reciprocal basis obtained for an IMS (see Section 4.6.3.1) and one can proceed in an analogous way to that for IMSs.

4.6.3.2.2. Diffraction symmetry

The symmetry of CSs can be described with basically the same formalism as used for IMSs. This is a consequence of the formally equivalent applicability of the higher-dimensional approach, in particular of the superspace-group theory developed for IMSs [see Janner & Janssen (1980*a*,*b*); van Smaalen (1991, 1992); Yamamoto (1992*a*)].

4.6.3.2.3. Structure factor

The structure factor $F(\mathbf{H})$ of a composite structure consists of the weighted contributions of the subsystem structure factors $F_\nu(\mathbf{H}_\nu)$:

$$F(\mathbf{H}) = \sum_\nu |J_\nu| F_\nu(\mathbf{H}_\nu);$$

$$F_\nu(\mathbf{H}) = \sum_{(R^\nu, \mathbf{t}^\nu)}^{\infty} \sum_{k=1}^{N'} \int_0^1 \mathrm{d}\bar{x}_{4,k}^\nu \ldots \int_0^1 \mathrm{d}\bar{x}_{3+d,k}^\nu f_k^\nu(\mathbf{H}^\parallel) p_k^\nu \times \exp\left(- \sum_{i,j=1}^{3+d} h_i^\nu [R^\nu B_{ijk}^\nu R^{\nu T}] h_j^\nu + 2\pi i \sum_{j=1}^{3+d} h_j^\nu R^\nu x_{jk}^\nu + h_j^\nu t_j^\nu \right),$$

with coefficients similar to those for IMSs.

The weights are the Jacobians of the transformations from $\mathbf{t}_\nu$ to $\mathbf{t}$, and $\mathbf{H}_\nu$ are the reflection indices with respect to the subsystem Fourier modules M_ν^* (van Smaalen, 1995, and references therein). The relative values of $|J_\nu|$, where $J_\nu = \det\left[(V_{d\nu} - \sigma_\nu \cdot Z_{d\nu})^{-1}\right]$, are related to the volume ratios of the contributing subsystems. The subsystem structure factors correspond to those for IMSs (see Section 4.6.3.1). Besides this formula, based on the publications of Yamamoto (1982) and van Smaalen (1995), different structure-factor equations have been discussed (Kato, 1990; Petricek, Maly, Coppens *et al.*, 1991).

4.6.3.3. Quasiperiodic structures (QSs)

4.6.3.3.1. 3D structures with 1D quasiperiodic order

Structures with quasiperiodic order in one dimension and lattice symmetry in the other two dimensions are the simplest representatives of quasicrystals. A few phases of this structure type have been identified experimentally (see Steurer, 1990). Since the Fibonacci chain represents the most important model of a 1D quasiperiodic structure, it will be used in this section to represent the quasiperiodic direction of 3D structures with 1D quasiperiodic order. As discussed in Section 4.6.2.4, 1D quasiperiodic structures are on the borderline between quasiperiodic and incommensurately modulated structures. They can be described using either of the two approaches. In the following, the quasiperiodic description will be preferred to take account of the scaling symmetry.

The electron-density-distribution function $\rho(\mathbf{r})$ of a 1D quasiperiodically ordered 3D crystal can be represented by a Fourier series:

$$\rho(\mathbf{r}) = (1/V) \sum_{\mathbf{H}} F(\mathbf{H}) \exp(-2\pi i \mathbf{H} \cdot \mathbf{r}).$$

The Fourier coefficients (*structure factors*) $F(\mathbf{H})$ differ from zero only for reciprocal-space vectors $\mathbf{H} = \sum_{i=1}^{3} h_i^\parallel \mathbf{a}_i^*$ with ${h_1}^\parallel \in \mathbb{R}$, ${h_2}^\parallel, {h_3}^\parallel \in \mathbb{Z}$ or with integer indexing $\mathbf{H} = \sum_{i=1}^{4} h_i \mathbf{a}_i^*$ with $h_i \in \mathbb{Z}$. The set of all vectors $\mathbf{H}$ forms a Fourier module $M^* = \{\mathbf{H}^\parallel = \sum_{i=1}^{4} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ of rank 4 which can be decomposed into two rank 2 submodules $M^* = M_1^* \oplus M_2^*$. $M_1^* = \{h_1 \mathbf{a}_1^* + h_2 \mathbf{a}_2^*\}$ corresponds to a $\mathbb{Z}$ module of rank 2 in a 1D subspace, $M_2^* = \{h_3 \mathbf{a}_3^* + h_4 \mathbf{a}_4^*\}$ corresponds to a $\mathbb{Z}$ module of rank 2 in a 2D subspace. Consequently, the first submodule can be considered as a projection from a 2D reciprocal lattice, $M_1^* = \pi^\parallel(\Sigma^*)$, while the second submodule is of the form of a reciprocal lattice, $M_2^* = \Lambda^*$.

Hence, the reciprocal-basis vectors $\mathbf{a}_i^*$, $i = 1, \ldots, 4$, can be considered to be projections of reciprocal-basis vectors $\mathbf{d}_i^*$, $i = 1, \ldots, 4$, spanning a 4D reciprocal lattice, onto the physical space $\Sigma^* = \{\mathbf{H} = \sum_{i=1}^{4} h_i \mathbf{d}_i^* | h_i \in \mathbb{Z}\}$, with

$$\mathbf{d}_1^* = a_1^* \begin{pmatrix} 1 \\ -\tau \\ 0 \\ 0 \end{pmatrix}, \quad \mathbf{d}_2^* = a_1^* \begin{pmatrix} \tau \\ 1 \\ 0 \\ 0 \end{pmatrix}, \quad \mathbf{d}_3^* = a_3^* \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}, \quad \mathbf{d}_4^* = a_4^* \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}.$$

A direct lattice Σ with basis $\mathbf{d}_i$, $i = 1, \ldots, 4$ and $\mathbf{d}_i \cdot \mathbf{d}_j^* = \delta_{ij}$, can be constructed according to (compare Fig. 4.6.2.8) $\Sigma = \{\mathbf{r} = \sum_{i=1}^{4} m_i \mathbf{d}_i | m_i \in \mathbb{Z}\}$, with

$$\mathbf{d}_1 = \frac{1}{a_1^*(2+\tau)} \begin{pmatrix} 1 \\ -\tau \\ 0 \\ 0 \end{pmatrix}, \mathbf{d}_2 = \frac{1}{a_1^*(2+\tau)} \begin{pmatrix} \tau \\ 1 \\ 0 \\ 0 \end{pmatrix},$$

$$\mathbf{d}_3^* = \frac{1}{a_3^*} \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}, \quad \mathbf{d}_4^* = \frac{1}{a_4^*} \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}.$$

Consequently, the structure in physical space $\mathbf{V}^\parallel$ is equivalent to a 3D section of the 4D hypercrystal.

4.6.3.3.1.1. Indexing

The reciprocal space of the Fibonacci chain is densely filled with Bragg reflections (Figs. 4.6.2.9 and 4.6.3.5). According to the nD embedding method, the shorter the parallel-space distance $\Delta\mathbf{H}^\parallel = \mathbf{H}_2^\parallel - \mathbf{H}_1^\parallel$ between two Bragg reflections, the larger the corresponding perpendicular-space distance $\Delta\mathbf{H}^\perp = \mathbf{H}_2^\perp - \mathbf{H}_1^\perp$ becomes. Since the structure factor $F(\mathbf{H})$ decreases rapidly as a

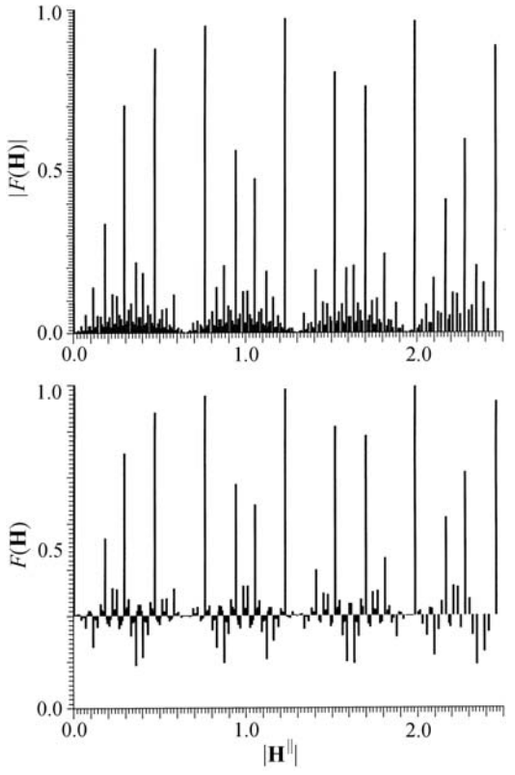

Fig. 4.6.3.5. The structure factors $F(\mathbf{H})$ (below) and their magnitudes $|F(\mathbf{H})|$ (above) of a Fibonacci chain decorated with equal point atoms are shown as a function of the parallel-space component $|\mathbf{H}^{\parallel}|$ of the diffraction vector. The short distance in the Fibonacci chain is S = 2.5 Å, all structure factors within $0 \leq |\mathbf{H}| \leq 2.5$ Å^{-1} have been calculated and normalized to $F(00) = 1$.

function of $\mathbf{H}^{\perp}$ (Fig. 4.6.3.6), 'neighbouring' reflections of strong Bragg peaks are extremely weak and, consequently, the reciprocal space appears to be filled with *discrete* Bragg peaks even for low-resolution experiments.

This property allows an unambiguous identification of a correct set of reciprocal-basis vectors. However, infinitely many sets allowing a correct indexing of the diffraction pattern with integer indices exist. Nevertheless, an optimum basis (low indices are assigned to strong reflections) can be derived: the intensity distribution, not the metrics, characterizes the best choice of indexing. Once the minimum distance S in the structure is identified from chemical considerations, the reciprocal basis should be chosen as described in Section 4.6.2.4. It has to be kept in mind, however, that the identification of the metrics is not sufficient to distinguish in the 1D aperiodic case between an incommensurately modulated structure, a quasiperiodic structure or special kinds of structures with fractally shaped atomic surfaces.

A correct set of reciprocal-basis vectors can be identified in the following way:

(1) Find pairs of strong reflections whose physical-space diffraction vectors are related to each other by the factor τ.

(2) Index these reflections by assigning an appropriate value to a^*. This value should be derived from the shortest interatomic distance S expected in the structure.

(3) The reciprocal basis is correct if all observable Bragg reflections can be indexed with integer numbers.

4.6.3.3.1.2. Diffraction symmetry

The possible Laue symmetry group K^{3D} of the Fourier module $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{4} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ is any one of the direct product $K^{3D} = K^{2D} \otimes K^{1D} \otimes \bar{1}$. K^{2D} corresponds to one of the ten crystallographic 2D point groups, $K^{1D} = \{1\}$ in the general case of a quasiperiodic stacking of periodic layers. Consequently, the nine Laue groups $\bar{1}$, $2/m$, mmm, $4/m$, $4/mmm$, $\bar{3}$, $\bar{3}m$, $6/m$ and $6/mmm$ are possible. These are all 3D crystallographic Laue groups except for the two cubic ones.

The (unweighted) Fourier module shows only 2D lattice symmetry. In the third dimension, the submodule M_1^* remains invariant under the scaling symmetry operation $S^n M_1^* = \tau^n M_1^*$ with $n \in \mathbb{Z}$. The scaling symmetry operators S^n form an infinite group $s = \{\ldots, S^{-1}, S^0, S^1, \ldots\}$ of reciprocal-basis transformations S^n in superspace,

$$S^n = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}_D^n, \quad S^{-1} = \begin{pmatrix} \bar{1} & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}_D,$$

$$S^0 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}_D,$$

and act on the reciprocal basis $\mathbf{d}_i^*$ in superspace.

4.6.3.3.1.3. Structure factor

The structure factor of a periodic structure is defined as the Fourier transform of the density distribution $\rho(\mathbf{r})$ of its unit cell (UC):

$$F(\mathbf{H}) = \int_{\mathrm{UC}} \rho(\mathbf{r}) \exp(2\pi i \mathbf{H} \cdot \mathbf{r}) \, \mathrm{d}\mathbf{r}.$$

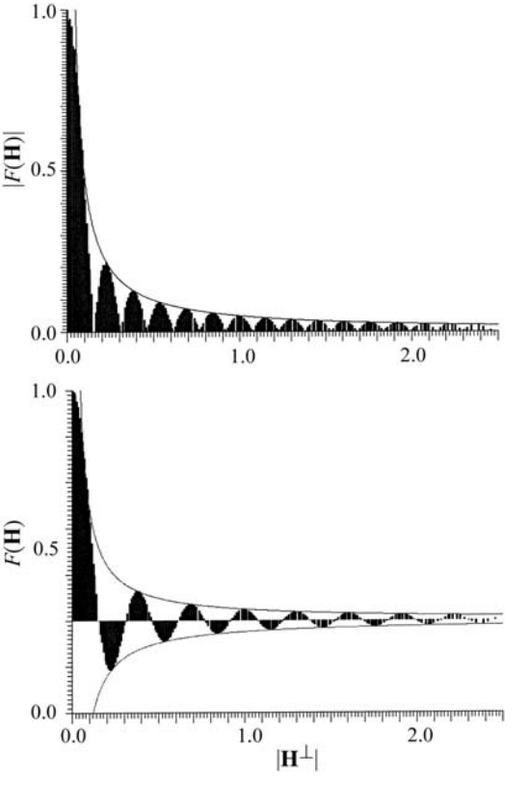

Fig. 4.6.3.6. The structure factors $F(\mathbf{H})$ (below) and their magnitudes $|F(\mathbf{H})|$ (above) of a Fibonacci chain decorated with equal point atoms are shown as a function of the perpendicular-space component $|\mathbf{H}^{\perp}|$ of the diffraction vector. The short distance in the Fibonacci chain is S = 2.5 Å, all structure factors within $0 \leq |\mathbf{H}| \leq 2.5$ Å^{-1} have been calculated and normalized to $F(00) = 1$.

The same is valid in the case of the nD description of a quasiperiodic structure. The parallel- and perpendicular-space components are orthogonal to each other and can be separated. In the case of the 1D Fibonacci sequence, the Fourier transform of the parallel-space component of the electron-density distribution of a single atom gives the usual atomic scattering factor $f(\mathbf{H}^{\parallel})$. Parallel to $x^{\perp}$, $\rho(\mathbf{r})$ adopts values $\neq 0$ only within the interval $-(1+\tau)/[2a^*(2+\tau)] \leq x^{\perp} \leq (1+\tau)/[2a^*(2+\tau)]$ and one obtains

$$F(\mathbf{H}) = f(\mathbf{H}^{\parallel})[a^*(2+\tau)]/(1+\tau) \times \int_{-(1+\tau)/[2a^*(2+\tau)]}^{+(1+\tau)/[2a^*(2+\tau)]} \exp(2\pi i \mathbf{H}^{\perp} \cdot x^{\perp})\, \mathrm{d}x^{\perp}.$$

The factor $[a^*(2+\tau)]/(1+\tau)$ results from the normalization of the structure factors to $F(\mathbf{0}) = f(0)$. With

$$\mathbf{H} = h_1\mathbf{d}_1^* + h_2\mathbf{d}_2^* + h_3\mathbf{d}_3^* + h_4\mathbf{d}_4^* = h_1a_1^*\begin{pmatrix}1\\-\tau\\0\\0\end{pmatrix} + h_2a_1^*\begin{pmatrix}\tau\\1\\0\\0\end{pmatrix} + h_3a_3^*\begin{pmatrix}0\\0\\1\\0\end{pmatrix} + h_4a_4^*\begin{pmatrix}0\\0\\0\\1\end{pmatrix}$$

and $\mathbf{H}^{\perp} = a_1^*(-\tau h_1 + h_2)$ the integrand can be rewritten as

$$F(\mathbf{H}) = f(\mathbf{H}^{\parallel})[a^*(2+\tau)]/(1+\tau) \times \int_{-(1+\tau)/[2a^*(2+\tau)]}^{+(1+\tau)/[2a^*(2+\tau)]} \exp[2\pi i(-\tau h_1 + h_2)x^{\perp}]\, \mathrm{d}x^{\perp},$$

yielding

$$F(\mathbf{H}) = f(\mathbf{H}^{\parallel})(2+\tau)/[2\pi i(-\tau h_1 + h_2)(1+\tau)] \times \exp[2\pi i(-\tau h_1 + h_2)x^{\perp}]\Big|_{-(1+\tau)/[2a^*(2+\tau)]}^{+(1+\tau)/[2a^*(2+\tau)]}.$$

Using $\sin x = (\mathrm{e}^{ix} - \mathrm{e}^{-ix})/2i$ gives

$$F(\mathbf{H}) = f(\mathbf{H}^{\parallel})(2+\tau)/[\pi(-\tau h_1 + h_2)(1+\tau)] \times \sin[\pi(1+\tau)(-\tau h_1 + h_2)]/(2+\tau).$$

Thus, the structure factor has the form of the function $\sin(x)/x$ with x a perpendicular reciprocal-space coordinate. The upper and lower limiting curves of this function are given by the hyperbolae $\pm 1/x$ (Fig. 4.6.3.6). The continuous shape of $F(\mathbf{H})$ as a function of $\mathbf{H}^{\perp}$ allows the estimation of an overall temperature factor and atomic scattering factor for reflection-data normalization (compare Figs. 4.6.3.6 and 4.6.3.7).

In the case of a 3D crystal structure which is quasiperiodic in one direction, the structure factor can be written in the form

$$F(\mathbf{H}) = \sum_{k=1}^{n}\big[T_k(\mathbf{H})f_k(\mathbf{H}^{\parallel})g_k(\mathbf{H}^{\perp})\exp(2\pi i\mathbf{H}\cdot\mathbf{r}_k)\big].$$

The sum runs over all n averaged hyperatoms in the 4D unit cell of the structure. The *geometric form factor* $g_k(\mathbf{H}^{\perp})$ corresponds to the Fourier transform of the kth atomic surface,

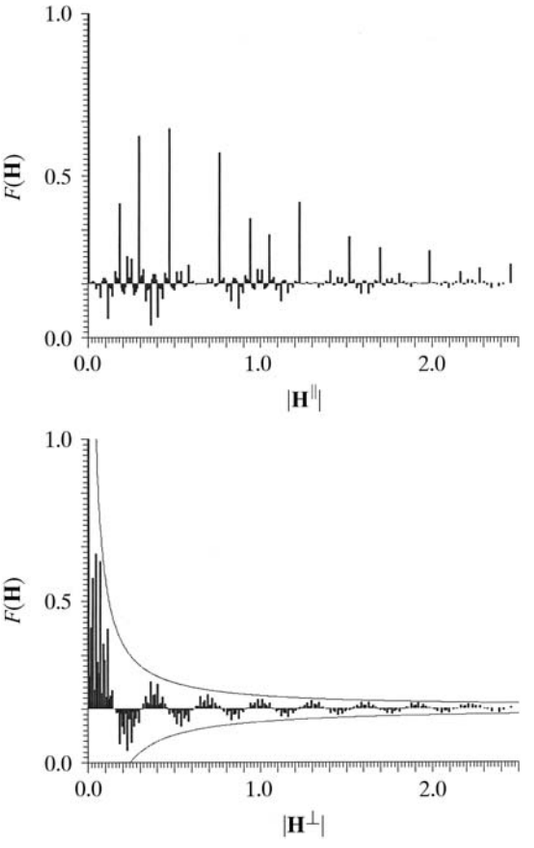

Fig. 4.6.3.7. The structure factors $F(\mathbf{H})$ of the Fibonacci chain decorated with aluminium atoms (U_{overall} = 0.005 Å^2) as a function of the parallel (above) and the perpendicular (below) component of the diffraction vector. The short distance is S = 2.5 Å, all structure factors within $0 \leq |\mathbf{H}| \leq 2.5$ Å^{-1} have been calculated and normalized to $F(00) = 1$.

$$g_k(\mathbf{H}^{\perp}) = (1/A_{\mathrm{UC}}^{\perp})\int_{A_k}\exp(2\pi i\mathbf{H}^{\perp}\cdot\mathbf{r}^{\perp})\ \mathrm{d}\mathbf{r}^{\perp},$$

normalized to $A_{\mathrm{UC}}^{\perp}$, the area of the 2D unit cell projected upon $\mathbf{V}^{\perp}$, and A_k, the area of the kth atomic surface.

The atomic temperature factor $T_k(\mathbf{H})$ can also have perpendicular-space components. Assuming only harmonic (static or dynamic) displacements in parallel and perpendicular space one obtains, in analogy to the usual expression (Willis & Pryor, 1975),

$$T_k(\mathbf{H}) = T_k(\mathbf{H}^{\parallel}, \mathbf{H}^{\perp}) = \exp(-2\pi^2\mathbf{H}^{\parallel T}\langle\mathbf{u}_i^{\parallel}\mathbf{u}_j^{\parallel T}\rangle\mathbf{H}^{\parallel})\exp(-2\pi^2\mathbf{H}^{\perp T}\langle\mathbf{u}_i^{\perp}\mathbf{u}_j^{\perp T}\rangle\mathbf{H}^{\perp}),$$

with

$$\langle\mathbf{u}_i^{\parallel}\mathbf{u}_j^{\parallel T}\rangle = \begin{pmatrix}\langle\mathbf{u}_1^{\parallel 2}\rangle & \langle\mathbf{u}_1^{\parallel}\cdot\mathbf{u}_2^{\parallel T}\rangle & \langle\mathbf{u}_1^{\parallel}\cdot\mathbf{u}_3^{\parallel T}\rangle\\ \langle\mathbf{u}_2^{\parallel}\cdot\mathbf{u}_1^{\parallel T}\rangle & \langle\mathbf{u}_2^{\parallel 2}\rangle & \langle\mathbf{u}_2^{\parallel}\cdot\mathbf{u}_3^{\parallel T}\rangle\\ \langle\mathbf{u}_3^{\parallel}\cdot\mathbf{u}_1^{\parallel T}\rangle & \langle\mathbf{u}_3^{\parallel}\cdot\mathbf{u}_2^{\parallel T}\rangle & \langle\mathbf{u}_3^{\parallel 2}\rangle\end{pmatrix}$$

and $\langle\mathbf{u}_i^{\perp}\mathbf{u}_j^{\perp T}\rangle = \langle\mathbf{u}_4^{\perp}\rangle$.

The elements of the type $\langle\mathbf{u}_i\cdot\mathbf{u}_j^T\rangle$ represent the average values of the atomic displacements along the ith axis times the displacement along the jth axis on the V basis.

4.6.3.3.1.4. Intensity statistics

In the following, only the properties of the quasiperiodic component of the 3D structure, namely the Fourier module M_1^*,

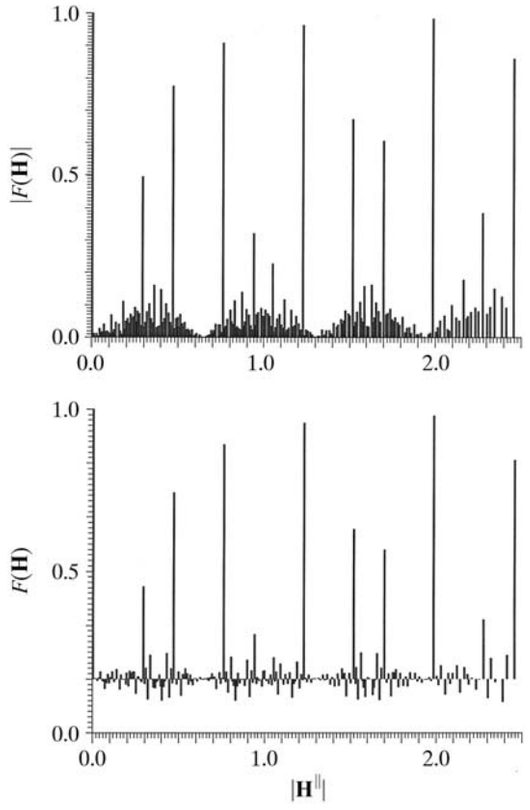

Fig. 4.6.3.8. The structure factors $F(\mathbf{H})$ (below) and their magnitudes $|F(\mathbf{H})|$ (above) of the squared Fibonacci chain decorated with equal point atoms are shown as a function of the parallel-space component $|\mathbf{H}^{\parallel}|$ of the diffraction vector. The short distance is S = 2.5 Å, all structure factors within $0 \leq |\mathbf{H}| \leq 2.5$ Å^{-1} have been calculated and normalized to $F(00) = 1$.

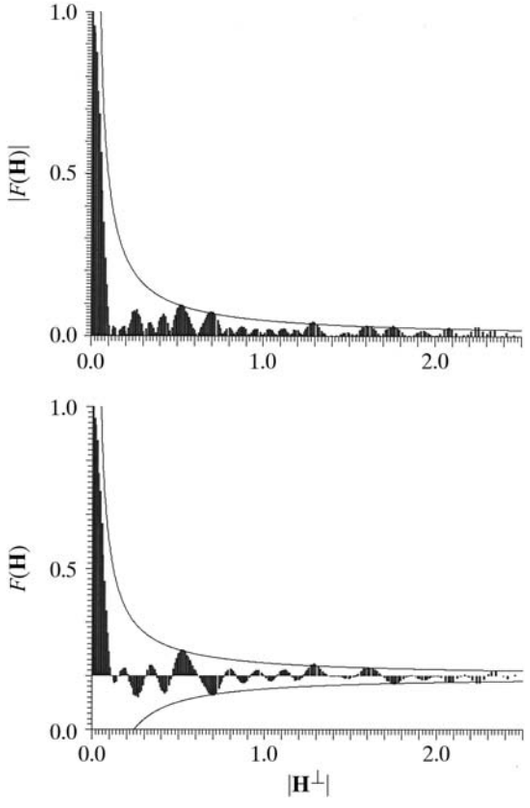

Fig. 4.6.3.9. The structure factors $F(\mathbf{H})$ (below) and their magnitudes $|F(\mathbf{H})|$ (above) of the squared Fibonacci chain decorated with equal point atoms are shown as a function of the perpendicular-space component $|\mathbf{H}^{\perp}|$ of the diffraction vector. The short distance is S = 2.5 Å, all structure factors within $0 \leq |\mathbf{H}| \leq 2.5$ Å^{-1} have been calculated and normalized to $F(00) = 1$.

are discussed. The intensities $I(\mathbf{H})$ of the Fibonacci chain decorated with point atoms are only a function of the perpendicular-space component of the diffraction vector. $|F(\mathbf{H})|$ and $F(\mathbf{H})$ are illustrated in Figs. 4.6.3.5 and 4.6.3.6 as a function of $\mathbf{H}^{\parallel}$ and of $\mathbf{H}^{\perp}$. The distribution of $|F(\mathbf{H})|$ as a function of their frequencies clearly resembles a centric distribution, as can be expected from the centrosymmetric 2D subunit cell. The shape of the distribution function depends on the radius $H_{\max}$ of the limiting sphere in reciprocal space. The number of weak reflections increases with the square of $H_{\max}$, that of strong reflections only linearly (strong reflections always have small $\mathbf{H}^{\perp}$ components).

The weighted reciprocal space of the Fibonacci sequence contains an infinite number of Bragg reflections within a limited region of the physical space. Contrary to the diffraction pattern of a periodic structure consisting of point atoms on the lattice nodes, the Bragg reflections show intensities depending on the perpendicular-space components of their diffraction vectors.

The reciprocal space of a sequence generated from hyperatoms with fractally shaped atomic surfaces (squared Fibonacci sequence) is very similar to that of the Fibonacci sequence (Figs. 4.6.3.8 and 4.6.3.9). However, there are significantly more weak reflections in the diffraction pattern of the 'fractal' sequence, caused by the geometric form factor.

4.6.3.3.1.5. Relationships between structure factors at symmetry-related points of the Fourier image

The two possible point-symmetry groups in the 1D quasiperiodic case, $K^{1D} = 1$ and $K^{1D} = \bar{1}$, relate the structure factors to

$$1: \qquad F(\mathbf{H}) = -F(\bar{\mathbf{H}}),$$
$$\bar{1}: \qquad F(\mathbf{H}) = F(\bar{\mathbf{H}}).$$

A 3D structure with 1D quasiperiodicity results from the stacking of atomic layers with distances following a quasiperiodic sequence. The point groups K^{3D} describing the symmetry of such structures result from the direct product $K^{3D} = K^{2D} \otimes K^{1D}$. K^{2D} corresponds to one of the ten crystallographic 2D point groups, K^{1D} can be $\{1\}$ or $\{1, m\}$. Consequently, 18 3D point groups are possible.

Since 1D quasiperiodic sequences can be described generically as incommensurately modulated structures, their possible point and space groups are equivalent to a subset of the (3 + 1)D superspace groups for IMSs with satellite vectors of the type (00γ), *i.e.* $\mathbf{q} = \gamma\mathbf{c}^*$, for the quasiperiodic direction [001] (Janssen *et al.*, 2004).

From the scaling properties of the Fibonacci sequence, some relationships between structure factors can be derived. Scaling the physical-space structure by a factor τ^n, $n \in \mathbb{Z}$, corresponds to a scaling of the perpendicular space by the inverse factor $(-\tau)^{-n}$. For the scaling of the corresponding reciprocal subspaces, the inverse factors compared to the direct spaces have to be applied.

The set of vectors $\mathbf{r}$, defining the vertices of a Fibonacci sequence $s(\mathbf{r})$, multiplied by a factor τ coincides with a subset of the vectors defining the vertices of the original sequence (Fig. 4.6.3.10). The residual vertices correspond to a particular decoration of the scaled sequence, *i.e.* the sequence $\tau^2 s(\mathbf{r})$. The Fourier transform of the sequence $s(\mathbf{r})$ then can be written as the sum of the Fourier transforms of the sequences $\tau s(\mathbf{r})$ and $\tau^2 s(\mathbf{r})$;

$$\sum_k \exp(2\pi i \mathbf{H} \cdot \mathbf{r}_k) = \sum_k \exp(2\pi i \mathbf{H} \tau \mathbf{r}_k) + \sum_k \exp[2\pi i \mathbf{H}(\tau^2 \mathbf{r}_k + \tau)].$$

In terms of structure factors, this can be reformulated as

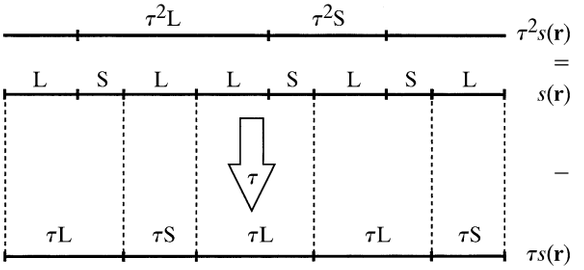

Fig. 4.6.3.10. Part ... LSLLSLSL ... of a Fibonacci sequence $s(\mathbf{r})$ before and after scaling by the factor τ. L is mapped onto τL, S onto τS = L. The vertices of the new sequence are a subset of those of the original sequence (the correspondence is indicated by dashed lines). The residual vertices $\tau^2 s(\mathbf{r})$, which give when decorating $\tau s(\mathbf{r})$ the Fibonacci sequence $s(\mathbf{r})$, form a Fibonacci sequence scaled by a factor τ^2.

$$F(\mathbf{H}) = F(\tau\mathbf{H}) + \exp(2\pi i\tau\mathbf{H})F(\tau^2\mathbf{H}).$$

Hence, phases of structure factors that are related by scaling symmetry can be determined from each other.

Further scaling relationships in reciprocal space exist: scaling a diffraction vector

$$\mathbf{H} = h_1\mathbf{d}_1^* + h_2\mathbf{d}_2^* = h_1 a^* \begin{pmatrix} 1 \\ -\tau \end{pmatrix}_V + h_2 a^* \begin{pmatrix} \tau \\ 1 \end{pmatrix}_V$$

with the matrix

$$S = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}_D,$$

$$\begin{aligned} \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}_D \begin{pmatrix} h_1 \\ h_2 \end{pmatrix}_D &= \begin{pmatrix} F_n & F_{n+1} \\ F_{n+1} & F_{n+2} \end{pmatrix}_D \begin{pmatrix} h_1 \\ h_2 \end{pmatrix}_D \\ &= \begin{pmatrix} F_n h_1 + F_{n+1} h_2 \\ F_{n+1} h_1 + F_{n+2} h_2 \end{pmatrix}_D, \end{aligned}$$

increases the magnitudes of structure factors assigned to this particular diffraction vector $\mathbf{H}$,

$$\left|F(S^n\mathbf{H})\right| > \left|F(S^{n-1}\mathbf{H})\right| > \ldots > \left|F(S\mathbf{H})\right| > \left|F(\mathbf{H})\right|.$$

This is due to the shrinking of the perpendicular-space component of the diffraction vector by powers of $(-\tau)^{-n}$ while expanding the parallel-space component by τ^n according to the eigenvalues τ and $-\tau^{-1}$ of S acting in the two eigenspaces $\mathbf{V}^{\parallel}$ and $\mathbf{V}^{\perp}$:

$$\begin{aligned} \pi^{\parallel}(S\mathbf{H}) &= (h_2 + \tau(h_1 + h_2))a^* = (\tau h_1 + h_2(\tau + 1))a^* \\ &= \tau(h_1 + \tau h_2)a^*, \\ \pi^{\perp}(S\mathbf{H}) &= (-\tau h_2 + h_1 + h_2)a^* = (h_1 - h_2(\tau - 1))a^* \\ &= -(1/\tau)(-\tau h_1 + h_2)a^*, \\ \left|F(\tau^n\mathbf{H}^{\parallel})\right| &> \left|F(\tau^{n-1}\mathbf{H}^{\parallel})\right| > \ldots > \left|F(\tau\mathbf{H}^{\parallel})\right| > \left|F(\mathbf{H}^{\parallel})\right|. \end{aligned}$$

Thus, for scaling n times we obtain

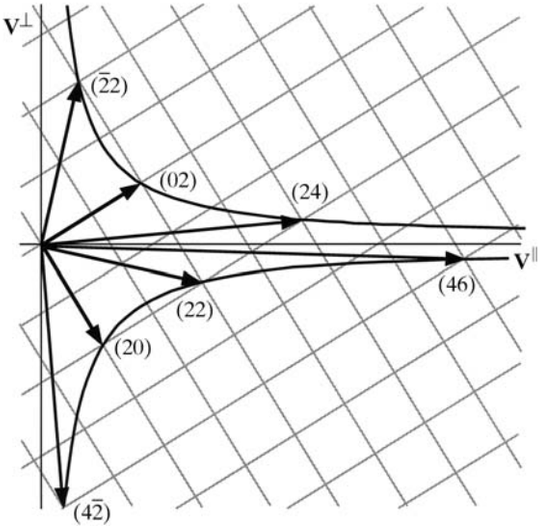

Fig. 4.6.3.11. Scaling operations of the Fibonacci sequence. The scaling operation S acts six times on the diffraction vector $\mathbf{H} = (4\bar{2})$ yielding the sequence $(4\bar{2}) \rightarrow (\bar{2}2) \rightarrow (20) \rightarrow (02) \rightarrow (22) \rightarrow (24) \rightarrow (46)$.

$$\begin{aligned} \pi^{\perp}(S^n\mathbf{H}) &= \left(-\tau\left(F_n h_1 + F_{n+1} h_2\right) + \left(F_{n+1} h_1 + F_{n+2} h_2\right)\right)a^* \\ &= \left(h_1\left(-\tau F_n + F_{n+1}\right) + h_2\left(-\tau F_{n+1} + F_{n+2}\right)\right)a^* \end{aligned}$$

with

$$\lim_{n\to\infty}\left(-\tau F_n + F_{n+1}\right) = 0 \text{ and } \lim_{n\to\infty}\left(-\tau F_{n+1} + F_{n+2}\right) = 0,$$

yielding eventually

$$\lim_{n\to\infty}\left(\pi^{\perp}(S^n\mathbf{H})\right) = 0 \text{ and } \lim_{n\to\infty}\left(F(S^n\mathbf{H})\right) = F(\mathbf{0}).$$

The scaling of the diffraction vectors $\mathbf{H}$ by S^n corresponds to a hyperbolic rotation (Janner, 1992) with angle $n\varphi$, where $\sinh\varphi = 1/2$ (Fig. 4.6.3.11):

$$\begin{aligned} \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}^{2n} &= \begin{pmatrix} \cosh 2n\varphi & \sinh 2n\varphi \\ \sinh 2n\varphi & \cosh 2n\varphi \end{pmatrix}, \\ \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}^{2n+1} &= \begin{pmatrix} \sinh[(2n+1)\varphi] & \cosh[(2n+1)\varphi] \\ \cosh[(2n+1)\varphi] & \sinh[(2n+1)\varphi] \end{pmatrix}. \end{aligned}$$

4.6.3.3.2. Decagonal phases

A structure quasiperiodic in two dimensions, periodic in the third dimension and with decagonal diffraction symmetry is called a decagonal phase. Its holohedral Laue symmetry group is $K = 10/mmm$. All reciprocal-space vectors $\mathbf{H} \in M^*$ can be represented on a basis (V basis) $\mathbf{a}_i^* = a_i^*(\cos 2\pi i/5, \sin 2\pi i/5, 0)$, $i = 1, \ldots, 4$ and $\mathbf{a}_5^* = a_5^*(0, 0, 1)$ (Fig. 4.6.3.12) as $\mathbf{H} = \sum_{i=1}^{5} h_i\mathbf{a}_i^*$. The vector components refer to a Cartesian coordinate system in physical (parallel) space. Thus, from the number of independent reciprocal-basis vectors necessary to index the Bragg reflections with integer numbers, the dimension of the embedding space has to be at least five. This can also be shown in a different way (Hermann, 1949).

The set M^* of all vectors $\mathbf{H}$ remains invariant under the action of the symmetry operators of the point group $10/mmm$. The symmetry-adapted matrix representations for the point-group

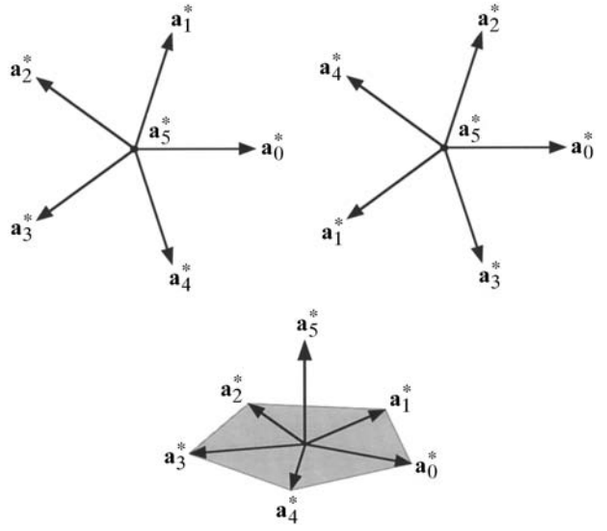

Fig. 4.6.3.12. Reciprocal basis of the decagonal phase in the 5D description projected upon $\mathbf{V}^{\parallel}$ (above left) and $\mathbf{V}^{\perp}$ (above right). Below, a perspective physical-space view is shown.

generators, the tenfold rotation $\alpha = 10$, the reflection plane $\beta = m_2$ (normal of the reflection plane along the vectors $\mathbf{a}_i^*$–$\mathbf{a}_{i+3}^*$ with $i = 1, \ldots, 4$ modulo 5) and the inversion operation $\Gamma(\gamma) = \bar{1}$ may be written in the form

$$\Gamma(\alpha) = \begin{pmatrix} 0 & 1 & \bar{1} & 0 & 0 \\ 0 & 1 & 0 & \bar{1} & 0 \\ 0 & 1 & 0 & 0 & 0 \\ \bar{1} & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}_D \quad \Gamma(\beta) = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}_D$$

$$\Gamma(\gamma) = \begin{pmatrix} \bar{1} & 0 & 0 & 0 & 0 \\ 0 & \bar{1} & 0 & 0 & 0 \\ 0 & 0 & \bar{1} & 0 & 0 \\ 0 & 0 & 0 & \bar{1} & 0 \\ 0 & 0 & 0 & 0 & \bar{1} \end{pmatrix}_D .$$

By block-diagonalization, these reducible symmetry matrices can be decomposed into non-equivalent irreducible representations. These can be assigned to the two orthogonal subspaces forming the 5D embedding space $\mathbf{V} = \mathbf{V}^{\parallel} \oplus \mathbf{V}^{\perp}$, the 3D parallel (physical) subspace $\mathbf{V}^{\parallel}$ and the perpendicular 2D subspace $\mathbf{V}^{\perp}$. Thus, using $W\Gamma W^{-1} = \Gamma_V = \Gamma_V^{\parallel} \oplus \Gamma_V^{\perp}$, we obtain

$$\Gamma_V(\alpha) = \left(\begin{array}{ccc|cc} \cos(\pi/5) & -\sin(\pi/5) & 0 & 0 & 0 \\ \sin(\pi/5) & \cos(\pi/5) & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 0 & \cos(3\pi/5) & -\sin(3\pi/5) \\ 0 & 0 & 0 & \sin(3\pi/5) & \cos(3\pi/5) \end{array}\right)_V$$

$$= \left(\begin{array}{c|c} \Gamma^{\parallel}(\alpha) & 0 \\ \hline 0 & \Gamma^{\perp}(\alpha) \end{array}\right)_V ,$$

$$\Gamma_V(\beta) = \left(\begin{array}{ccc|cc} 1 & 0 & 0 & 0 & 0 \\ 0 & \bar{1} & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & \bar{1} \end{array}\right)_V , \quad \Gamma_V(\gamma) \left(\begin{array}{ccc|cc} \bar{1} & 0 & 0 & 0 & 0 \\ 0 & \bar{1} & 0 & 0 & 0 \\ 0 & 0 & \bar{1} & 0 & 0 \\ \hline 0 & 0 & 0 & \bar{1} & 0 \\ 0 & 0 & 0 & 0 & \bar{1} \end{array}\right)_V ,$$

where

$$W = \left(\begin{array}{ccccc} a_1^* \cos(2\pi/5) & a_2^* \cos(4\pi/5) & a_3^* \cos(6\pi/5) & a_4^* \cos(8\pi/5) & 0 \\ a_1^* \sin(2\pi/5) & a_2^* \sin(4\pi/5) & a_3^* \sin(6\pi/5) & a_4^* \sin(8\pi/5) & 0 \\ 0 & 0 & 0 & 0 & a_5^* \\ \hline a_1^* \cos(6\pi/5) & a_2^* \cos(2\pi/5) & a_3^* \cos(8\pi/5) & a_4^* \cos(4\pi/5) & 0 \\ a_1^* \sin(6\pi/5) & a_2^* \sin(2\pi/5) & a_3^* \sin(8\pi/5) & a_4^* \sin(4\pi/5) & 0 \end{array}\right).$$

The column vectors of the matrix W give the parallel- (above the partition line) and perpendicular-space components (below the partition line) of a reciprocal basis in V space. Thus, W can be rewritten using the physical-space reciprocal basis defined above as

$$W = \left(\mathbf{d}_1^*, \quad \mathbf{d}_2^*, \quad \mathbf{d}_3^*, \quad \mathbf{d}_4^*, \quad \mathbf{d}_5^*\right),$$

yielding the reciprocal basis $\mathbf{d}_i^*, i = 1, \ldots, 5$, in the 5D embedding space (D space):

$$\mathbf{d}_i^* = a_i^* \begin{pmatrix} \cos(2\pi i/5) \\ \sin(2\pi i/5) \\ 0 \\ \cos(6\pi i/5) \\ \sin(6\pi i/5) \end{pmatrix}_V , \; i = 1, \ldots, 4 \text{ and } \mathbf{d}_5^* = a_5^* \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}_V .$$

The 5×5 symmetry matrices can each be decomposed into a 3×3 matrix and a 2×2 matrix. The first one, $\Gamma^{\parallel}$, acts on the parallel-space component, the second one, $\Gamma^{\perp}$, on the perpendicular-space component. In the case of $\Gamma(\alpha)$, the coupling factor between a rotation in parallel and perpendicular space is 3. Thus, a $\pi/5$ rotation in physical space is related to a $3\pi/5$ rotation in perpendicular space (Fig. 4.6.3.12).

With the condition $\mathbf{d}_i \cdot \mathbf{d}_j^* = \delta_{ij}$, a basis in direct 5D space is obtained:

$$\mathbf{d}_i = \frac{2}{5a_i^*} \begin{pmatrix} \cos(2\pi i/5) - 1 \\ \sin(2\pi i/5) \\ 0 \\ \cos(6\pi i/5) - 1 \\ \sin(6\pi i/5) \end{pmatrix}, \; i = 1, \ldots, 4, \text{ and } \mathbf{d}_5 = \frac{1}{a_5^*} \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}.$$

The metric tensors G, G^* are of the type

$$\begin{pmatrix} A & C & C & C & 0 \\ C & A & C & C & 0 \\ C & C & A & C & 0 \\ C & C & C & A & 0 \\ 0 & 0 & 0 & 0 & B \end{pmatrix}$$

with $A = 2a_1^{*2}$, $B = a_5^{*2}$, $C = -(1/2)a_1^{*2}$ for the reciprocal space and $A = 4/5a_1^{*2}$, $B = 1/a_5^{*2}$, $C = 2/5a_1^{*2}$ for the direct space. Thus, for the lattice parameters in reciprocal space we obtain $d_i^* = a_i^*(2)^{1/2}$, $i = 1, \ldots, 4$; $d_5^* = a_5^*$; $\alpha_{ij}^* = 104.5^\circ$, $i, j = 1, \ldots, 4$; $\alpha_{i5}^* = 90^\circ$, $i = 1, \ldots, 4$, and for those in direct space $d_i = 2/[a_i^*(5)^{1/2}]$, $i = 1, \ldots, 4$; $d_5 = 1/a_5^*$; $\alpha_{ij} = 60^\circ$, $i, j = 1, \ldots, 4$; $\alpha_{i5} = 90^\circ$, $i = 1, \ldots, 4$. The volume of the 5D unit cell can be calculated from the metric tensor G:

$$V = [\det(G)]^{1/2} = \frac{4}{5(5)^{1/2}(a_1^*)^4 a_5^*} = \frac{(5)^{1/2}}{4}(d_1)^4 d_5.$$

Since decagonal phases are only quasiperiodic in two dimensions, it is sufficient to demonstrate their characteristics on a 2D

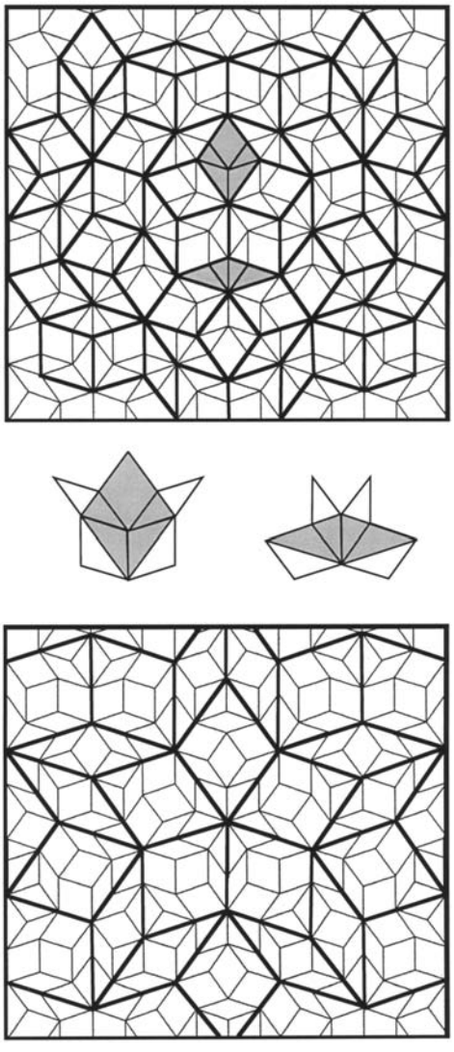

Fig. 4.6.3.13. A section of a Penrose tiling (thin lines) superposed by its τ-deflated tiling (above, thick lines) and by its τ^2-deflated tiling (below, thick lines). In the middle, the inflation rule of the Penrose tiling is illustrated.

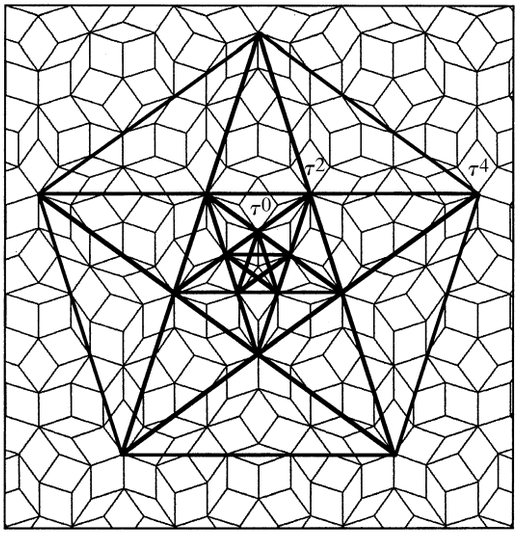

Fig. 4.6.3.14. Scaling symmetry of a pentagram superposed on the Penrose tiling. A vector pointing to a corner of a pentagon (star) is mapped by the rotoscaling operation (rotation around $\pi/5$ and dilatation by a factor τ^2) onto the next largest pentagon (star).

example, the canonical *Penrose tiling* (Penrose, 1974). It can be constructed from two unit tiles: a skinny (acute angle $\alpha_s = \pi/5$) and a fat (acute angle $\alpha_f = 2\pi/5$) rhomb with equal edge lengths a_r and areas $A_S = a_r^2 \sin(\pi/5)$, $A_F = a_r^2 \sin(2\pi/5)$ (Fig. 4.6.3.13). The areas and frequencies of these two unit tiles in the Penrose tiling are both in a ratio 1 to τ. By replacing each skinny and fat rhomb according to the inflation rule, a τ-inflated tiling is obtained. Inflation (deflation) means that the number of tiles is inflated (deflated), their edge lengths are decreased (increased) by a factor τ. By infinite repetition of this inflation operation, an infinite Penrose tiling is generated. Consequently, this substitution operation leaves the tiling invariant.

From Fig. 4.6.3.13 it can be seen that the sets of vertices of the deflated tilings are subsets of the set of vertices of the original tiling. The τ-deflated tiling is dual to the original tiling; a further deflation by a factor τ gives the original tiling again. However, the edge lengths of the tiles are increased by a factor τ^2, and the tiling is rotated around 36°. Only the fourth deflation of the original tiling yields the original tiling in its original orientation but with all lengths multiplied by a factor τ^4.

Contrary to the reciprocal-space scaling behaviour of $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{4} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$, the set of vertices $M = \{\mathbf{r} = \sum_{i=1}^{4} n_i \mathbf{a}_i | n_i \in \mathbb{Z}\}$ of the Penrose tiling is not invariant by scaling the length scale simply by a factor τ using the scaling matrix S:

$$S = \begin{pmatrix} 0 & 1 & 0 & \bar{1} \\ 0 & 1 & 1 & \bar{1} \\ \bar{1} & 1 & 1 & 0 \\ \bar{1} & 0 & 1 & 0 \end{pmatrix}_D \text{ acting on vectors } \mathbf{r} = \begin{pmatrix} n_1 \\ n_2 \\ n_3 \\ n_4 \end{pmatrix}_D .$$

The square of S, however, maps all vertices of the Penrose tiling upon other ones:

$$S^2 = \begin{pmatrix} 1 & 1 & 0 & \bar{1} \\ 0 & 2 & 1 & \bar{1} \\ \bar{1} & 1 & 2 & 0 \\ \bar{1} & 0 & 1 & 1 \end{pmatrix}_D , \quad \Gamma(\alpha)S^2 = \begin{pmatrix} 1 & 1 & \bar{1} & \bar{1} \\ 1 & 2 & 0 & \bar{2} \\ 0 & 2 & 1 & \bar{1} \\ \bar{1} & 1 & 1 & 0 \end{pmatrix}_D .$$

S^2 corresponds to a hyperbolic rotation with $\chi = \cosh^{-1}(3/2)$ in superspace (Janner, 1992). However, only operations of the type S^{4n}, $n = 0, 1, 2 \ldots$, scale the Penrose tiling in a way which is equivalent to the ($4n$th) substitutional operations discussed above. The rotoscaling operation $\Gamma(\alpha)S^2$, also a symmetry operation of the Penrose tiling, leaves a pentagram invariant as demonstrated in Fig. 4.6.3.14 (Janner, 1992). Block-diagonalization of the scaling matrix S decomposes it into two non-equivalent irreducible representations which give the scaling properties in the two orthogonal subspaces of the 4D embedding space, $\mathbf{V} = \mathbf{V}^{\parallel} \oplus \mathbf{V}^{\perp}$, the 2D parallel (physical) subspace $\mathbf{V}^{\parallel}$ and the perpendicular 2D subspace $\mathbf{V}^{\perp}$. Thus, using $WSW^{-1} = S_V = S_V^{\parallel} \oplus S_V^{\perp}$, we obtain

$$S_V = \left(\begin{array}{cc|cc} \tau & 0 & 0 & 0 \\ 0 & \tau & 0 & 0 \\ \hline 0 & 0 & -1/\tau & 0 \\ 0 & 0 & 0 & -1/\tau \end{array}\right)_V = \left(\begin{array}{cc|cc} S_V^{\parallel} & & 0 & \\ & & & \\ \hline 0 & & S_V^{\perp} & \end{array}\right)_V ,$$

where

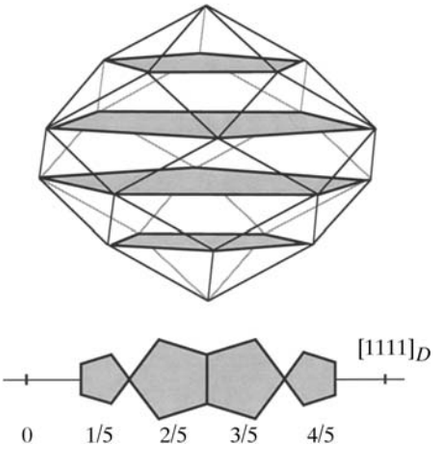

Fig. 4.6.3.15. Atomic surface of the Penrose tiling in the 5D hypercubic description. The projection of the 5D hypercubic unit cell upon $\mathbf{V}^{\perp}$ gives a rhomb-icosahedron (above). The Penrose tiling is generated by four equidistant pentagons (shaded) inscribed in the rhomb-icosahedron. Below is a perpendicular-space projection of the same pentagons, which are located on the $[1111]_D$ diagonal of the 4D hyper-rhombohedral unit cell in the 4D description.

$$W = \begin{pmatrix} a_1^* \cos(2\pi/5) & a_2^* \cos(4\pi/5) & a_3^* \cos(6\pi/5) & a_4^* \cos(8\pi/5) \\ a_1^* \sin(2\pi/5) & a_2^* \sin(4\pi/5) & a_3^* \sin(6\pi/5) & a_4^* \sin(8\pi/5) \\ \hline a_1^* \cos(4\pi/5) & a_2^* \cos(8\pi/5) & a_3^* \cos(2\pi/5) & a_4^* \cos(6\pi/5) \\ a_1^* \sin(4\pi/5) & a_2^* \sin(8\pi/5) & a_3^* \sin(2\pi/5) & a_4^* \sin(6\pi/5) \end{pmatrix}.$$

The 2D Penrose tiling can also be embedded canonically in the 5D space. Canonically means that the 5D lattice is hypercubic and that the projection of one unit cell upon the 3D perpendicular space $\mathbf{V}^{\perp}$, giving a rhomb-icosahedron, defines the atomic surface. However, the parallel-space image $\mathbf{a}_i^*$, $i = 1, \ldots, 4$, with $\mathbf{a}_0^* = -(\mathbf{a}_1^* + \mathbf{a}_2^* + \mathbf{a}_3^* + \mathbf{a}_4^*)$, of the 5D basis $\mathbf{d}_i^*$, $i = 1, \ldots, 4$ is not linearly independent. Consequently, the atomic surface consists of only a subset of the points contained in the rhomb-icosahedron: five equidistant pentagons (one with diameter zero) resulting as sections of the rhomb-icosahedron with five equidistant parallel planes (Fig. 4.6.3.15). The linear dependence of the 5D basis allows the embedding in the 4D space. The resulting hyper-rhombohedral hyperlattice is spanned by the basis $\mathbf{d}_i$, $i = 1, \ldots, 4$, discussed above. The atomic surfaces occupy the positions $p/5(1111)$, $p = 1, \ldots, 4$, on the body diagonal of the 4D unit cell. Neighbouring pentagons are in an *anti* position to each other (Fig. 4.6.3.16). Thus the 4D unit cell is decorated centrosymmetrically. The edge length a_r of a Penrose rhomb is related to the length of physical-space basis vectors a_i^* by $a_r = \tau S$, with the smallest distance $S = (2\tau/5a_i^*)$, $i = 1, \ldots, 4$. The *point density* (number of vertices per unit area) of a Penrose tiling with Penrose rhombs of edge length a_r can be calculated from the ratio of the relative number of unit tiles in the tiling to their area:

$$\rho = \frac{1+\tau}{a_r^2[\sin(\pi/5) + \tau \sin(2\pi/5)]} = (5/2)a_i^{*2}(2-\tau)^2 \tan(2\pi/5).$$

This is equivalent to the calculation from the 4D description,

$$\rho = \frac{\sum_{i=1}^{4} \Omega_{\rm AS}^i}{\Omega_{\rm UC}} = \frac{\sum_{i=1}^{4} (5/2)\lambda^2 \sin(2\pi/5)}{4/[5(5)^{1/2}|a_i^*|^4]} = (5/2)a_i^{*2}(2-\tau)^2 \tan(2\pi/5),$$

where $\Omega_{\rm AS}$ and $\Omega_{\rm UC}$ are the area of the atomic surface and the volume of the 4D unit cell, respectively. The pentagon radii are

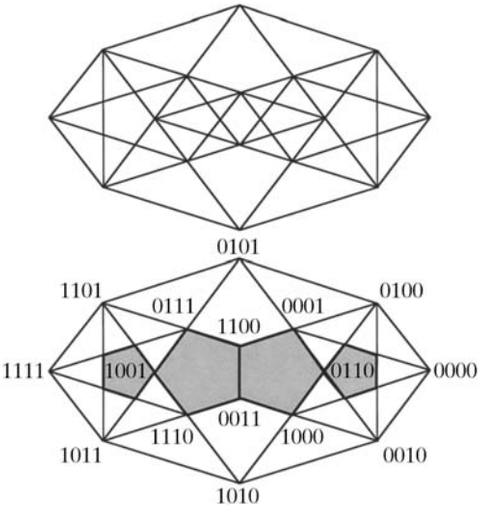

Fig. 4.6.3.16. Projection of the 4D hyper-rhombohedral unit cell of the Penrose tiling in the 4D description upon the perpendicular space. In the upper drawing all edges between the 16 corners are shown. In the lower drawing the corners are indexed and the four pentagonal atomic surfaces of the Penrose tiling are shaded.

$\lambda_{1,4} = 2(2-\tau)/5a^*$ and $\lambda_{2,3} = 2(\tau-1)/5a^*$ for the atomic surfaces in $(p/5)(1111)$ with $p = 1, 4$ and $p = 2, 3$. A detailed discussion of the properties of Penrose tiling is given in the papers of Penrose (1974, 1979), Jaric (1986) and Pavlovitch & Kleman (1987).

4.6.3.3.2.1. Indexing

The indexing of the submodule M_1^* of the diffraction pattern of a decagonal phase is not unique. Since M_1^* corresponds to a $\mathbb{Z}$ module of rank 4 with decagonal point symmetry, it is invariant under scaling by $\tau^n, n \in \mathbb{Z}$: $S^n M^* = \tau^n M^*$. Nevertheless, an optimum basis (low indices are assigned to strong reflections) can be derived: not the metrics, as for regular periodic crystals, but the intensity distribution characterizes the best choice of indexing.

A correct set of reciprocal-basis vectors can be identified experimentally in the following way:

(1) Find directions of systematic absences or pseudo-absences determining the possible orientations of the reciprocal-basis vectors (see Rabson *et al.*, 1991).

(2) Find pairs of strong reflections whose physical-space diffraction vectors are related to each other by the factor τ.

(3) Index these reflections by assigning an appropriate value to a^*. This value should be derived from the shortest interatomic distance S and the edge length of the unit tiles expected in the structure.

(4) The reciprocal basis is correct if all observable Bragg reflections can be indexed with integer numbers.

4.6.3.3.2.2. Diffraction symmetry

The diffraction symmetry of decagonal phases can be described by the Laue groups $10/mmm$ or $10/m$. The set of all vectors $\mathbf{H}$ forms a Fourier module $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{5} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ of rank 5 in physical space which can be decomposed into two submodules $M^* = M_1^* \oplus M_2^*$. $M_1^* = \{h_1\mathbf{a}_1^* + h_2\mathbf{a}_2^* + h_3\mathbf{a}_3^* + h_4\mathbf{a}_4^*\}$ corresponds to a $\mathbb{Z}$ module of rank 4 in a 2D subspace, $M_2^* = \{h_5\mathbf{a}_5^*\}$ corresponds to a $\mathbb{Z}$ module of rank 1 in a 1D subspace. Consequently, the first submodule can be considered as a projection from a 4D reciprocal lattice, $M_1^* = \pi^{\parallel}(\Sigma^*)$, while the second submodule is of the form of a regular 1D reciprocal lattice, $M_2^* = \Lambda^*$. The diffraction pattern of the Penrose tiling decorated with equal point scatterers on its vertices is shown in Fig. 4.6.3.17. All Bragg reflections within

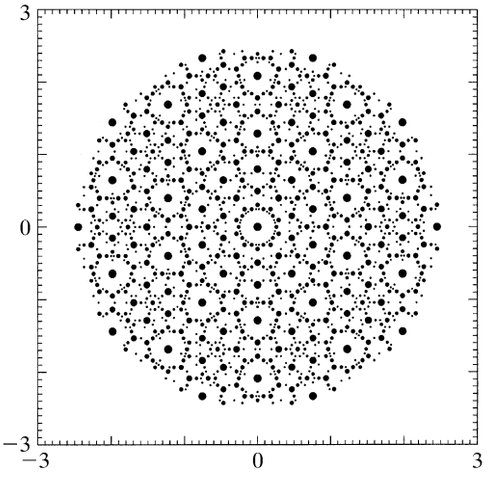

Fig. 4.6.3.17. Schematic diffraction pattern of the Penrose tiling (edge length of the Penrose unit rhombs a_r = 4.04 Å). All reflections are shown within $10^{-2}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $0 \le |\mathbf{H}^{\parallel}| \le 2.5$ Å^{-1}.

$10^{-2}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ are depicted. Without intensity-truncation limit, the diffraction pattern would be densely filled with discrete Bragg reflections. To illustrate their spatial and intensity distribution, an enlarged section of Fig. 4.6.3.17 is shown in Fig. 4.6.3.18. This picture shows all Bragg reflections within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$. The projected 4D reciprocal-lattice unit cell is drawn and several reflections are indexed. All reflections are arranged along lines in five symmetry-equivalent orientations. The perpendicular-space diffraction patterns (Figs. 4.6.3.19 and 4.6.3.20) show a characteristic star-like distribution of the Bragg reflections. This is a consequence of the pentagonal shape of the atomic surfaces: the Fourier transform of a pentagon has a star-like distribution of strong Fourier coefficients.

The 5D decagonal space groups that may be of relevance for the description of decagonal phases are listed in Table 4.6.3.1. These space groups are a subset of all 5D decagonal space groups fulfilling the condition that the 5D point groups they are associated with are isomorphous to the 3D point groups describing the diffraction symmetry. Their structures are comparable to 3D hexagonal groups. Hence, only primitive lattices exist. The orientation of the symmetry elements in the 5D space is defined by the isomorphism of the 3D and 5D point groups. However, the action of the tenfold rotation is different in the subspaces $\mathbf{V}^{\parallel}$ and

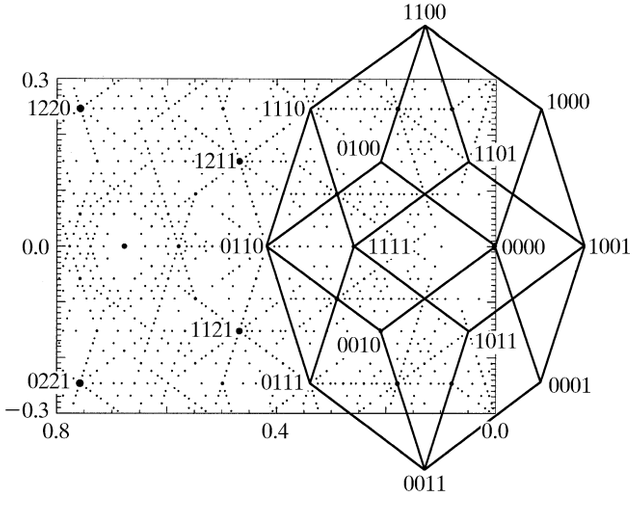

Fig. 4.6.3.18. Enlarged section of Fig. 4.6.3.17. All reflections shown are selected within the given limits from a data set within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $0 \le |\mathbf{H}^{\parallel}| \le 2.5$ Å^{-1}. The projected 4D reciprocal-lattice unit cell is drawn and several reflections are indexed.

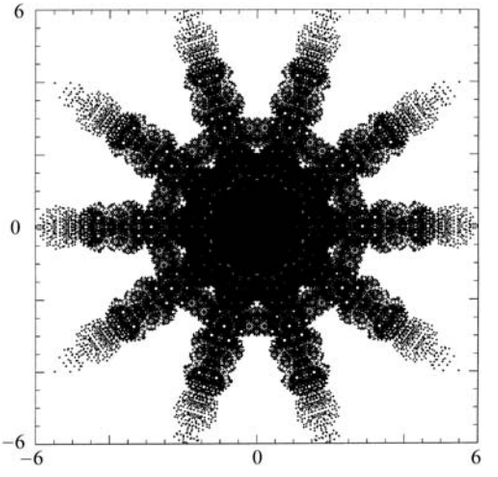

Fig. 4.6.3.19. The perpendicular-space diffraction pattern of the Penrose tiling (edge length of the Penrose unit rhombs a_r = 4.04 Å). All reflections are shown within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $0 \le |\mathbf{H}^{\parallel}| \le 2.5$ Å^{-1}.

$\mathbf{V}^{\perp}$: a rotation of $\pi/5$ in $\mathbf{V}^{\parallel}$ is correlated with a rotation of $3\pi/5$ in $\mathbf{V}^{\perp}$. The reflection and inversion operations are equivalent in both subspaces.

4.6.3.3.2.3. Structure factor

The structure factor for the decagonal phase corresponds to the Fourier transform of the 5D unit cell,

$$F(\mathbf{H}) = \sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}, \mathbf{H}^{\perp}) g_k(\mathbf{H}^{\perp}) \exp(2\pi i \mathbf{H} \cdot \mathbf{r}_k),$$

with 5D diffraction vectors $\mathbf{H} = \sum_{i=1}^{5} h_i \mathbf{d}_i^*$, N hyperatoms, parallel-space atomic scattering factor $f_k(\mathbf{H}^{\parallel})$, temperature factor $T_k(\mathbf{H}^{\parallel}, \mathbf{H}^{\perp})$ and perpendicular-space geometric form factor $g_k(\mathbf{H}^{\perp})$. $T_k(\mathbf{H}^{\parallel}, \mathbf{0})$ is equivalent to the conventional Debye–Waller factor and $T_k(\mathbf{0}, \mathbf{H}^{\perp})$ describes random fluctuations along the perpendicular-space coordinate. These fluctuations cause characteristic jumps of vertices in physical space (*phason flips*). Even random phason flips map the vertices onto positions which can still be described by physical-space vectors of the type $\mathbf{r} = \sum_{i=1}^{5} n_i \mathbf{a}_i$. Consequently, the set $M = \{\mathbf{r} = \sum_{i=1}^{5} n_i \mathbf{a}_i | n_i \in \mathbb{Z}\}$ of all possible vectors forms a $\mathbb{Z}$ module. The shape of the atomic surfaces corresponds to a selection rule for the positions actually occupied. The geometric form factor $g_k(\mathbf{H}^{\perp})$ is equivalent to the

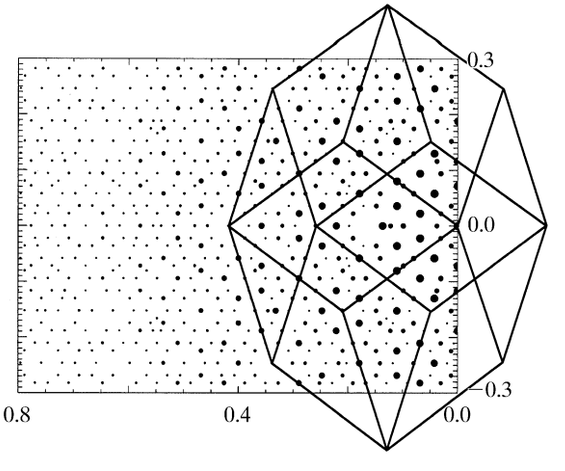

Fig. 4.6.3.20. Enlarged section of Fig. 4.6.3.19 showing the projected 4D reciprocal-lattice unit cell.

Fourier transform of the *atomic surface*, *i.e.* the 2D perpendicular-space component of the 5D *hyperatoms*.

For example, the canonical Penrose tiling $g_k(\mathbf{H}^\perp)$ corresponds to the Fourier transform of pentagonal atomic surfaces:

$$g_k(\mathbf{H}^\perp) = (1/A_{\rm UC}^\perp)\int_{A_k} \exp(2\pi i\mathbf{H}^\perp\cdot\mathbf{r})\ \mathrm{d}\mathbf{r},$$

where $A_{\rm UC}^\perp$ is the area of the 5D unit cell projected upon $\mathbf{V}^\perp$ and A_k is the area of the kth atomic surface. The area $A_{\rm UC}^\perp$ can be calculated using the formula

$$A_{\rm UC}^\perp = (4/25a_i^{*2})[(7+\tau)\sin(2\pi/5) + (2+\tau)\sin(4\pi/5)].$$

Evaluating the integral by decomposing the pentagons into triangles, one obtains

$$g_k(\mathbf{H}^\perp) = \frac{1}{A_{\rm UC}^\perp}\sin\left(\frac{2\pi}{5}\right) \times \sum_{j=0}^{4}\frac{A_j[\exp(iA_{j+1}\lambda_k)-1] - A_{j+1}[\exp(iA_j\lambda_k)-1]}{A_jA_{j+1}(A_j - A_{j+1})}$$

with $j = 0, \ldots, 4$ running over the five triangles, where the radii of the pentagons are λ_j, $A_j = 2\pi\mathbf{H}^\perp\mathbf{e}_j$,

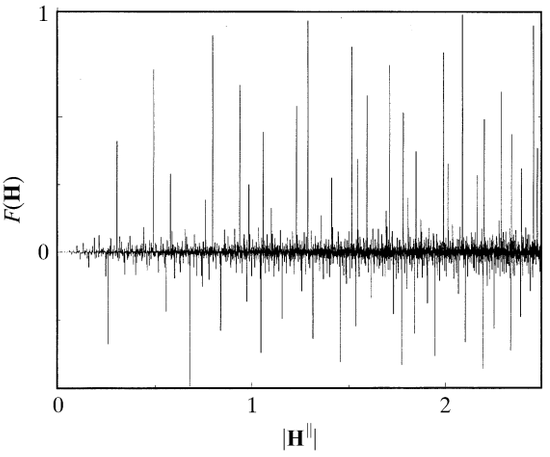

Fig. 4.6.3.21. Radial distribution function of the structure factors $F(\mathbf{H})$ of the Penrose tiling (edge length of the Penrose unit rhombs a_r = 4.04 Å) decorated with point atoms as a function of $\mathbf{H}^\parallel$. All structure factors within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $0 \le |\mathbf{H}^\parallel| \le 2.5$ Å^{-1} have been used and normalized to $F(0000) = 1$.

$$\mathbf{H}^\perp = \pi^\perp(\mathbf{H}) = \sum_{j=0}^{4} h_j a_j^* \begin{pmatrix} 0 \\ 0 \\ 0 \\ \cos(6\pi j/5) \\ \sin(6\pi j/5) \end{pmatrix}$$

and the vectors

$$\mathbf{e}_j = \frac{1}{a_j^*}\begin{pmatrix} 0 \\ 0 \\ 0 \\ \cos(2\pi j/5) \\ \sin(2\pi j/5) \end{pmatrix} \text{ with } j = 0, \ldots, 4.$$

As shown by Ishihara & Yamamoto (1988), the Penrose tiling can be considered to be a superstructure of a pentagonal tiling with only one type of pentagonal atomic surface in the nD unit cell. Thus, for the Penrose tiling, three special reflection classes can be distinguished: for $|\sum_{i=1}^4 h_i| = m \bmod 5$ and $m = 0$ the class of strong main reflections is obtained, and for $m = \pm1, \pm2$ the classes of weaker first- and second-order satellite reflections are obtained (see Fig. 4.6.3.18).

4.6.3.3.2.4. Intensity statistics

This section deals with the reciprocal-space characteristics of the 2D quasiperiodic component of the 3D structure, namely the Fourier module M_1^*. The radial structure-factor distributions of the Penrose tiling decorated with point scatterers are plotted in Figs. 4.6.3.21 and 4.6.3.22 as a function of parallel and perpendicular space. The distribution of $|F(\mathbf{H})|$ as a function of their frequencies clearly resembles a centric distribution, as can be expected from the centrosymmetric 4D subunit cell. The shape of the distribution function depends on the radius of the limiting sphere in reciprocal space. The number of weak reflections increases to the power of four, that of strong reflections only quadratically (strong reflections always have small $\mathbf{H}^\perp$ components). The radial distribution of the structure-factor amplitudes as a function of perpendicular space clearly shows three branches, corresponding to the reflection classes $\sum_{i=1}^4 h_i = m \bmod 5$ with $|m| = 0$, $|m| = 1$ and $|m| = 2$ (Fig. 4.6.3.23).

The weighted reciprocal space of the Penrose tiling contains an infinite number of Bragg reflections within a limited region of the physical space. Contrary to the diffraction pattern of a periodic

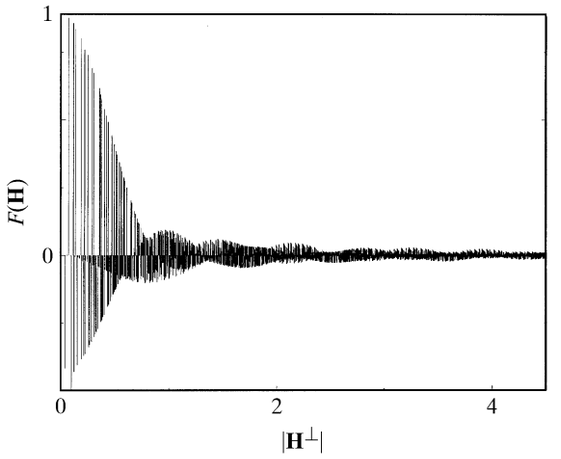

Fig. 4.6.3.22. Radial distribution function of the structure factors $F(\mathbf{H})$ of the Penrose tiling (edge length of the Penrose unit rhombs a_r = 4.04 Å) decorated with point atoms as a function of $\mathbf{H}^{\perp}$. All structure factors within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $0 \le |\mathbf{H}^{\parallel}| \le 2.5$ Å^{-1} have been used and normalized to $F(0000) = 1$.

structure consisting of point atoms on the lattice nodes, the Bragg reflections show intensities depending on the perpendicular-space components of their diffraction vectors (Figs. 4.6.3.19, 4.6.3.20 and 4.6.3.22).

4.6.3.3.2.5. Relationships between structure factors at symmetry-related points of the Fourier image

Scaling the Penrose tiling by a factor τ^{-n} by employing the matrix S^{-n} scales at the same time its reciprocal space by a factor τ^n:

$$\boldsymbol{S}\mathbf{H} = \begin{pmatrix} 0 & 1 & 0 & \bar{1} & 0 \\ 0 & 1 & 1 & \bar{1} & 0 \\ \bar{1} & 1 & 1 & 0 & 0 \\ \bar{1} & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}_D \begin{pmatrix} h_1 \\ h_2 \\ h_3 \\ h_4 \\ h_5 \end{pmatrix} = \begin{pmatrix} h_2 - h_4 \\ h_2 + h_3 - h_4 \\ -h_1 + h_2 + h_3 \\ -h_1 + h_3 \\ h_5 \end{pmatrix}.$$

Since this operation increases the lengths of the diffraction vectors by the factor τ in parallel space and decreases them by the factor $1/\tau$ in perpendicular space, the following distribution of structure-factor magnitudes (for point atoms at rest) is obtained:

$$\begin{aligned} \big|F(S^n\mathbf{H})\big| > \big|F(S^{n-1}\mathbf{H})\big| > \ldots > \big|F(S^1\mathbf{H})\big| > \big|F(\mathbf{H})\big|, \\ \big|F(\tau^n\mathbf{H}^{\parallel})\big| > \big|F(\tau^{n-1}\mathbf{H}^{\parallel})\big| > \ldots > \big|F(\tau\mathbf{H}^{\parallel})\big| > \big|F(\mathbf{H})\big|. \end{aligned}$$

The scaling operations S^n, $n \in \mathbb{Z}$, the rotoscaling operations $(\Gamma(\alpha)S^2)^n$ (Fig. 4.6.3.14) and the tenfold rotation $(\Gamma(\alpha))^n$, where

$$(\Gamma(\alpha)S^2)^n = \begin{pmatrix} 1 & 1 & \bar{1} & \bar{1} & 0 \\ 1 & 2 & 0 & \bar{2} & 0 \\ 0 & 2 & 1 & \bar{1} & 0 \\ \bar{1} & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}^n_D,$$

connect all structure factors with diffraction vectors pointing to the nodes of an infinite series of pentagrams. The structure factors with positive signs are predominantly on the vertices of the pentagram while the ones with negative signs are arranged on circles around the vertices (Figs. 4.6.3.24 to 4.6.3.27).

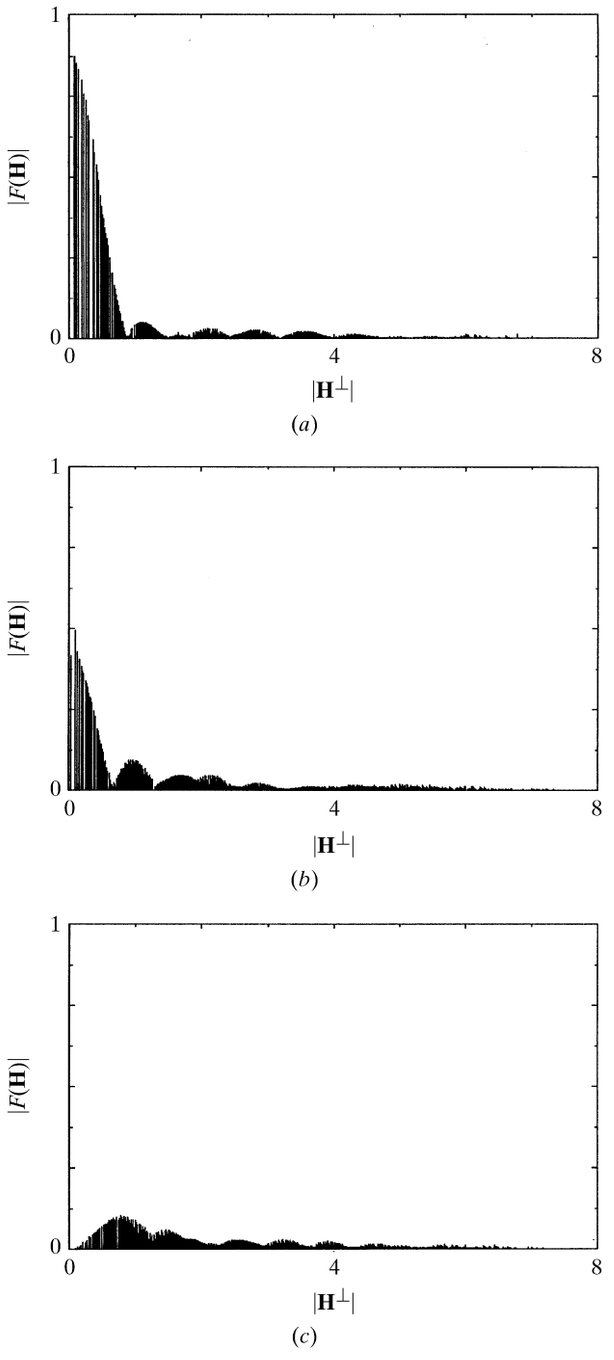

Fig. 4.6.3.23. Radial distribution function of the structure-factor magnitudes $|F(\mathbf{H})|$ of the Penrose tiling (edge length of the Penrose unit rhombs a_r = 4.04 Å) decorated with point atoms as a function of $\mathbf{H}^{\perp}$. All structure factors within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $0 \le |\mathbf{H}^{\parallel}| \le 2.5$ Å^{-1} have been used and normalized to $F(0000) = 1$. The branches with (*a*) $|\sum_{i=1}^4 h_i| = 0 \bmod 5$, (*b*) $|\sum_{i=1}^4 h_i| = 1 \bmod 5$ and (*c*) $|\sum_{i=1}^4 h_i| = 2 \bmod 5$ are shown.

4.6.3.3.3. Icosahedral phases

A structure that is quasiperiodic in three dimensions and exhibits icosahedral diffraction symmetry is called an icosahedral phase. Its holohedral Laue symmetry group is $K = m\bar{3}\bar{5}$. All reciprocal-space vectors $\mathbf{H} = \sum_{i=1}^6 h_i \mathbf{a}_i^* \in M^*$ can be represented on a basis $\mathbf{a}_1^* = a^*(0, 0, 1)$, $\mathbf{a}_i^* = a^*[\sin\theta\cos(2\pi i/5), \sin\theta\sin(2\pi i/5), \cos\theta]$, $i = 2, \ldots, 6$ where $\sin\theta = 2/(5)^{1/2}$, $\cos\theta = 1/(5)^{1/2}$ and $\theta \simeq 63.44^\circ$, the angle between two neighbouring fivefold axes (Fig. 4.6.3.28). This can be rewritten as

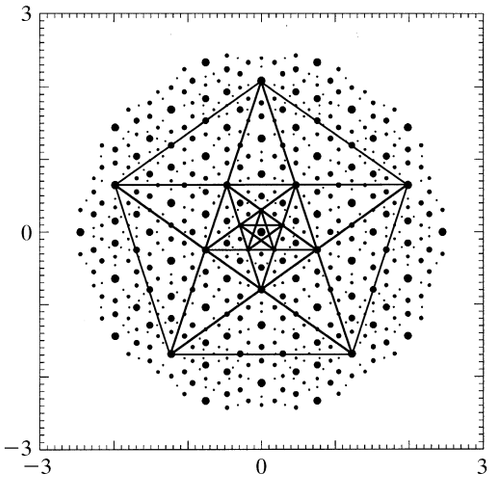

Fig. 4.6.3.24. Pentagrammal relationships between scaling symmetry-related positive structure factors $F(\mathbf{H})$ of the Penrose tiling (edge length $a_r = 4.04$ Å) in parallel space. The magnitudes of the structure factors are indicated by the diameters of the filled circles.

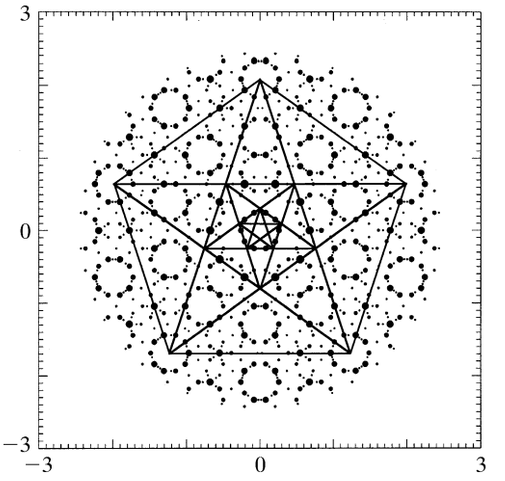

Fig. 4.6.3.25. Pentagrammal relationships between scaling symmetry-related negative structure factors $F(\mathbf{H})$ of the Penrose tiling (edge length $a_r = 4.04$ Å) in parallel space. The magnitudes of the structure factors are indicated by the diameters of the filled circles.

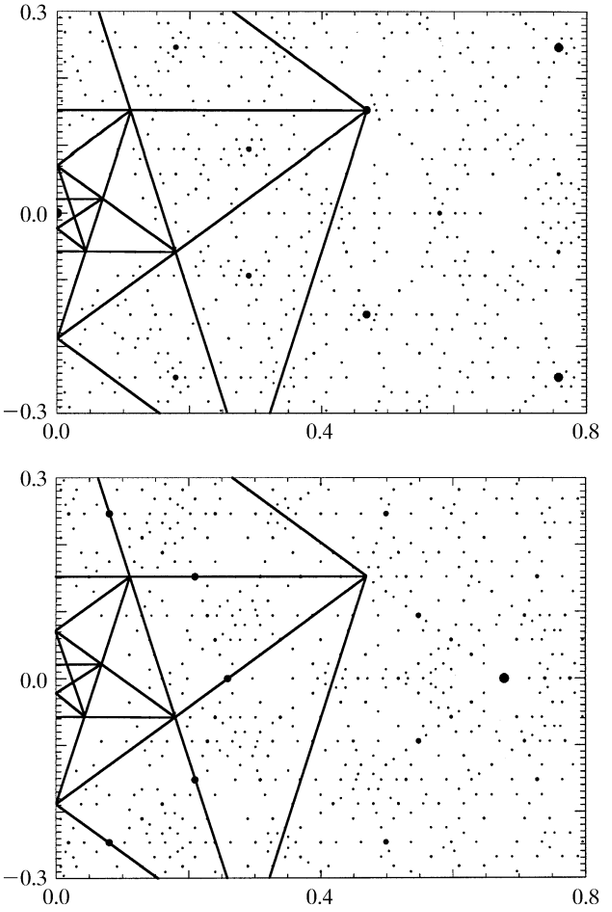

Fig. 4.6.3.26. Pentagrammal relationships between scaling symmetry-related structure factors $F(\mathbf{H})$ of the Penrose tiling (edge length $a_r = 4.04$ Å) in parallel space. Enlarged sections of Figs. 4.6.3.24 (above) and 4.6.3.25 (below) are shown.

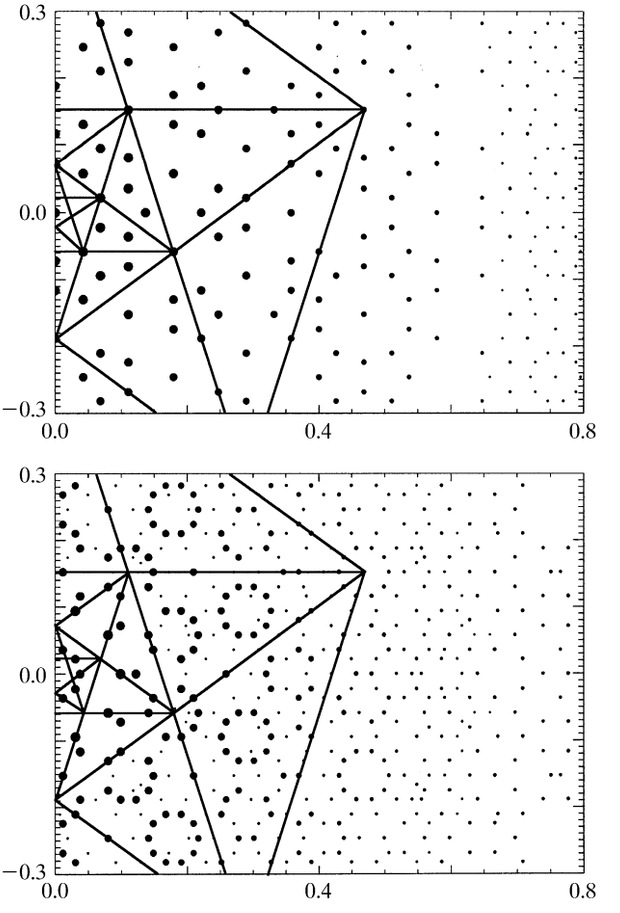

Fig. 4.6.3.27. Pentagrammal relationships between scaling symmetry-related structure factors $F(\mathbf{H})$ of the Penrose tiling (edge length $a_r = 4.04$ Å) in perpendicular space. Enlarged sections of positive (above) and negative structure factors (below) are shown.

$$\begin{pmatrix} \mathbf{a}_1^* \\ \mathbf{a}_2^* \\ \mathbf{a}_3^* \\ \mathbf{a}_4^* \\ \mathbf{a}_5^* \\ \mathbf{a}_6^* \end{pmatrix} = a^* \begin{pmatrix} 0 & 0 & 1 \\ \sin\theta\cos(4\pi/5) & \sin\theta\sin(4\pi/5) & \cos\theta \\ \sin\theta\cos(6\pi/5) & \sin\theta\sin(6\pi/5) & \cos\theta \\ \sin\theta\cos(8\pi/5) & \sin\theta\sin(8\pi/5) & \cos\theta \\ \sin\theta & 0 & \cos\theta \\ \sin\theta\cos(2\pi/5) & \sin\theta\sin(2\pi/5) & \cos\theta \end{pmatrix} \begin{pmatrix} \mathbf{e}_1^V \\ \mathbf{e}_2^V \\ \mathbf{e}_3^V \end{pmatrix},$$

where $\mathbf{e}_i^V$ are Cartesian basis vectors. Thus, from the number of independent reciprocal-basis vectors needed to index the Bragg reflections with integer numbers, the dimension of the embedding space has to be six. The vector components refer to a Cartesian coordinate system (V basis) in the physical (parallel) space.

The set $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{6} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ of all diffraction vectors remains invariant under the action of the symmetry operators of the icosahedral point group $K = m\bar{3}\bar{5}$. The symmetry-adapted matrix representations for the point-group generators, one five-

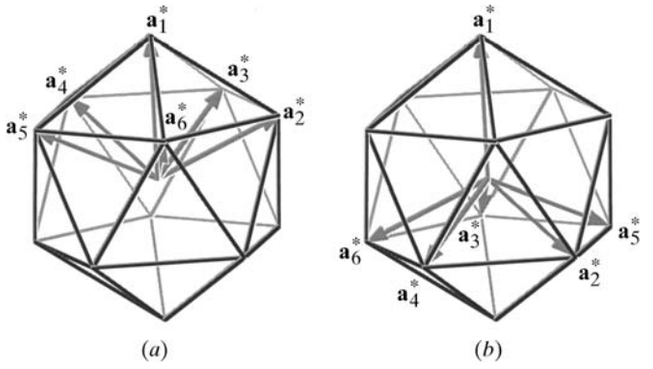

Fig. 4.6.3.28. Perspective (*a*) parallel- and (*b*) perpendicular-space views of the reciprocal basis of the 3D Penrose tiling. The six rationally independent vectors $\mathbf{a}_i^*$ point to the edges of an icosahedron.

fold rotation α, a threefold rotation β and the inversion operation γ, can be written in the form

$$\Gamma(\alpha) = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}_D, \Gamma(\beta) = \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & \bar{1} & 0 & 0 \\ 0 & 0 & 0 & 0 & \bar{1} & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}_D,$$

$$\Gamma(\gamma) = \begin{pmatrix} \bar{1} & 0 & 0 & 0 & 0 & 0 \\ 0 & \bar{1} & 0 & 0 & 0 & 0 \\ 0 & 0 & \bar{1} & 0 & 0 & 0 \\ 0 & 0 & 0 & \bar{1} & 0 & 0 \\ 0 & 0 & 0 & 0 & \bar{1} & 0 \\ 0 & 0 & 0 & 0 & 0 & \bar{1} \end{pmatrix}_D.$$

Block-diagonalization of these reducible symmetry matrices decomposes them into non-equivalent irreducible representations. These can be assigned to the two orthogonal subspaces forming the 6D embedding space $\mathbf{V} = \mathbf{V}^{\parallel} \oplus \mathbf{V}^{\perp}$, the 3D parallel (physical) subspace $\mathbf{V}^{\parallel}$ and the perpendicular 3D subspace $\mathbf{V}^{\perp}$. Thus, using $W\Gamma W^{-1} = \Gamma^{\rm red} = \Gamma^{\parallel} \oplus \Gamma^{\perp}$, we obtain

$$\Gamma(\alpha) = \left(\begin{array}{ccc|ccc} \cos(2\pi/5) & -\sin(2\pi/5) & 0 & 0 & 0 & 0 \\ \sin(2\pi/5) & \cos(2\pi/5) & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & \cos(4\pi/5) & -\sin(4\pi/5) & 0 \\ 0 & 0 & 0 & \sin(4\pi/5) & \cos(4\pi/5) & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{array}\right)_V = \left(\begin{array}{c|c} \Gamma^{\parallel} & 0 \\ \hline 0 & \Gamma^{\perp} \end{array}\right)_V,$$

where

$$W = a^* \begin{pmatrix} 0 & sc4 & sc6 & sc8 & s & sc2 \\ 0 & ss4 & ss6 & ss8 & 0 & ss2 \\ 1 & c & c & c & c & c \\ \hline 0 & -sc8 & -sc2 & -sc6 & -s & -sc4 \\ 0 & -ss8 & -ss2 & -ss6 & 0 & -ss4 \\ 1 & -c & -c & -c & -c & -c \end{pmatrix}_V,$$

$c = \cos\theta$, $s = \sin\theta$, $scn = \sin\theta\cos(n\pi/5)$, $ssn = \sin\theta\sin(n\pi/5)$. The column vectors of the matrix W give the parallel- (above the partition line) and perpendicular-space components (below the partition line) of a reciprocal basis in $\mathbf{V}$. Thus, W can be rewritten using the physical-space reciprocal basis defined above and an arbitrary constant c,

$$W = \begin{pmatrix} \mathbf{a}_1^* & \mathbf{a}_2^* & \mathbf{a}_3^* & \mathbf{a}_4^* & \mathbf{a}_5^* & \mathbf{a}_6^* \\ c\mathbf{a}_1^* & -c\mathbf{a}_4^* & -c\mathbf{a}_6^* & -c\mathbf{a}_3^* & -c\mathbf{a}_5^* & -c\mathbf{a}_2^* \end{pmatrix} = \begin{pmatrix} \mathbf{d}_1^* & \mathbf{d}_2^* & \mathbf{d}_3^* & \mathbf{d}_4^* & \mathbf{d}_5^* & \mathbf{d}_6^* \end{pmatrix},$$

yielding the reciprocal basis $\mathbf{d}_i^*, i = 1, \ldots, 6$, in the 6D embedding space (D space)

$$\mathbf{d}_1^* = a^* \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ c \end{pmatrix} \text{ and } \mathbf{d}_i^* = a^* \begin{pmatrix} \sin\theta\cos(2\pi i/5) \\ \sin\theta\sin(2\pi i/5) \\ \cos\theta \\ -c\sin\theta\cos(4\pi i/5) \\ -c\sin\theta\sin(4\pi i/5) \\ -c\cos\theta \end{pmatrix}, i = 2, \ldots, 6.$$

The 6×6 symmetry matrices can each be decomposed into two 3×3 matrices. The first one, $\Gamma^{\parallel}$, acts on the parallel-space component, the second one, $\Gamma^{\perp}$, on the perpendicular-space component. In the case of $\Gamma(\alpha)$, the coupling factor between a rotation in parallel and perpendicular space is 2. Thus a $2\pi/5$ rotation in physical space is related to a $4\pi/5$ rotation in perpendicular space (Figs. 4.6.3.28 and 4.6.3.29).

With the condition $\mathbf{d}_i \cdot \mathbf{d}_j^* = \delta_{ij}$, the basis in direct 6D space is obtained:

$$\mathbf{d}_1 = \frac{1}{2a^*} \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 1/c \end{pmatrix} \text{ and } \mathbf{d}_i = \frac{1}{2a^*} \begin{pmatrix} \sin\theta\cos(2\pi i/5) \\ \sin\theta\sin(2\pi i/5) \\ \cos\theta \\ -(1/c)\sin\theta\cos(4\pi i/5) \\ -(1/c)\sin\theta\sin(4\pi i/5) \\ -(1/c)\cos\theta \end{pmatrix}, \quad i = 2, \ldots, 6.$$

The metric tensors G, G^* are of the type

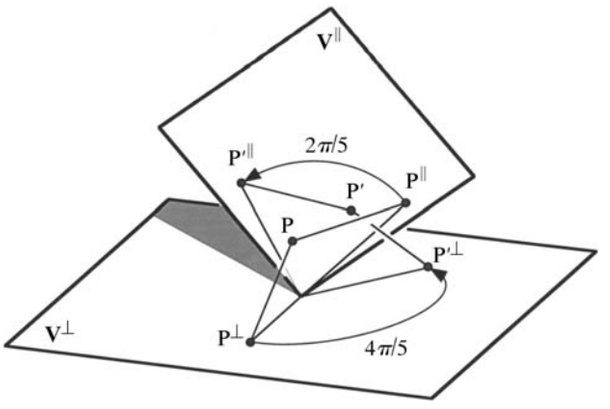

Fig. 4.6.3.29. Schematic representation of a rotation in 6D space. The point P is rotated to P′. The component rotations in parallel and perpendicular space are illustrated.

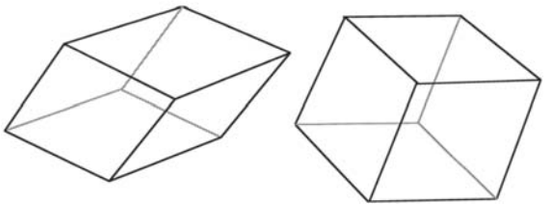

Fig. 4.6.3.30. The two unit tiles of the 3D Penrose tiling: a prolate [$\alpha_p = \arccos(5^{-1/2}) \simeq 63.44^\circ$] and an oblate ($\alpha_o = 180^\circ - \alpha_p$) rhombohedron with equal edge lengths a_r.

$$\begin{pmatrix} A & B & B & B & B & B \\ B & A & B & -B & -B & B \\ B & B & A & B & -B & -B \\ B & -B & B & A & B & -B \\ B & -B & -B & B & A & B \\ B & B & -B & -B & B & A \end{pmatrix},$$

with $A = (1 + c^2)a^{*2}$, $B = [(5)^{1/2}/5](1 - c^2)a^{*2}$ for the reciprocal space and $A = (1 + c^2)/[4(ca^*)^2]$, $B = [(5)^{1/2}(c^2 - 1)]/[20(ca^*)^2]$ for the direct space. For $c = 1$ we obtain hypercubic direct and reciprocal 6D lattices.

The lattice parameters in reciprocal and direct space are $d_i^* = a^*(2)^{1/2}$ and $d_i = 1/[(2)^{1/2}a^*]$ with $i = 1, \ldots, 6$, respectively. The volume of the 6D unit cell can be calculated from the metric tensor G. For $c = 1$ it is simply $V = [\det(G)]^{1/2} = \{1/[(2)^{1/2}a^*]\}^6$.

The best known example of a 3D quasiperiodic structure is the canonical 3D *Penrose tiling* (see Janssen, 1986). It can be constructed from two unit tiles: a prolate and an oblate rhombohedron with equal edge lengths a_r (Fig. 4.6.3.30). Each face of the rhombohedra is a rhomb with acute angles $\alpha_r = \arccos[1/(5)^{1/2}] \simeq 63.44^\circ$. Their volumes are $V_p = (4/5)a_r^3 \sin(2\pi/5)$, $V_o = (4/5)a_r^3 \sin(\pi/5) = V_p/\tau$, and their frequencies $\nu_p{:}\nu_o = \tau{:}1$. The resulting point density (number of vertices per unit volume) is $\rho_p = (\tau + 1)/(\tau V_p + V_o) = (\tau/a_r^3)\sin(2\pi/5)$. Ten prolate and ten oblate rhombohedra can be packed to form a rhombic triacontahedron. The icosahedral symmetry of this zonohedron is broken by the many possible decompositions into the rhombohedra. Removing one zone of the triacontahedron gives a rhomb-icosahedron consisting of five prolate and five oblate rhombohedra. Again, the singular fivefold axis of the rhomb-icosahedron is broken by the decomposition into rhombohedra. Removing one zone again gives a rhombic dodecahedron consisting of two prolate and two oblate rhombohedra. Removing the last remaining zone leads finally to a single prolate rhombohedron. Using these zonohedra as elementary clusters, a matching rule can be derived for the 3D construction of the 3D Penrose tiling (Levine & Steinhardt, 1986; Socolar & Steinhardt, 1986).

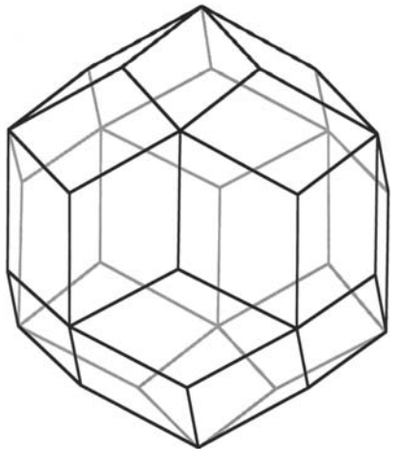

Fig. 4.6.3.31. Atomic surface of the 3D Penrose tiling in the 6D hypercubic description. The projection of the 6D hypercubic unit cell upon $\mathbf{V}^\perp$ gives a rhombic triacontahedron.

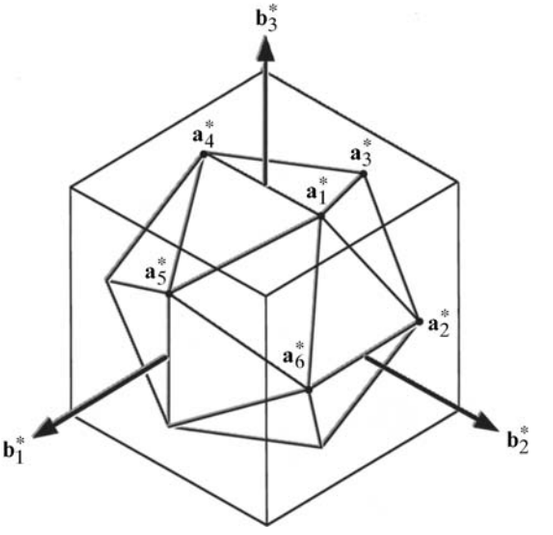

Fig. 4.6.3.32. Perspective parallel-space view of the two alternative reciprocal bases of the 3D Penrose tiling: the cubic and the icosahedral setting, represented by the bases $\mathbf{b}_i^*$, $i = 1, \ldots, 3$, and $\mathbf{a}_i^*$, $i = 1, \ldots, 6$, respectively.

The 3D Penrose tiling can be embedded in the 6D space as shown above. The 6D hypercubic lattice is decorated on the lattice nodes with 3D triacontahedra obtained from the projection of a 6D unit cell upon the perpendicular space $\mathbf{V}^\perp$ (Fig. 4.6.3.31). Thus the edge length of the rhombs covering the triacontahedron is equivalent to the length $\pi^\perp(\mathbf{d}_i) = 1/2a^*$ of the perpendicular-space component of the vectors spanning the 6D hypercubic lattice $\Sigma = \{\mathbf{r} = \sum_{i=1}^6 n_i\mathbf{d}_i | n_i \in \mathbb{Z}\}$.

4.6.3.3.3.1. Indexing

There are several indexing schemes in use. The generic one uses a set of six rationally independent reciprocal-basis vectors pointing to the corners of an icosahedron, $\mathbf{a}_1^* = a^*(0, 0, 1)$, $\mathbf{a}_i^* = a^*[\sin\theta\cos(2\pi i/5), \sin\theta\sin(2\pi i/5), \cos\theta]$, $i = 2, \ldots, 6$, $\sin\theta = 2/(5)^{1/2}$, $\cos\theta = 1/(5)^{1/2}$, with $\theta \simeq 63.44^\circ$, the angle between two neighbouring fivefold axes (setting 1) (Fig. 4.6.3.28). In this case, the physical-space basis corresponds to a simple projection of the 6D reciprocal basis $\mathbf{d}_i^*$, $i = 1, \ldots, 6$. Sometimes, the same set of six reciprocal-basis vectors is referred to a differently oriented Cartesian reference system (C basis, with basis vectors $\mathbf{e}_i$ along the twofold axes) (Bancel *et al.*, 1985). The reciprocal basis is

$$\begin{pmatrix} \mathbf{a}_1^* \\ \mathbf{a}_2^* \\ \mathbf{a}_3^* \\ \mathbf{a}_4^* \\ \mathbf{a}_5^* \\ \mathbf{a}_6^* \end{pmatrix} = \frac{a^*}{(1+\tau^2)^{1/2}} \begin{pmatrix} 0 & 1 & \tau \\ -1 & \tau & 0 \\ -\tau & 0 & 1 \\ 0 & -1 & \tau \\ \tau & 0 & 1 \\ 1 & \tau & 0 \end{pmatrix}_C \begin{pmatrix} \mathbf{e}_1^C \\ \mathbf{e}_2^C \\ \mathbf{e}_3^C \end{pmatrix}.$$

An alternate way of indexing is based on a 3D set of cubic reciprocal-basis vectors $\mathbf{b}_i^*$, $i = 1, \ldots, 3$ (setting 2) (Fig. 4.6.3.32):

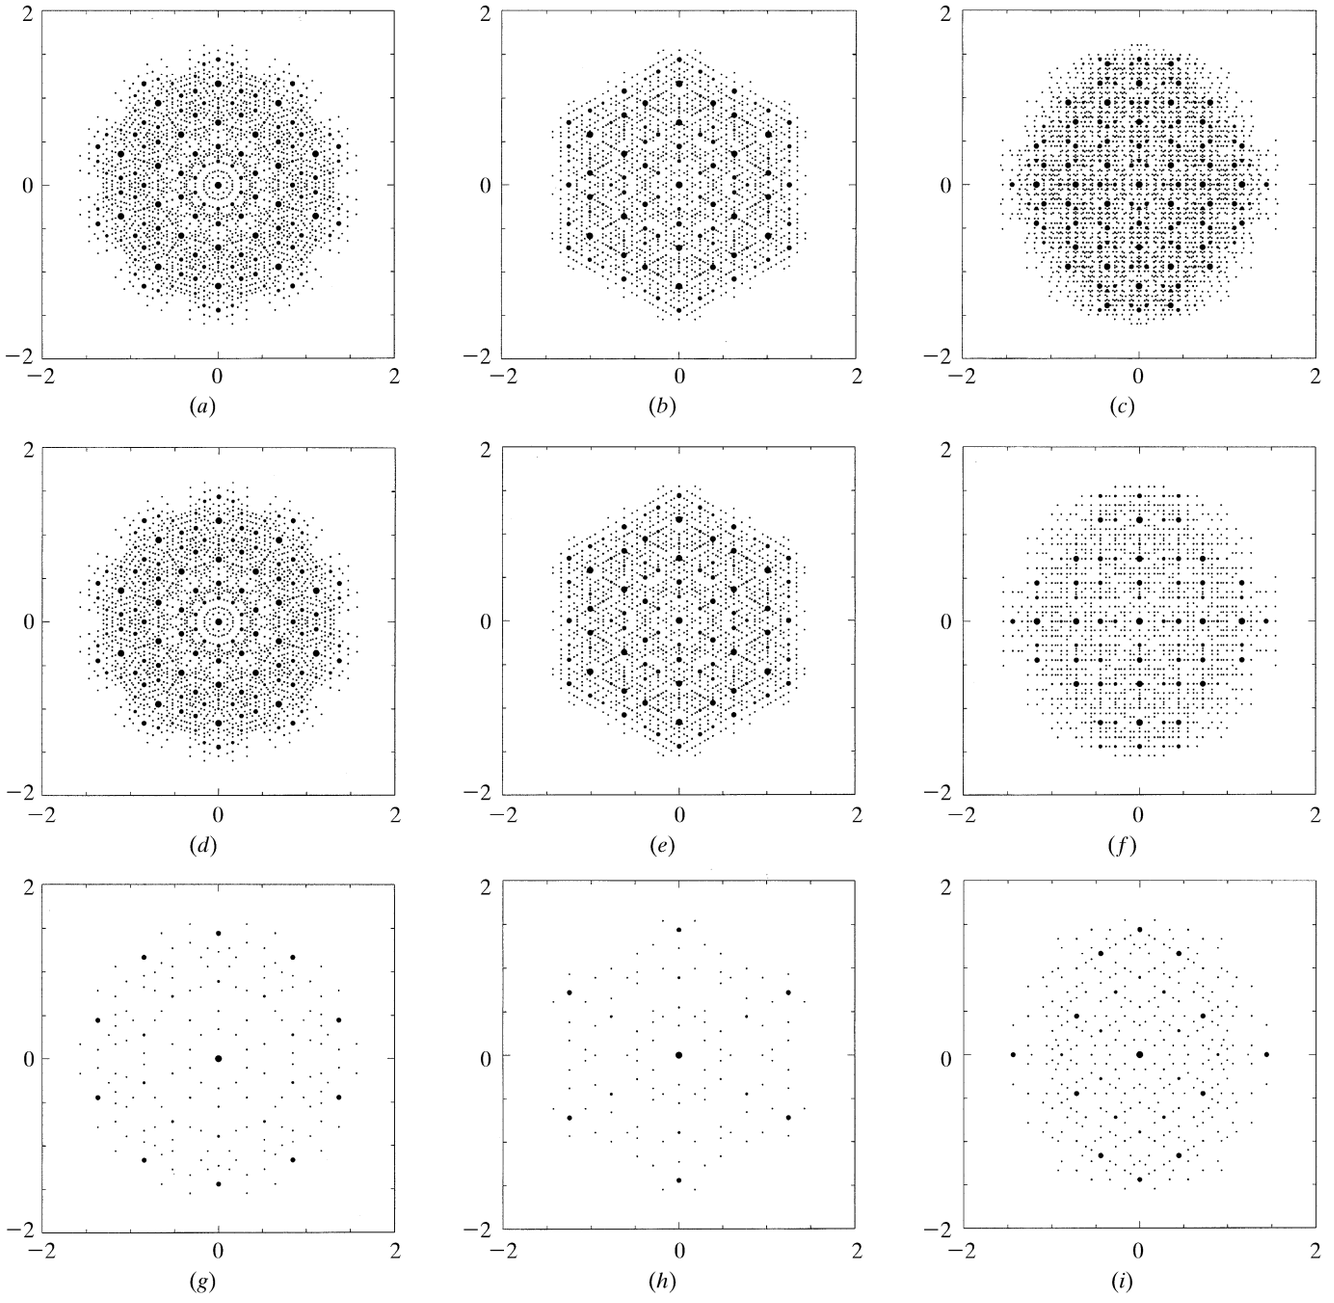

Fig. 4.6.3.33. Physical-space diffraction patterns of the 3D Penrose tiling decorated with point atoms (edge lengths of the Penrose unit rhombohedra $a_r = 5.0$ Å). Sections with five-, three- and twofold symmetry are shown for the primitive 6D analogue of Bravais type P in (a, b, c), the body-centred 6D analogue to Bravais type I in (d, e, f) and the face-centred 6D analogue to Bravais type F in (g, h, i). All reflections are shown within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $-6 \le h_i \le 6, i = 1, \ldots, 6$.

$$\begin{pmatrix} \mathbf{b}_1^* \\ \mathbf{b}_2^* \\ \mathbf{b}_3^* \end{pmatrix} = \tfrac{1}{2}\begin{pmatrix} 0 & \bar{1} & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & \bar{1} & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 \end{pmatrix}_D \begin{pmatrix} \mathbf{a}_1^* \\ \mathbf{a}_2^* \\ \mathbf{a}_3^* \\ \mathbf{a}_4^* \\ \mathbf{a}_5^* \\ \mathbf{a}_6^* \end{pmatrix}$$

$$= \frac{a^*}{(1+\tau^2)^{1/2}} \begin{pmatrix} \mathbf{e}_1^C \\ \mathbf{e}_2^C \\ \mathbf{e}_3^C \end{pmatrix}.$$

The Cartesian C basis is related to the V basis by a $\theta/2$ rotation around $[100]_C$, yielding $[001]_V$, followed by a $\pi/10$ rotation around $[001]_C$:

$$\begin{pmatrix} \mathbf{e}_1^C \\ \mathbf{e}_2^C \\ \mathbf{e}_3^C \end{pmatrix} = \begin{pmatrix} \cos(\pi/10) & \sin(\pi/10) & 0 \\ -\cos(\theta/2)\sin(\pi/10) & \cos(\theta/2)\cos(\pi/10) & \sin(\theta/2) \\ \sin(\theta/2)\sin(\pi/10) & -\sin(\theta/2)\cos(\pi/10) & \cos(\theta/2) \end{pmatrix}_V \begin{pmatrix} \mathbf{e}_1^V \\ \mathbf{e}_2^V \\ \mathbf{e}_3^V \end{pmatrix}.$$

Thus, indexing the diffraction pattern of an icosahedral phase with integer indices, one obtains for setting 1 $\mathbf{H} = \sum_{i=1}^{6} h_i \mathbf{a}_i^*, h_i \in \mathbb{Z}$. These indices $(h_1\ h_2\ h_3\ h_4\ h_5\ h_6)$ transform into the second setting to $(h/h'\ k/k'\ l/l')$ with the fractional cubic indices $h_1^c = h + h'\tau$, $h_2^c = k + k'\tau$, $h_3^c = l + l'\tau$. The transformation matrix is

4.6.3.3.3.2. Diffraction symmetry

The diffraction symmetry of icosahedral phases can be described by the Laue group $K = m\bar{3}\bar{5}$. The set of all vectors $\mathbf{H}$ forms a Fourier module $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{6} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ of rank 6 in physical space. Consequently, it can be considered as a projection from a 6D reciprocal lattice, $M^* = \pi^{\parallel}(\Sigma^*)$. The parallel and perpendicular reciprocal-space sections of the 3D Penrose tiling decorated with equal point scatterers on its vertices are shown in Figs. 4.6.3.33 and 4.6.3.34. The diffraction pattern in perpendicular space is the Fourier transform of the triacontahedron. All Bragg reflections within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ are depicted. Without intensity-truncation limit, the diffraction pattern would be densely filled with discrete Bragg reflections.

The 6D icosahedral space groups that are relevant to the description of icosahedral phases (six symmorphous and five non-symmorphous groups) are listed in Table 4.6.3.2. These space groups are a subset of all 6D icosahedral space groups fulfilling the condition that the 6D point groups they are associated with are isomorphous to the 3D point groups $\frac{2}{m}\bar{3}\bar{5}$ and 235 describing the diffraction symmetry. From 826 6D (analogues to) Bravais groups (Levitov & Rhyner, 1988), only three fulfil the condition that the projection of the 6D hypercubic lattice upon the 3D physical space is compatible with the icosahedral point groups $\frac{2}{m}\bar{3}\bar{5}$, 235: the primitive hypercubic Bravais lattice P, the body-centred Bravais lattice I with translation 1/2(111111), and the face-centred Bravais lattice F with translations 1/2(110000) + 14 further cyclic permutations. Hence, the I lattice is twofold primitive (*i.e.* it contains two vertices per unit cell) and the F lattice is 16-fold primitive. The orientation of the symmetry elements in the 6D space is defined by the isomorphism of the 3D and 6D point groups. The action of the fivefold rotation, however, is different in the subspaces $\mathbf{V}^{\parallel}$ and $\mathbf{V}^{\perp}$: a rotation of $2\pi/5$ in $\mathbf{V}^{\parallel}$ is correlated with a rotation of $4\pi/5$ in $\mathbf{V}^{\perp}$. The reflection and inversion operations are equivalent in both subspaces.

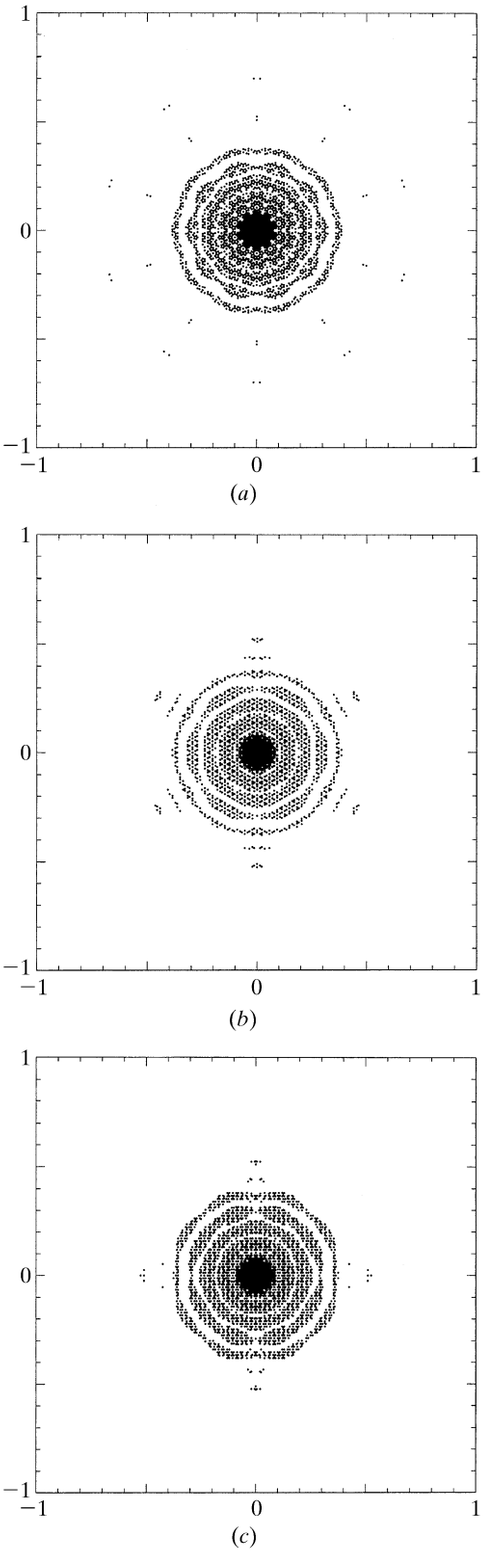

Fig. 4.6.3.34. Perpendicular-space diffraction patterns of the 3D Penrose tiling decorated with point atoms (edge lengths of the Penrose unit rhombohedra a_r = 5.0 Å). Sections with (*a*) five-, (*b*) three- and (*c*) twofold symmetry are shown for the primitive 6D analogue of Bravais type P. All reflections are shown within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $-6 \leq h_i \leq 6, i = 1, \ldots, 6$.

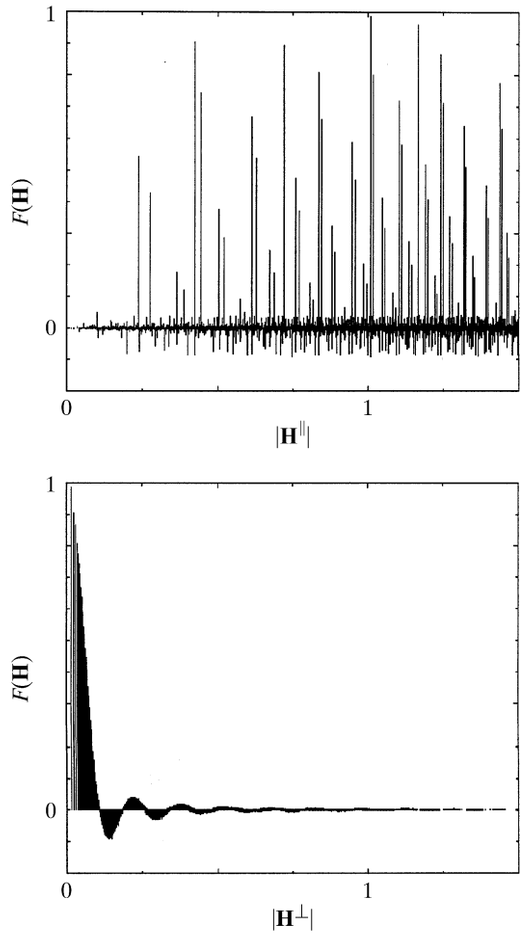

Fig. 4.6.3.35. Radial distribution function of the structure factors $F(\mathbf{H})$ of the 3D Penrose tiling (edge lengths of the Penrose unit rhombohedra $a_r = 5.0$ Å) decorated with point atoms as a function of $|\mathbf{H}^{\parallel}|$ (above) and $|\mathbf{H}^{\perp}|$ (below). All reflections are shown within $10^{-6}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $-6 \le h_i \le 6, i = 1, \ldots, 6$.

4.6.3.3.3.3. Structure factor

The structure factor of the icosahedral phase corresponds to the Fourier transform of the 6D unit cell,

$$F(\mathbf{H}) = \sum_{k=1}^{N} f_k(\mathbf{H}^{\parallel}) T_k(\mathbf{H}^{\parallel}, \mathbf{H}^{\perp}) g_k(\mathbf{H}^{\perp}) \exp(2\pi i \mathbf{H} \cdot \mathbf{r}_k),$$

with 6D diffraction vectors $\mathbf{H} = \sum_{i=1}^{6} h_i \mathbf{d}_i^*$, parallel-space atomic scattering factor $f_k(H^{\parallel})$, temperature factor $T_k(\mathbf{H}^{\parallel}, \mathbf{H}^{\perp})$ and perpendicular-space geometric form factor $g_k(\mathbf{H}^{\perp})$. $T_k(\mathbf{H}^{\parallel}, \mathbf{0})$ is equivalent to the conventional Debye–Waller factor and $T_k(\mathbf{0}, \mathbf{H}^{\perp})$ describes random fluctuations in perpendicular space. These fluctuations cause characteristic jumps of vertices (*phason flips*) in the physical space. Even random phason flips map the vertices onto positions that can still be described by physical-space vectors of the type $\mathbf{r} = \sum_{i=1}^{6} n_i \mathbf{a}_i$. Consequently, the set $M = \{\mathbf{r} = \sum_{i=1}^{6} n_i \mathbf{a}_i | n_i \in \mathbb{Z}\}$ of all possible vectors forms a $\mathbb{Z}$ module. The shape of the atomic surfaces corresponds to a selection rule for the positions actually occupied. The geometric form factor $g_k(\mathbf{H}^{\perp})$ is equivalent to the Fourier transform of the *atomic surface*, *i.e.* the 3D perpendicular-space component of the 6D *hyperatoms*.

For the example of the canonical 3D Penrose tiling, $g_k(\mathbf{H}^{\perp})$ corresponds to the Fourier transform of a triacontahedron:

$$g_k(\mathbf{H}^{\perp}) = (1/A_{\mathrm{UC}}^{\perp}) \int_{A_k} \exp(2\pi i \mathbf{H}^{\perp} \cdot \mathbf{r})\, \mathrm{d}\mathbf{r},$$

where $A_{\mathrm{UC}}^{\perp}$ is the volume of the 6D unit cell projected upon $\mathbf{V}^{\perp}$ and A_k is the volume of the triacontahedron. $A_{\mathrm{UC}}^{\perp}$ and A_k are equal in the present case and amount to the volumes of ten prolate and ten oblate rhombohedra: $A_{\mathrm{UC}}^{\perp} = 8a_r^3[\sin(2\pi/5) + \sin(\pi/5)]$. Evaluating the integral by decomposing the triacontahedron into trigonal pyramids, each one directed from the centre of the triacontahedron to three of its corners given by the vectors $\mathbf{e}_i$, $i = 1, \ldots, 3$, one obtains

$$g(\mathbf{H}^{\perp}) = (1/A_{\mathrm{UC}}^{\perp}) \sum_{R} g_k(R^T \mathbf{H}^{\perp}),$$

with $k = 1, \ldots, 60$ running over all site-symmetry operations R of the icosahedral group,

$$\begin{aligned} g_k(\mathbf{H}^{\perp}) = -iV_r[&A_2A_3A_4 \exp(iA_1) + A_1A_3A_5 \exp(iA_2) \\ &+ A_1A_2A_6 \exp(iA_3) + A_4A_5A_6] \\ &\times (A_1A_2A_3A_4A_5A_6)^{-1}, \end{aligned}$$

$A_j = 2\pi \mathbf{H}^{\perp} \cdot \mathbf{e}_j$, $j = 1, \ldots, 3$, $A_4 = A_2 - A_3$, $A_5 = A_3 - A_1$, $A_6 = A_1 - A_2$ and $V_r = \mathbf{e}_1 \cdot (\mathbf{e}_2 \times \mathbf{e}_3)$ the volume of the parallelepiped defined by the vectors $\mathbf{e}_i$, $i = 1, \ldots, 3$ (Yamamoto, 1992*b*).

4.6.3.3.3.4. Intensity statistics

The radial structure-factor distributions of the 3D Penrose tiling decorated with point scatterers are plotted in Fig. 4.6.3.35 as a function of parallel and perpendicular space. The distribution of $|F(\mathbf{H})|$ as a function of their frequencies clearly resembles a centric distribution, as can be expected from the centrosymmetric unit cell. The shape of the distribution function depends on the radius of the limiting sphere in reciprocal space. The number of weak reflections increases as the power 6, that of strong reflections only as the power 3 (strong reflections always have small $\mathbf{H}^{\perp}$ components).

The weighted reciprocal space of the 3D Penrose tiling contains an infinite number of Bragg reflections within a limited region of the physical space. Contrary to the diffraction pattern of a periodic structure consisting of point atoms on the lattice nodes, the Bragg reflections show intensities depending on the perpendicular-space components of their diffraction vectors.

4.6.3.3.3.5. Relationships between structure factors at symmetry-related points of the Fourier image

The weighted 3D reciprocal space $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{6} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ exhibits the icosahedral point symmetry $K = m\bar{3}5$. It is invariant under the action of the scaling matrix S^3:

$$S = \tfrac{1}{2}\begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & 1 & 1 & -1 \\ 1 & -1 & -1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 & 1 & 1 \end{pmatrix}_D, \quad S^3 = \begin{pmatrix} 2 & 1 & 1 & 1 & 1 & 1 \\ 1 & 2 & 1 & -1 & -1 & 1 \\ 1 & 1 & 2 & 1 & -1 & -1 \\ 1 & -1 & 1 & 2 & 1 & -1 \\ 1 & -1 & -1 & 1 & 2 & 1 \\ 1 & 1 & -1 & -1 & 1 & 2 \end{pmatrix}_D,$$

$$\begin{pmatrix} 2 & 1 & 1 & 1 & 1 & 1 \\ 1 & 2 & 1 & -1 & -1 & 1 \\ 1 & 1 & 2 & 1 & -1 & -1 \\ 1 & -1 & 1 & 2 & 1 & -1 \\ 1 & -1 & -1 & 1 & 2 & 1 \\ 1 & 1 & -1 & -1 & 1 & 2 \end{pmatrix}_D \begin{pmatrix} \mathbf{a}_1^* \\ \mathbf{a}_2^* \\ \mathbf{a}_3^* \\ \mathbf{a}_4^* \\ \mathbf{a}_5^* \\ \mathbf{a}_6^* \end{pmatrix} = \tau^3 \begin{pmatrix} \mathbf{a}_1^* \\ \mathbf{a}_2^* \\ \mathbf{a}_3^* \\ \mathbf{a}_4^* \\ \mathbf{a}_5^* \\ \mathbf{a}_6^* \end{pmatrix}.$$

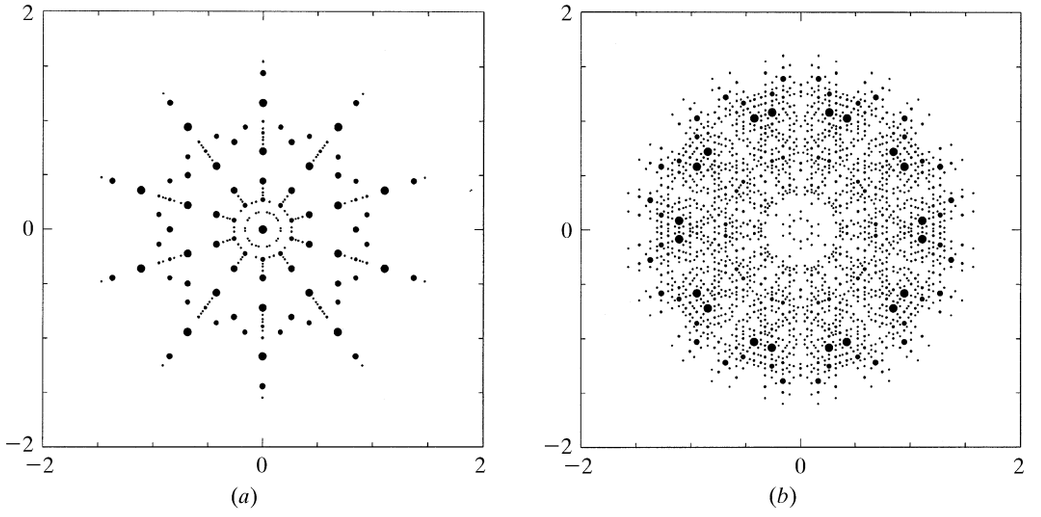

Fig. 4.6.3.36. Parallel-space distribution of (*a*) positive and (*b*) negative structure factors of the 3D Penrose tiling of the 6D *P* lattice type decorated with point atoms (edge lengths of the Penrose unit rhombohedra a_r = 5.0 Å). The magnitudes of the structure factors are indicated by the diameters of the filled circles. All reflections are shown within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $-6 \le h_i \le 6, i = 1, \ldots, 6$.

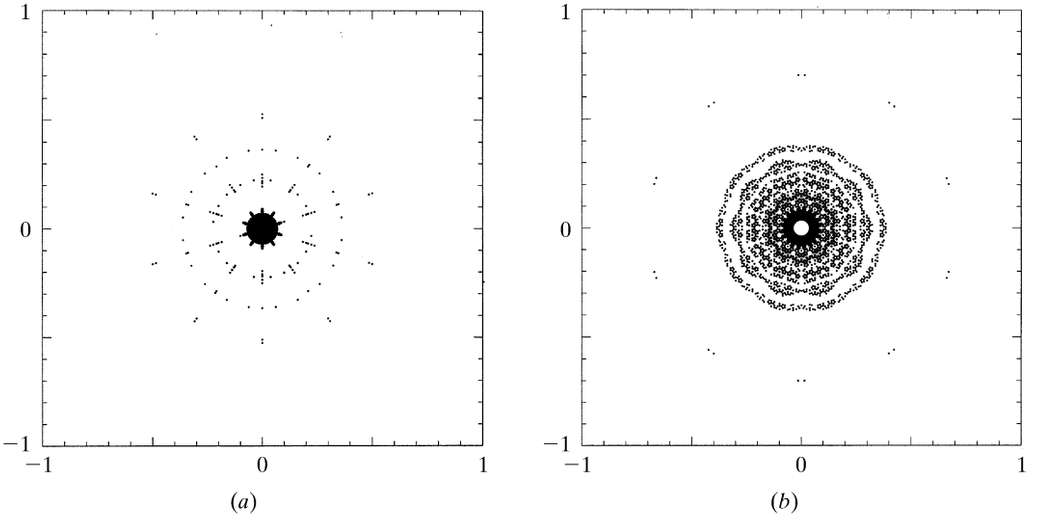

Fig. 4.6.3.37. Perpendicular-space distribution of (*a*) positive and (*b*) negative structure factors of the 3D Penrose tiling of the 6D *P* lattice type decorated with point atoms (edge lengths of the Penrose unit rhombohedra a_r = 5.0 Å). The magnitudes of the structure factors are indicated by the diameters of the filled circles. All reflections are shown within $10^{-4}|F(\mathbf{0})|^2 < |F(\mathbf{H})|^2 < |F(\mathbf{0})|^2$ and $-6 \le h_i \le 6, i = 1, \ldots, 6$.

Table 4.6.4.1. *Intensity statistics of the Fibonacci chain for a total of 161 322 reflections with* $-1000 \le h_i \le 1000$ *and* $0 \le \sin\theta/\lambda \le 2$ Å^{-1}

In the upper line, the number of reflections in the respective interval is given; in the lower line the partial sums $\sum I(\mathbf{H})$ of the intensities $I(\mathbf{H})$ are given as a percentage of the total diffracted intensity. The $F(00)$ reflection is not included in the sums.

	$F(\mathbf{H})/F(\mathbf{H})_{max} \ge 0.1$	$0.1 > F(\mathbf{H})/F(\mathbf{H})_{max} \ge 0.01$	$0.01 > F(\mathbf{H})/F(\mathbf{H})_{max} \ge 0.001$	$F(\mathbf{H})/F(\mathbf{H})_{max} < 0.001$
$0 \le \sin\theta/\lambda \le 0.2$ Å^{-1}	17	148	1505	14 511
$\sum I(\mathbf{H})$	52.53%	2.56%	0.27%	0.03%
$0.2 \le \sin\theta/\lambda \le 0.4$ Å^{-1}	11	107	1066	14 998
$\sum I(\mathbf{H})$	27.03%	2.03%	0.19%	0.02%
$0.4 \le \sin\theta/\lambda \le 0.6$ Å^{-1}	9	64	654	15 456
$\sum I(\mathbf{H})$	9.84%	0.96%	0.12%	0.01%
$0.6 \le \sin\theta/\lambda \le 0.8$ Å^{-1}	6	27	326	15 823
$\sum I(\mathbf{H})$	2.94%	0.34%	0.07%	0.01%
$0.8 \le \sin\theta/\lambda \le 2$ Å^{-1}	1	35	338	96 720
$\sum I(\mathbf{H})$	0.23%	0.79%	0.06%	0.01%
Total sum	44	381	3389	157 508
	92.57%	6.67%	0.70%	0.06%

The scaling transformation $(S^{-3})^T$ leaves a primitive 6D reciprocal lattice invariant as can easily be seen from its application on the indices:

$$\begin{pmatrix} h_1' \\ h_2' \\ h_3' \\ h_4' \\ h_5' \\ h_6' \end{pmatrix} = \begin{pmatrix} -2 & 1 & 1 & 1 & 1 & 1 \\ 1 & -2 & 1 & -1 & -1 & 1 \\ 1 & 1 & -2 & 1 & -1 & -1 \\ 1 & -1 & 1 & -2 & 1 & -1 \\ 1 & -1 & -1 & 1 & -2 & 1 \\ 1 & 1 & -1 & -1 & 1 & -2 \end{pmatrix}_D \begin{pmatrix} h_1 \\ h_2 \\ h_3 \\ h_4 \\ h_5 \\ h_6 \end{pmatrix}.$$

The matrix $(S^{-1})^T$ leaves $M^* = \{\mathbf{H}^{\parallel} = \sum_{i=1}^{6} h_i \mathbf{a}_i^* | h_i \in \mathbb{Z}\}$ invariant,

$$\begin{pmatrix} h_1' \\ h_2' \\ h_3' \\ h_4' \\ h_5' \\ h_6' \end{pmatrix} = \tfrac{1}{2}\begin{pmatrix} -1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & -1 & 1 \\ 1 & 1 & -1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & 1 & -1 \end{pmatrix}_D \begin{pmatrix} h_1 \\ h_2 \\ h_3 \\ h_4 \\ h_5 \\ h_6 \end{pmatrix},$$

for any $\mathbf{H} = \sum_{i=1}^{6} h_i \mathbf{d}_i^*$ with h_i all even or all odd, corresponding to a 6D face-centred hypercubic lattice. In a second case the sum $\sum_{i=1}^{6} h_i$ is even, corresponding to a 6D body-centred hypercubic lattice. Block-diagonalization of the matrix S decomposes it into two irreducible representations. With $WSW^{-1} = S_V = S_V^{\parallel} \oplus S_V^{\perp}$ we obtain

$$S_V = \left(\begin{array}{ccc|ccc} \tau & 0 & 0 & 0 & 0 & 0 \\ 0 & \tau & 0 & 0 & 0 & 0 \\ 0 & 0 & \tau & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & -1/\tau & 0 & 0 \\ 0 & 0 & 0 & 0 & -1/\tau & 0 \\ 0 & 0 & 0 & 0 & 0 & -1/\tau \end{array}\right)_V = \left(\begin{array}{c|c} S^{\parallel} & 0 \\ \hline 0 & S^{\perp} \end{array}\right)_V,$$

the scaling properties in the two 3D subspaces: scaling by a factor τ in parallel space corresponds to a scaling by a factor $(-\tau)^{-1}$ in perpendicular space. For the intensities of the scaled reflections analogous relationships are valid, as discussed for decagonal phases (Figs. 4.6.3.36 and 4.6.3.37, Section 4.6.3.3.2.5).

4.6.4. Experimental aspects of the reciprocal-space analysis of aperiodic crystals

4.6.4.1. Data-collection strategies

Theoretically, aperiodic crystals show an infinite number of reflections within a given diffraction angle, contrary to periodic crystals. The number of reflections to be included in a structure analysis of a *periodic* crystal may be very high (one million for virus crystals, for instance) but there is no ambiguity in the selection of reflections to be collected: all Bragg reflections within a limiting sphere in reciprocal space, usually given by $0 \leq \sin\theta/\lambda \leq 0.7$ Å^{-1}, are used. All reflections, observed and unobserved, are included to fit a reliable structure model.

However, for *aperiodic* crystals it is not possible to collect the infinite number of dense Bragg reflections within $0 \leq \sin\theta/\lambda \leq 0.7$ Å^{-1}. The number of observable reflections within this limiting sphere depends only on the spatial and intensity resolution.

What happens if not all reflections are included in a structure analysis? How important is the contribution of reflections with large perpendicular-space components of the diffraction vector which are weak but densely distributed? These problems are illustrated using the example of the Fibonacci sequence. An infinite model structure consisting of Al atoms with isotropic thermal parameter $B = 1$ Å^2, and distances S = 2.5 Å and L = τS, was used for the calculations (Table 4.6.4.1).

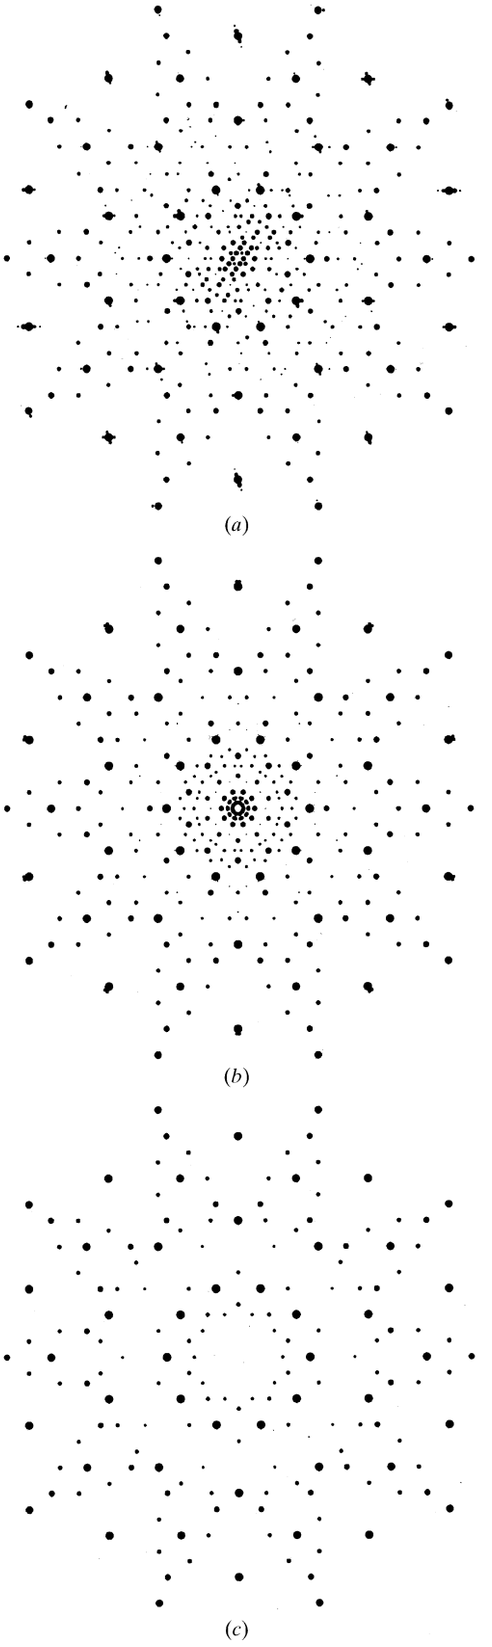

Fig. 4.6.4.1. Simulated diffraction patterns of (*a*) the $\simeq 52$ Å single-crystal approximant of decagonal Al–Co–Ni, (*b*) the fivefold twinned approximant, and (*c*) the decagonal phase itself (Estermann *et al.*, 1994).

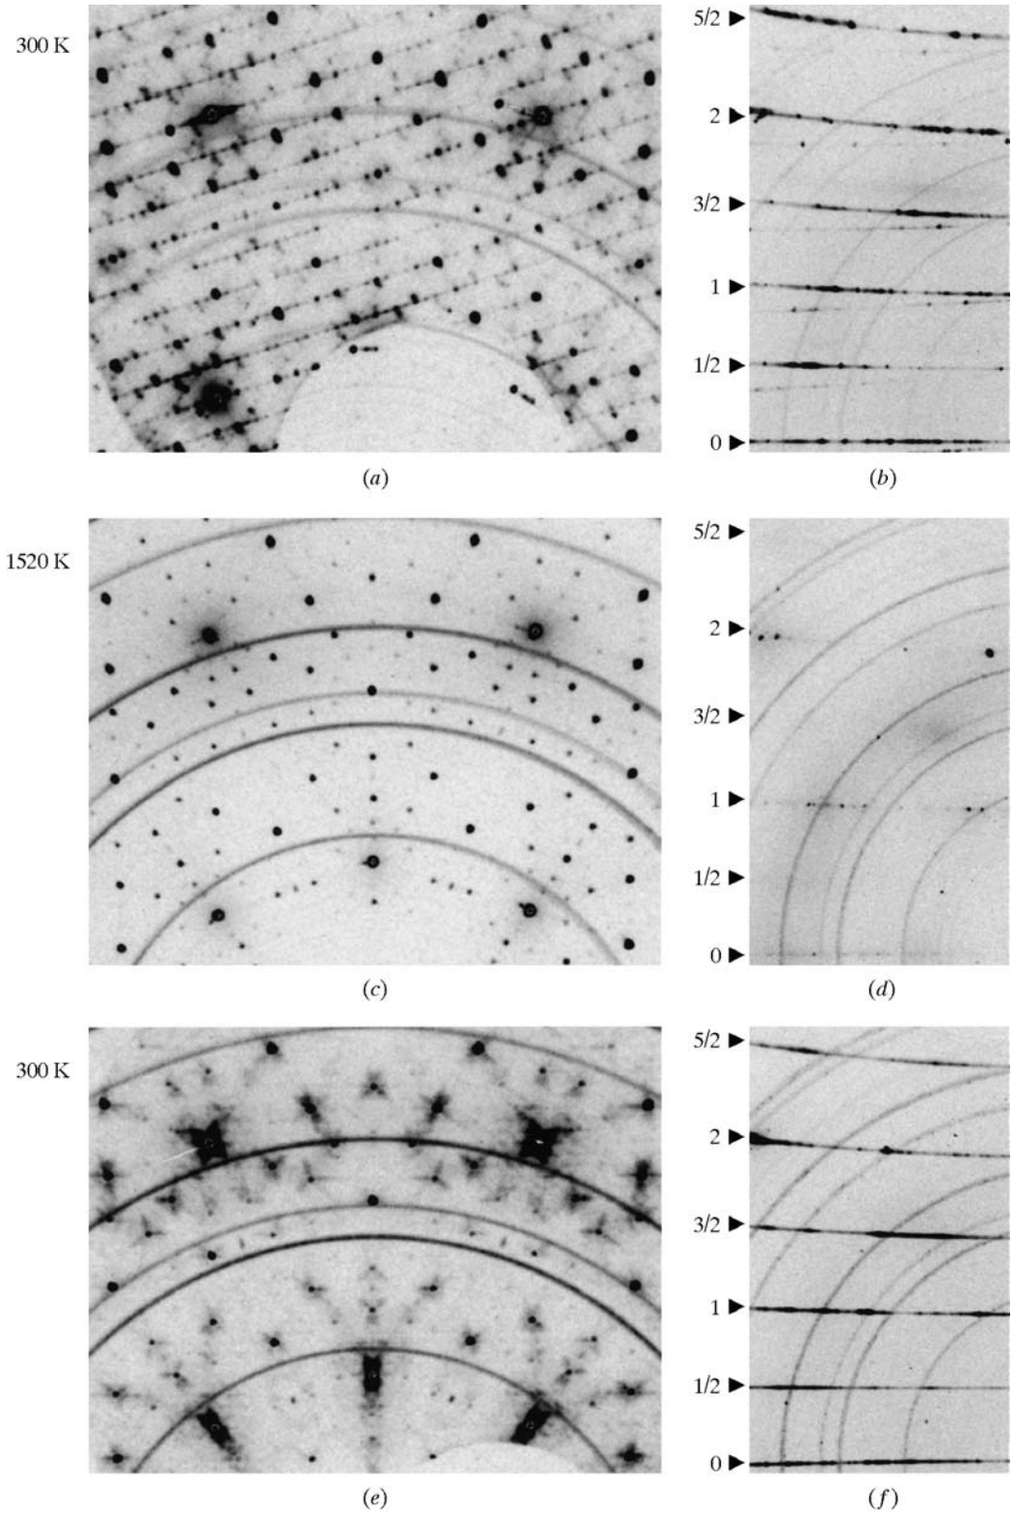

Fig. 4.6.4.2. Zero-layer X-ray diffraction patterns of decaprismatic $Al_{73.5}C_{21.7}Ni_{4.8}$ crystals taken parallel and perpendicular to the crystal axis on an image-plate scanner (Mar Research) at different temperatures. In (*a*) and (*b*), room-temperature (RT) diffraction patterns from a sample quenched after annealing at 1073 K are shown. Reflections from both a crystalline approximant and a decagonal phase are visible. The period along the unique direction in the decagonal phase and the corresponding period in the approximant phase is $\simeq 8$ Å (*b*). At 1520 K, a single-phase decagonal quasicrystal is present with $\simeq 4$ Å fundamental structure (*c*, *d*). In (*e*, *f*), the RT diffraction patterns of the slowly cooled sample indicate a single-phase nanodomain structure with $\simeq 8$ Å periodicity along the unique direction.

It turns out that 92.6% of the total diffracted intensity of 161 322 reflections is included in the 44 strongest reflections and 99.2% in the strongest 425 reflections. It is remarkable, however, that in all the experimental data for icosahedral and decagonal quasicrystals collected so far, rarely more than 20 to 50 reflections along reciprocal-lattice lines corresponding to net planes with Fibonacci-sequence-like distances could be observed. The consequences for structure determinations with such truncated data sets are primarily a lower resolution in perpendicular space than in physical space. This corresponds to a smearing of the hyperatoms in the perpendicular space. For the derivation of the local structure-building elements (clusters) of aperiodic crystals this is only a minor problem: the smeared hyperatoms give rise to split atoms and a biased electron-density distribution. The information on the global aperiodic structure, however, which is contained in the detailed shape of the atomic surfaces, is severely

reduced when using a low-resolution diffraction data set. A combination of high-resolution electron microscopy, lattice imaging and diffraction techniques allows a good characterization of the local and global order even in these cases. For a more detailed analysis of these problems see Steurer (1995).

4.6.4.2. Commensurability versus incommensurability

The question whether an aperiodic crystal is really aperiodic or rather a high-order approximant is of different importance depending on the point of view. As far as real finite crystals are considered, definitions of *periodic* and *aperiodic real crystals* and of *periodic* and *aperiodic perfect crystals* have to be given first. *Real crystals*, despite periodicity or aperiodicity, are the actual samples under investigation. Partial information about their actual structure can be obtained today by imaging methods (scanning tunnelling microscopy, atomic force microscopy, high-resolution transmission electron microscopy, ...). Basically, the real crystal structure can be determined using full diffraction information from Bragg and diffuse scattering. In practice, however, only 'Bragg reflections' are included in a structure analysis. 'Bragg reflections' result from the integration of diffraction intensities from extended volumes around a limited number of Bragg-reflection positions ($\mathbb{Z}$ module). This process of intensity condensation at Bragg points corresponds in direct space to an averaging process. The real crystal structure is projected upon one unit cell in direct space defined by the $\mathbb{Z}$ module in reciprocal space. Generally, the identification of appropriate reciprocal-space metrics is not a problem in the case of crystals. It can be problematic, however, in the case of aperiodic crystals, in particular quasicrystals (see Lancon *et al.*, 1994). The metrics, and to some extent the global order in the case of quasicrystals, are fixed by assigning the reciprocal basis. The spatial resolution of a diffraction experiment defines the accuracy of the resulting metrics. The decision whether the rational number obtained for the relative length of a satellite vector indicates a commensurate or an incommensurate modulation can only be made considering temperature- and pressure-dependent chemical and physical properties of the material. The same is valid for other types of aperiodic crystals.

4.6.4.3. Twinning and nanodomain structures

High-order approximants of quasicrystals often occur in orientationally twinned form or, on a smaller scale, as oriented nanodomain structures. These structures can be identified by electron microscopy, and, in certain cases, also by high-resolution X-ray diffractometry (Kalning *et al.*, 1994). If the intensity and spatial resolution is sufficient, characteristic reflection splitting and diffuse diffraction phenomena can be observed. It has been demonstrated that for the determination of the local structure (structure-building elements) it does not matter greatly whether one uses a data set for a real quasicrystal or one for a twinned approximant (Estermann *et al.*, 1994). Examples of reciprocal-space images of an approximant, a twinned approximant and the related decagonal phase are shown schematically in Fig. 4.6.4.1 and for real samples in Fig. 4.6.4.2.

5.1. Dynamical theory of X-ray diffraction

By A. Authier

5.1.1. Introduction

The first experiment on X-ray diffraction by a crystal was performed by W. Friedrich, P. Knipping and M. von Laue in 1912 and Bragg's law was derived in 1913 (Bragg, 1913). Geometrical and dynamical theories for the intensities of the diffracted X-rays were developed by Darwin (1914*a*,*b*). His dynamical theory took into account the interaction of X-rays with matter by solving recurrence equations that describe the balance of partially transmitted and partially reflected amplitudes at each lattice plane. This is the first form of the dynamical theory of X-ray diffraction. It gives correct expressions for the reflected intensities and was extended to the absorbing-crystal case by Prins (1930). A second form of dynamical theory was introduced by Ewald (1917) as a continuation of his previous work on the diffraction of optical waves by crystals. He took into account the interaction of X-rays with matter by considering the crystal to be a periodic distribution of dipoles which were excited by the incident wave. This theory also gives the correct expressions for the reflected and transmitted intensities, and it introduces the fundamental notion of a wavefield, which is necessary to understand the propagation of X-rays in perfect or deformed crystals. Ewald's theory was later modified by von Laue (1931), who showed that the interaction could be described by solving Maxwell's equations in a medium with a continuous, triply periodic distribution of dielectric susceptibility. It is this form which is most widely used today and which will be presented in this chapter.

The geometrical (or kinematical) theory, on the other hand, considers that each photon is scattered only once and that the interaction of X-rays with matter is so small it can be neglected. It can therefore be assumed that the amplitude incident on every diffraction centre inside the crystal is the same. The total diffracted amplitude is then simply obtained by adding the individual amplitudes diffracted by each diffracting centre, taking into account only the geometrical phase differences between them and neglecting the interaction of the radiation with matter. The result is that the distribution of diffracted amplitudes in reciprocal space is the Fourier transform of the distribution of diffracting centres in physical space. Following von Laue (1960), the expression *geometrical theory* will be used throughout this chapter when referring to these geometrical phase differences.

The first experimentally measured reflected intensities were not in agreement with the theoretical values obtained with the more rigorous dynamical theory, but rather with the simpler geometrical theory. The integrated reflected intensities calculated using geometrical theory are proportional to the square of the structure factor, while the corresponding expressions calculated using dynamical theory for an infinite perfect crystal are proportional to the modulus of the structure factor. The integrated intensity calculated by geometrical theory is also proportional to the volume of the crystal bathed in the incident beam. This is due to the fact that one neglects the decrease of the incident amplitude as it progresses through the crystal and a fraction of it is scattered away. According to geometrical theory, the diffracted intensity would therefore increase to infinity if the volume of the crystal was increased to infinity, which is of course absurd. The theory only works because the strength of the interaction is very weak and if it is applied to very small crystals. How small will be shown quantitatively in Sections 5.1.6.5 and 5.1.7.2. Darwin (1922) showed that it can also be applied to large imperfect crystals. This is done using the model of mosaic crystals (Bragg *et al.*, 1926). For perfect or nearly perfect crystals, dynamical theory should be used. Geometrical theory presents another drawback: it gives no indication as to the phase of the reflected wave. This is due to the fact that it is based on the Fourier transform of the electron density limited by the external shape of the crystal. This is not important when one is only interested in measuring the reflected intensities. For any problem where the phase is important, as is the case for multiple reflections, interference between coherent blocks, standing waves *etc.*, dynamical theory should be used, even for thin or imperfect crystals.

Until the 1940s, the applications of dynamical theory were essentially intensity measurements. From the 1950s to the 1970s, applications were related to the properties (absorption, interference, propagation) of wavefields in perfect or nearly perfect crystals: anomalous transmission, diffraction of spherical waves, interpretation of images on X-ray topographs, accurate measurement of form factors, lattice-parameter mapping. In recent years, they have been concerned mainly with crystal optics, focusing and the design of monochromators for synchrotron radiation [see, for instance, Batterman & Bilderback (1991)], the location of atoms at crystal surfaces and interfaces using the standing-waves method, determination of phases using multiple reflections [for reviews of *n*-beam diffraction, see Weckert & Hümmer (1997) and Chang (2004); for recent determinations of phases, see Chang *et al.* (2002), Mo *et al.* (2002), Weckert *et al.* (2002), Shen & Wang (2003)], characterization of the crystal perfection of epilayers and superlattices by high-resolution diffractometry [see, for instance, Tanner (1990) and Fewster (1993)], *etc.*

Modern developments include the extension of dynamical theory to time-dependent phenomena (Chukhovskii & Förster, 1995; Shastri *et al.*, 2001; Graeff, 2002*a*,*b*, 2004; Malgrange & Graeff, 2003; Sondhauss & Wark, 2003; Adams, 2004) and the study of the influence of the coherence of the source (Yamazaki & Ishikawa, 2002, 2004).

For reviews of dynamical theory, see Zachariasen (1945), von Laue (1960), James (1963), Batterman & Cole (1964), Authier (1970), Kato (1974), Brümmer & Stephanik (1976), Pinsker (1978), Authier *et al.* (1996), Authier & Malgrange (1998), and Authier (2005). Topography is described in Chapter 2.7 of *IT* C (2004), in Tanner (1976) and in Tanner & Bowen (1992). For the use of Bragg-angle measurements for accurate lattice-parameter mapping, see Hart (1981). For online calculations in the case of multiple diffraction, grazing incidence or for strained crystals, see http://sergey.gmca.aps.anl.gov.

A reminder of some basic concepts in electrodynamics is given in Section A5.1.1.1 of the Appendix.

5.1.2. Fundamentals of plane-wave dynamical theory

5.1.2.1. Propagation equation

The wavefunction Ψ associated with an electron or a neutron beam is *scalar* while an electromagnetic wave is a *vector* wave. When propagating in a medium, these waves are solutions of a *propagation equation*. For electrons and neutrons, this is Schrödinger's equation, which can be rewritten as

$$\Delta\Psi + 4\pi^2 k^2(1+\chi)\Psi = 0, \qquad (5.1.2.1)$$

Copyright © 2010 International Union of Crystallography

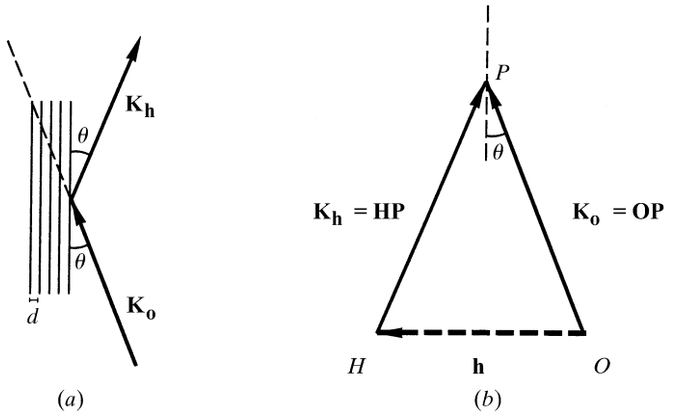

Fig. 5.1.2.1. Bragg reflection. (*a*) Direct space. Bragg reflection of a wave of wavevector $\mathbf{K_o}$ incident on a set of lattice planes of spacing d. The reflected wavevector is $\mathbf{K_h}$. Bragg's law $2d\sin\theta = n\lambda$ can also be written $2d_{hkl}\sin\theta = \lambda$, where $d_{hkl} = d/n = 1/OH = 1/h$ is the inverse of the length of the corresponding reciprocal-lattice vector $\mathbf{OH} = \mathbf{h}$ (see part *b*). (*b*) Reciprocal space. P is the tie point of the wavefield consisting of the incident wave $\mathbf{K_o} = \mathbf{OP}$ and the reflected wave $\mathbf{K_h} = \mathbf{HP}$. Note that the wavevectors are oriented *towards* the tie point.

where $k = 1/\lambda$ is the wavenumber in a vacuum, $\chi = \varphi/W$ (φ is the potential in the crystal and W is the accelerating voltage) in the case of electron diffraction and $\chi = -2mV(\mathbf{r})/h^2k^2$ [$V(\mathbf{r})$ is the Fermi pseudo-potential and h is Planck's constant] in the case of neutron diffraction. The dynamical theory of electron diffraction is treated in Chapter 5.2 [note that a different convention is used in Chapter 5.2 for the scalar wavenumber: $k = 2\pi/\lambda$; compare, for example, equation (5.2.2.1) and its equivalent, equation (5.1.2.1)] and the dynamical theory of neutron diffraction is treated in Chapter 5.3.

In the case of X-rays, the propagation equation is deduced from Maxwell's equations after neglecting the interaction with protons. Following von Laue (1931, 1960), it is assumed that the positive charge of the nuclei is distributed in such a way that the medium is everywhere locally neutral and that there is no current. As a first approximation, magnetic interaction, which is very weak, is not taken into account in this review. The propagation equation is derived in Section A5.1.1.2 of the Appendix. Expressed in terms of the local electric displacement, $\mathbf{D}(\mathbf{r})$, it is given for monochromatic waves by

$$\Delta\mathbf{D}(\mathbf{r}) + \text{ curl curl } \chi\mathbf{D}(\mathbf{r}) + 4\pi^2k^2\mathbf{D}(\mathbf{r}) = 0. \qquad (5.1.2.2)$$

The interaction of X-rays with matter is characterized in equation (5.1.2.2) by the parameter χ, which is the dielectric susceptibility. It is classically related to the electron density $\rho(\mathbf{r})$ by

$$\chi(\mathbf{r}) = -R\lambda^2\rho(\mathbf{r})/\pi, \qquad (5.1.2.3)$$

where $R = 2.81794 \times 10^{-6}$ nm is the classical radius of the electron [see equation (A5.1.1.2) in Section A5.1.1.2 of the Appendix].

The dielectric susceptibility, being proportional to the electron density, is triply periodic in a crystal. It can therefore be expanded in Fourier series:

$$\chi = \sum_{\mathbf{h}} \chi_h \exp(2\pi i\mathbf{h}\cdot\mathbf{r}), \qquad (5.1.2.4)$$

where $\mathbf{h}$ is a reciprocal-lattice vector and the summation is extended over all reciprocal-lattice vectors. The sign convention adopted here for Fourier expansions of periodic functions is the *standard crystallographic* sign convention defined in Section 2.5.2.3. The relative orientations of wavevectors and reciprocal-lattice vectors are defined in Fig. 5.1.2.1, which represents schematically a Bragg reflection in direct and reciprocal space (Figs. 5.1.2.1*a* and 5.1.2.1*b*, respectively).

The coefficients χ_h of the Fourier expansion of the dielectric susceptibility are related to the usual structure factor F_h by

$$\chi_h = -R\lambda^2F_h/(\pi V), \qquad (5.1.2.5)$$

where V is the volume of the unit cell and the structure factor is given by

$$\begin{aligned} F_h &= \sum_j (f_j + f_j' + if_j'')\exp(-M_j - 2\pi i\mathbf{h}\cdot\mathbf{r}_j) \\ &= |F_h|\exp(i\varphi_h). \end{aligned} \qquad (5.1.2.6)$$

f_j is the form factor of atom j, f_j' and f_j'' are the dispersion corrections [see, for instance, *IT* C, Section 4.2.6] and $\exp(-M_j)$ is the Debye–Waller factor. The summation is over all the atoms in the unit cell. The phase φ_h of the structure factor depends of course on the choice of origin of the unit cell. The Fourier coefficients χ_h are dimensionless. Their order of magnitude varies from 10^{-5} to 10^{-7} depending on the wavelength and the structure factor. For example, χ_h is -9.24×10^{-6} for the 220 reflection of silicon for Cu $K\alpha$ radiation.

In an absorbing crystal, absorption is taken into account phenomenologically through the imaginary parts of the index of refraction and of the wavevectors. The dielectric susceptibility is written

$$\chi = \chi_\mathrm{r} + i\chi_\mathrm{i}. \qquad (5.1.2.7)$$

The real and imaginary parts of the susceptibility are triply periodic in a crystalline medium and can be expanded in a Fourier series,

$$\begin{aligned} \chi_\mathrm{r} &= \sum_{\mathbf{h}} \chi_{\mathrm{r}h}\exp(2\pi i\mathbf{h}\cdot\mathbf{r}) \\ \chi_\mathrm{i} &= \sum_{\mathbf{h}} \chi_{\mathrm{i}h}\exp(2\pi i\mathbf{h}\cdot\mathbf{r}), \end{aligned} \qquad (5.1.2.8)$$

where

$$\begin{aligned} \chi_{\mathrm{r}h} &= -R\lambda^2F_{\mathrm{r}h}/(\pi V), \\ \chi_{\mathrm{i}h} &= -R\lambda^2F_{\mathrm{i}h}/(\pi V) \end{aligned} \qquad (5.1.2.9)$$

and

$$\begin{aligned} F_{\mathrm{r}h} &= \sum_j (f_j + f_j')\exp(-M_j - 2\pi i\mathbf{h}\cdot\mathbf{r}_j) \\ &= |F_{\mathrm{r}h}|\exp(i\varphi_{\mathrm{r}h}), \qquad (5.1.2.10a) \\ F_{\mathrm{i}h} &= \sum_j (f_j'')\exp(-M_j - 2\pi i\mathbf{h}\cdot\mathbf{r}_j) \\ &= |F_{\mathrm{i}h}|\exp(i\varphi_{\mathrm{i}h}). \qquad (5.1.2.10b) \end{aligned}$$

It is important to note that

$$F_{\mathrm{r}h}^* = F_{\mathrm{r}\bar{\mathbf{h}}} \text{ and } F_{\mathrm{i}h}^* = F_{\mathrm{i}\bar{\mathbf{h}}} \text{ but that } F_h^* \neq F_{\bar{\mathbf{h}}}, \qquad (5.1.2.11)$$

where f^* is the imaginary conjugate of f.

The *index of refraction* of the medium for X-rays is

$$n = 1 + \chi_{ro}/2 = 1 - R\lambda^2 F_o/(2\pi V), \qquad (5.1.2.12)$$

where F_o/V is the number of electrons per unit volume. This index is very slightly smaller than one. It is for this reason that specular reflection of X-rays takes place at grazing angles. From the value of the critical angle, $(-\chi_{ro})^{1/2}$, the electron density F_o/V of a material can be determined.

The linear absorption coefficient is

$$\mu_o = -2\pi k \chi_{io} = 2R\lambda F_{io}/V. \qquad (5.1.2.13)$$

For example, it is 143.2 cm^{-1} for silicon and Cu $K\alpha$ radiation.

5.1.2.2. Wavefields

The notion of a wavefield, introduced by Ewald (1917), is one of the most fundamental concepts in dynamical theory. It results from the fact that since the propagation equation (5.1.2.2) is a second-order partial differential equation with a periodic interaction coefficient, its solution has the same periodicity,

$$\mathbf{D} = \exp(-2\pi i \mathbf{K_o} \cdot \mathbf{r}) \sum_{\mathbf{h}} \mathbf{D_h} \exp(2\pi i \mathbf{h} \cdot \mathbf{r}), \qquad (5.1.2.14)$$

where the summation is over all reciprocal-lattice vectors **h**. Equation (5.1.2.14) can also be written

$$\mathbf{D} = \sum_{\mathbf{h}} \mathbf{D_h} \exp(-2\pi i \mathbf{K_h} \cdot \mathbf{r}), \qquad (5.1.2.15)$$

where

$$\mathbf{K_h} = \mathbf{K_o} - \mathbf{h}. \qquad (5.1.2.16)$$

Expression (5.1.2.15) shows that the solution of the propagation equation can be interpreted as an infinite sum of plane waves with amplitudes $\mathbf{D_h}$ and wavevectors $\mathbf{K_h}$. This sum is a *wavefield*, or *Ewald wave*. The same expression is used to describe the propagation of any wave in a periodic medium, such as phonons or electrons in a solid. Expression (5.1.2.14) was later called a *Bloch wave* by solid-state physicists.

The wavevectors in a wavefield are deduced from one another by translations of the reciprocal lattice [expression (5.1.2.16)]. They can be represented geometrically as shown in Fig. 5.1.2.1(*b*). The wavevectors $\mathbf{K_o} = \mathbf{OP}$; $\mathbf{K_h} = \mathbf{HP}$ are drawn *away* from reciprocal-lattice points. Their common extremity, *P*, called the *tie point* by Ewald, characterizes the wavefield.

In an absorbing crystal, wavevectors have an imaginary part,

$$\mathbf{K_o} = \mathbf{K_{or}} + i\mathbf{K_{oi}}; \quad \mathbf{K_h} = \mathbf{K_{hr}} + i\mathbf{K_{hi}},$$

and (5.1.2.16) shows that all wavevectors have the same imaginary part,

$$\mathbf{K_{oi}} = \mathbf{K_{hi}}, \qquad (5.1.2.17)$$

and therefore undergo the same absorption. This is one of the most important properties of wavefields.

The first experimental evidence of the physical existence of Ewald's wavefields is to be found in the light–dark structure of Kossel lines, observed by Borrmann (1936) and explained by von Laue (1937) using the properties of the standing waves formed by the wavefields inside the crystal. It was followed by the discovery of anomalous absorption (Borrmann, 1941, 1950) and the theoretical determination of the wavefield trajectories (von Laue, 1952; Kato, 1952, 1958; Ewald, 1958), which was confirmed by the experimental observation of spherical wave *Pendellösung* (Kato & Lang, 1959) and by that of the double refraction of X-rays, predicted by Borrmann (1955) and observed by Authier (1960, 1961).

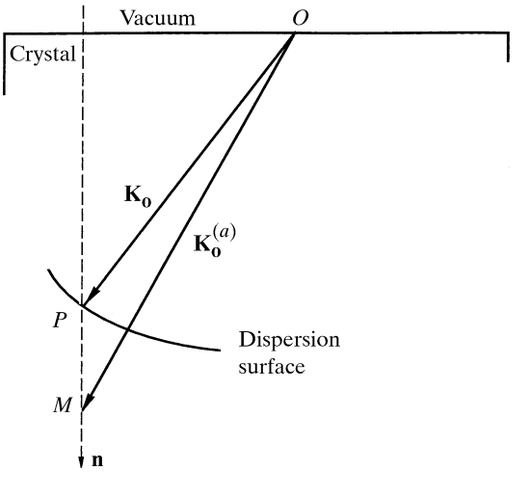

Fig. 5.1.2.2. Boundary condition for wavevectors at the entrance surface of the crystal.

5.1.2.3. Boundary conditions at the entrance surface

The choice of the '**o**' component of expansion (5.1.2.15) is arbitrary in an infinite medium. In a semi-infinite medium where the waves are created at the interface with a vacuum or air by an incident plane wave with wavevector $\mathbf{K_o^{(a)}}$ (using von Laue's notation), the choice of $\mathbf{K_o}$ is determined by the boundary conditions.

This condition for wavevectors at an interface demands that their tangential components should be continuous across the boundary, in agreement with Descartes–Snell's law. This condition is satisfied when the difference between the wavevectors on each side of the interface is parallel to the normal to the interface. This is shown geometrically in Fig. 5.1.2.2 and formally in (5.1.2.18):

$$\mathbf{K_o} - \mathbf{K_o^{(a)}} = \mathbf{OP} - \mathbf{OM} = \overline{MP} \cdot \mathbf{n}, \qquad (5.1.2.18)$$

where **n** is a unit vector normal to the crystal surface, oriented towards the inside of the crystal.

There is no absorption in a vacuum and the incident wavevector $\mathbf{K_o^{(a)}}$ is real. Equation (5.1.2.18) shows that it is the component normal to the interface of wavevector $\mathbf{K_o}$ which has an imaginary part,

$$\mathbf{K_{oi}} = \mathcal{I}(\overline{MP}) \cdot \mathbf{n} = -\mu \mathbf{n}/(4\pi\gamma_o), \qquad (5.1.2.19)$$

where $\mathcal{I}(f)$ is the imaginary part of f, $\gamma_o = \cos(\mathbf{n} \cdot \mathbf{s_o})$ and $\mathbf{s_o}$ is a unit vector in the incident direction. When there is more than one wave in the wavefield, the effective absorption coefficient μ can differ significantly from the normal value, μ_o, given by (5.1.2.13) – see Section 5.1.5.

5.1.2.4. Fundamental equations of dynamical theory

In order to obtain the solution of dynamical theory, one inserts expansions (5.1.2.15) and (5.1.2.4) into the propagation equation (5.1.2.2). This leads to an equation with an infinite sum of terms. It is shown to be equivalent to an infinite system of linear equations which are the *fundamental equations* of dynamical

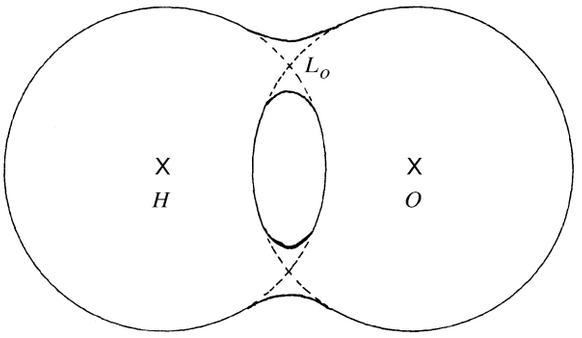

Fig. 5.1.2.3. Intersection of the dispersion surface with the plane of incidence. The dispersion surface is a connecting surface between the two spheres centred at reciprocal-lattice points O and H and with radius nk. L_o is the Lorentz point.

theory. Only those terms in (5.1.2.15) whose wavevector magnitudes K_h are very close to the vacuum value, k, have a non-negligible amplitude. These wavevectors are associated with reciprocal-lattice points that lie very close to the Ewald sphere. Far from any Bragg reflection, their number is equal to 1 and a single plane wave propagates through the medium. In general, for X-rays, there are only two reciprocal-lattice points on the Ewald sphere. This is the so-called *two-beam* case to which this treatment is limited. There are, however, many instances where several reciprocal-lattice points lie simultaneously on the Ewald sphere. This corresponds to the *many-beam* case which has interesting applications for the determination of phases of reflections [see, for instance, Chang (1987, 2004), Hümmer & Weckert (1995) and Weckert & Hümmer (1997)]. On the other hand, for electrons, there are in general many reciprocal-lattice points close to the Ewald sphere and many wavefields are excited simultaneously (see Chapter 5.2).

In the two-beam case, for reflections that are not highly asymmetric and for Bragg angles that are not close to $\pi/2$, the fundamental equations of dynamical theory reduce to

$$\begin{aligned} 2X_oD_o - kC\chi_{\bar{h}}D_h &= 0 \\ -kC\chi_hD_o + 2X_hD_h &= 0, \end{aligned} \qquad (5.1.2.20)$$

where $C = 1$ if $\mathbf{D_h}$ is normal to the $\mathbf{K_o}$, $\mathbf{K_h}$ plane and $C = \cos 2\theta$ if $\mathbf{D_h}$ lies in the plane; this is due to the fact that the amplitude with which electromagnetic radiation is scattered is proportional to the sine of the angle between the direction of the electric vector of the incident radiation and the direction of scattering (see, for instance, *IT* C, Section 6.2.2). The polarization of an electromagnetic wave is classically related to the orientation of the electric vector; in dynamical theory it is that of the electric displacement which is considered (see Section A5.1.1.3 of the Appendix).

The system (5.1.2.20) is therefore a system of four equations which admits four solutions, two for each direction of polarization. In the *non-absorbing* case, to a very good approximation,

$$\begin{aligned} X_o &= K_o - nk, \\ X_h &= K_h - nk. \end{aligned} \qquad (5.1.2.21)$$

In the case of an *absorbing crystal*, X_o and K_h are complex. Equation (5.1.5.2) gives the full expression for X_o.

5.1.2.5. Dispersion surface

The fundamental equations (5.1.2.20) of dynamical theory are a set of linear homogeneous equations whose unknowns are the amplitudes of the various waves which make up a wavefield. For the solution to be nontrivial, the determinant of the set must be set equal to zero. This provides a secular equation relating the magnitudes of the wavevectors of a given wavefield. This equation is that of the locus of the tie points of all the wavefields that may propagate in the crystal with a given frequency. This locus is called the *dispersion surface*. It is a constant-energy surface and is the equivalent of the index surface in optics. It is the X-ray analogue of the constant-energy surfaces known as Fermi surfaces in the electron band theory of solids.

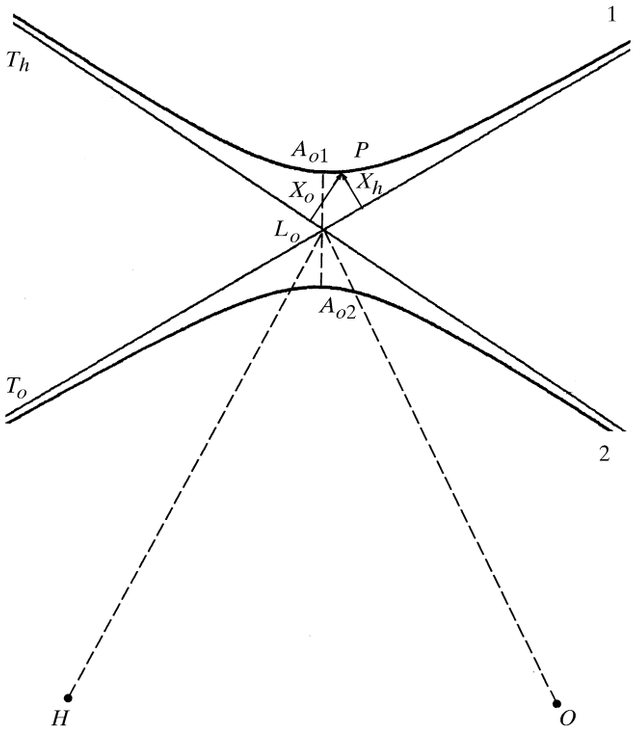

Fig. 5.1.2.4. Intersection of the dispersion surface with the plane of incidence shown in greater detail. The Lorentz point L_o is far away from the nodes O and H of the reciprocal lattice: $OL_o = HL_o = 1/\lambda$ is about 10^5 to 10^6 times larger than the diameter $A_{o1}A_{o2}$ of the dispersion surface.

In the two-beam case, the dispersion surface is a surface of revolution around the diffraction vector **OH**. It is made from two spheres and a connecting surface between them. The two spheres are centred at O and H and have the same radius, nk. Fig. 5.1.2.3 shows the intersection of the dispersion surface with a plane passing through **OH**. When the tie point lies on one of the two spheres, far from their intersection, only one wavefield propagates inside the crystal. When it lies on the connecting surface, two waves are excited simultaneously. The equation of this surface is obtained by equating to zero the determinant of system (5.1.2.20):

$$X_oX_h = k^2C^2\chi_h\chi_{\bar{h}}/4. \qquad (5.1.2.22)$$

Equations (5.1.2.21) show that, in the zero-absorption case, X_o and X_h are to be interpreted as the distances of the tie point P from the spheres centred at O and H, respectively. From (5.1.2.20) it can be seen that they are of the order of the vacuum wavenumber times the Fourier coefficient of the dielectric susceptibility, that is five or six orders of magnitude smaller than k. The two spheres can therefore be replaced by their tangential planes. Equation (5.1.2.22) shows that the product of the distances of the tie point from these planes is constant. The intersection of the dispersion surface with the plane passing through **OH** is therefore a hyperbola (Fig. 5.1.2.4) whose diameter [using (5.1.2.5) and (5.1.2.22)] is

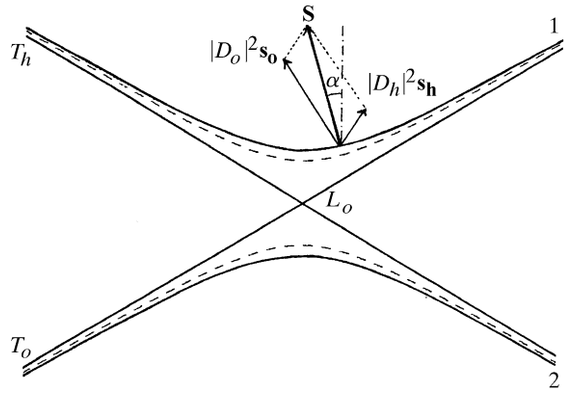

Fig. 5.1.2.5. Dispersion surface for the two states of polarization. Solid curve: polarization normal to the plane of incidence ($C = 1$); broken curve: polarization parallel to the plane of incidence ($C = \cos 2\theta$). The direction of propagation of the energy of the wavefields is along the Poynting vector, **S**, normal to the dispersion surface.

$$\overline{A_{o2}A_{o1}} = |C|R\lambda(F_hF_{\bar{h}})^{1/2}/(\pi V\cos\theta). \qquad (5.1.2.23)$$

It can be noted that the larger the diameter of the dispersion surface, the larger the structure factor, that is, the stronger the interaction of the waves with the matter. When the polarization is parallel to the plane of incidence ($C = \cos 2\theta$), the interaction is weaker.

The asymptotes T_o and T_h to the hyperbola are tangents to the circles centred at O and H, respectively. Their intersection, L_o, is called the *Lorentz point* (Fig. 5.1.2.4).

A wavefield propagating in the crystal is characterized by a tie point P on the dispersion surface and two waves with wavevectors $\mathbf{K_o} = \mathbf{OP}$ and $\mathbf{K_h} = \mathbf{HP}$, respectively. The ratio, ξ, of their amplitudes D_h and D_o is given by means of (5.1.2.20):

$$\xi = \frac{D_h}{D_o} = \frac{2X_o}{kC\chi_{\bar{h}}} = \frac{-2\pi VX_o}{R\lambda CF_{\bar{h}}}. \qquad (5.1.2.24)$$

The hyperbola has two branches, 1 and 2, for each direction of polarization, that is, for $C = 1$ or $\cos 2\theta$ (Fig. 5.1.2.5). Branch 2 is the one situated on the same side of the asymptotes as the reciprocal-lattice points O and H. Given the orientation of the wavevectors, which has been chosen away from the reciprocal-lattice points (Fig. 5.1.2.1*b*), the coordinates of the tie point, X_o and X_h, are positive for branch 1 and negative for branch 2. The phase of ξ is therefore equal to $\pi + \varphi_h$ and to φ_h for the two branches, respectively, where φ_h is the phase of the structure factor [equation (5.1.2.6)]. This difference of π between the two branches has important consequences for the properties of the wavefields.

As mentioned above, owing to absorption, wavevectors are actually complex and so is the dispersion surface (see Authier, 2008).

5.1.2.6. Propagation direction

The energy of all the waves in a given wavefield propagates in a common direction, which is given by that of the Poynting vector (von Laue, 1952) [see Section A5.1.1.4, equation (A5.1.1.8) of the Appendix]. It can be shown that, averaged over time and the unit cell, the Poynting vector of a wavefield is

$$\mathbf{S} = (c/\varepsilon_0)\exp(4\pi\mathbf{K_{oi}}\cdot\mathbf{r})\big[|D_o|^2\mathbf{s_o} + |D_h|^2\mathbf{s_h}\big], \qquad (5.1.2.25)$$

where $\mathbf{s_o}$ and $\mathbf{s_h}$ are unit vectors in the $\mathbf{K_o}$ and $\mathbf{K_h}$ directions, respectively, c is the velocity of light and ε_0 is the dielectric permittivity of a vacuum.

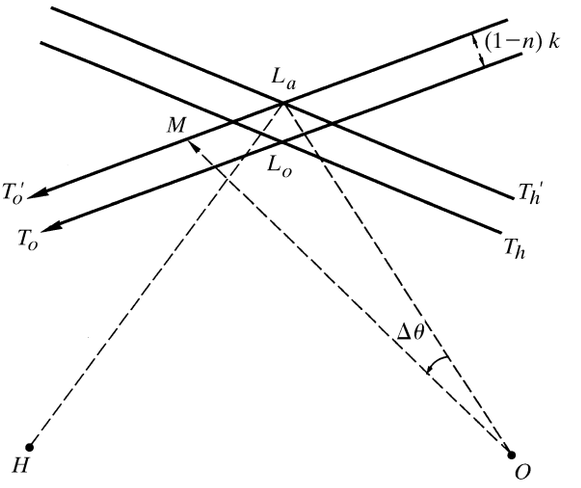

Fig. 5.1.3.1. Departure from Bragg's law of an incident wave.

From (5.1.2.25) and equation (5.1.2.22) of the dispersion surface, it can be shown that the propagation direction of the wavefield lies along the normal to the dispersion surface at the tie point (Fig. 5.1.2.5). This result was first shown by Kato (1952) in the two-beam case for electron diffraction and generalized by him to the n-beam case for X-rays (Kato, 1958). It is also obtained by considering the group velocity of the wavefield (Ewald, 1958; Wagner, 1959). The angle α between the propagation direction and the lattice planes is given by

$$\tan\alpha = \big[(1 - |\xi|^2)/(1 + |\xi|^2)\big]\tan\theta. \qquad (5.1.2.26)$$

It should be noted that the propagation direction varies between $\mathbf{K_o}$ and $\mathbf{K_h}$ for both branches of the dispersion surface.

5.1.3. Solutions of plane-wave dynamical theory

5.1.3.1. Departure from Bragg's law of the incident wave

The wavefields excited in the crystal by the incident wave are determined by applying the boundary condition mentioned above for the continuity of the tangential component of the wavevectors (Section 5.1.2.3). Waves propagating in a vacuum have wavenumber $k = 1/\lambda$. Depending on whether they propagate in the incident or in the reflected direction, the common extremity, M, of their wavevectors

$$\mathbf{OM} = \mathbf{K_o^{(a)}} \text{ and } \mathbf{HM} = \mathbf{K_h^{(a)}}$$

lies on spheres of radius k and centred at O and H, respectively. The intersections of these spheres with the plane of incidence are two circles which can be approximated by their tangents T_o' and T_h' at their intersection point, L_a, or *Laue point* (Fig. 5.1.3.1).

Bragg's condition is exactly satisfied according to the geometrical theory of diffraction when M lies at L_a. The departure $\Delta\theta$ from Bragg's incidence of an incident wave is defined as the angle between the corresponding wavevectors **OM** and $\mathbf{OL}_a$. As $\Delta\theta$ is very small compared to the Bragg angle in the general case of X-rays or neutrons, one may write

$$\begin{aligned}\mathbf{K_o^{(a)}} &= \mathbf{OM} = \mathbf{OL}_a + \mathbf{L}_a\mathbf{M},\\ \Delta\theta &= \overline{L_aM}/k.\end{aligned} \qquad (5.1.3.1)$$

The tangent T_o' is oriented in such a way that $\Delta\theta$ is negative when the angle of incidence is smaller than the Bragg angle.

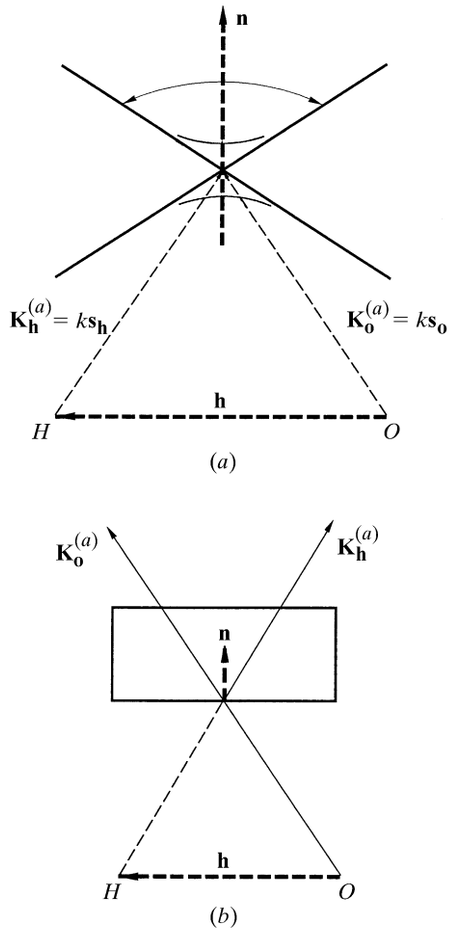

Fig. 5.1.3.2. Transmission, or Laue, geometry. (*a*) Reciprocal space; (*b*) direct space.

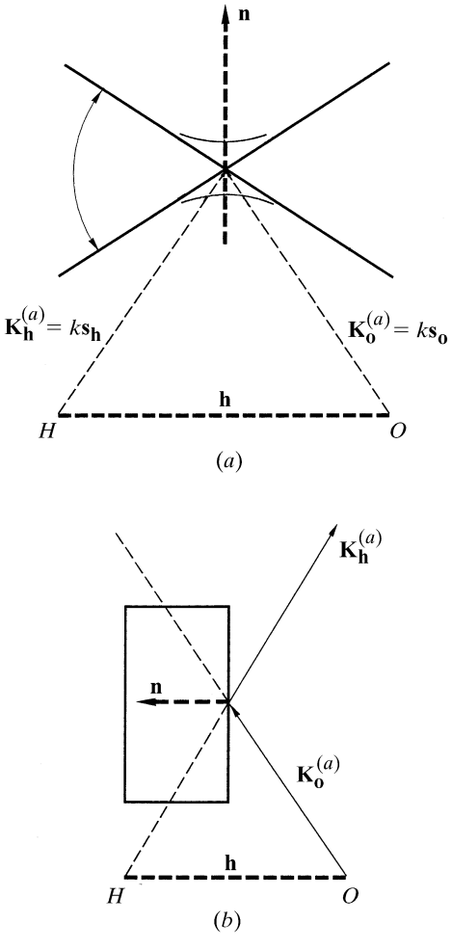

Fig. 5.1.3.3. Reflection, or Bragg, geometry. (*a*) Reciprocal space; (*b*) direct space.

5.1.3.2. Transmission and reflection geometries

The boundary condition for the continuity of the tangential component of the wavevectors is applied by drawing from M a line, **Mz**, parallel to the normal **n** to the crystal surface. The tie points of the wavefields excited in the crystal by the incident wave are at the intersections of this line with the dispersion surface. Two different situations may occur:

(*a*) *Transmission, or Laue case* (Fig. 5.1.3.2). The normal to the crystal surface drawn from M intersects *both* branches of the dispersion surface (Fig. 5.1.3.2*a*). The reflected wave is then directed towards the *inside* of the crystal (Fig. 5.1.3.2*b*). Let γ_o and γ_h be the cosines of the angles between the normal to the crystal surface, **n**, and the incident and reflected directions, respectively:

$$\gamma_o = \cos(\mathbf{n}, \mathbf{s_o}); \quad \gamma_h = \cos(\mathbf{n}, \mathbf{s_h}). \tag{5.1.3.2}$$

It will be noted that they are both positive, as is their ratio,

$$\gamma = \gamma_h/\gamma_o. \tag{5.1.3.3}$$

This is the *asymmetry ratio*, which is very important since the width of the rocking curve is proportional to its square root [equation (5.1.3.6)].

(*b*) *Reflection, or Bragg case* (Fig. 5.1.3.3). In this case there are three possible situations: the normal to the crystal surface drawn from M intersects either branch 1 or branch 2 of the dispersion surface, or the intersection points are imaginary (Fig. 5.1.3.3*a*). The reflected wave is directed towards the *outside* of the crystal (Fig. 5.1.3.3*b*). The cosines defined by (5.1.3.2) are now positive for γ_o and negative for γ_h. The asymmetry factor is therefore also negative.

5.1.3.3. Middle of the reflection domain

It will be apparent from the equations given later that the incident wavevector corresponding to the middle of the reflection domain is, in both cases, **OI**, where I is the intersection of the normal to the crystal surface drawn from the Lorentz point, L_o, with T_o' (Figs. 5.1.3.4 and 5.1.3.5), while, according to Bragg's law, it should be $\mathbf{OL}_a$. The angle $\Delta\theta$ between the incident wavevectors $\mathbf{OL}_a$ and **OI**, corresponding to the middle of the reflecting domain according to the geometrical and dynamical theories, respectively, is

$$\Delta\theta_o = \overline{L_a I}/k = R\lambda^2 F_o(1-\gamma)/(2\pi V \sin 2\theta). \tag{5.1.3.4}$$

In the Bragg case, the asymmetry ratio γ is negative and $\Delta\theta_o$ is never equal to zero. This difference in Bragg angle between the two theories is due to the refraction effect, which is neglected in geometrical theory. In the Laue case, $\Delta\theta_o$ is equal to zero for symmetric reflections ($\gamma = 1$).

5.1.3.4. Deviation parameter

The solutions of dynamical theory are best described by introducing a reduced parameter called the *deviation parameter*,

$$\eta = (\Delta\theta - \Delta\theta_o)/\delta, \tag{5.1.3.5}$$

where

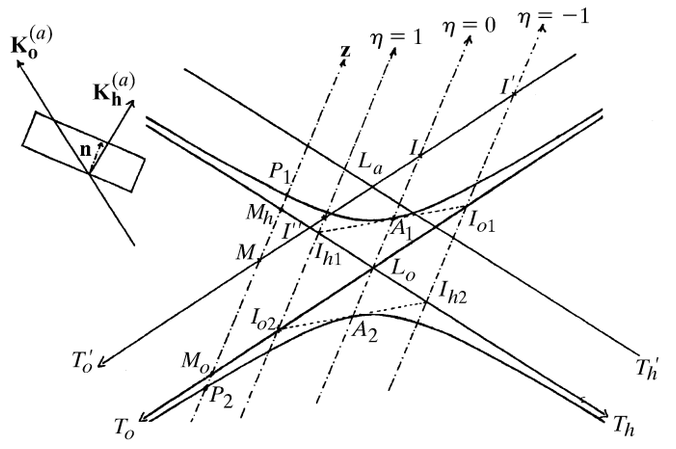

Fig. 5.1.3.4. Boundary conditions at the entrance surface for transmission geometry.

$$\delta = R\lambda^2|C|(|\gamma|F_hF_{\bar{h}})^{1/2}/(\pi V \sin 2\theta), \tag{5.1.3.6}$$

whose real part is equal to the half width of the rocking curve (Sections 5.1.6 and 5.1.7). The width 2δ of the rocking curve is sometimes called the *Darwin width*.

The definition (5.1.3.5) of the deviation parameter is independent of the geometrical situation (reflection or transmission case); this is not followed by some authors. The present convention has the advantage of being quite general.

In an absorbing crystal, η, $\Delta\theta_o$ and δ are complex, and it is the real part, $\Delta\theta_{or}$, of $\Delta\theta_o$ which has the geometrical interpretation given in Section 5.1.3.3. One obtains

$$\begin{aligned}
&\eta = \eta_r + i\eta_i \\
&\eta_r = (\Delta\theta - \Delta\theta_{or})/\delta_r; \;\; \eta_i = A\eta_r + B \\
&A = -\tan\beta \\
&B = \left\{\chi_{io}/\left[|C|(|\chi_h\chi_{\bar{h}}|)^{1/2}\cos\beta\right]\right\}(1-\gamma)/2(|\gamma|)^{1/2},
\end{aligned} \tag{5.1.3.7}$$

where β is the phase angle of $(\chi_h\chi_{\bar{h}})^{1/2}$ [or that of $(F_hF_{\bar{h}})^{1/2}$].

5.1.3.5. Pendellösung and extinction distances

Let

$$\Lambda_o = \pi V(\gamma_o|\gamma_h|)^{1/2}/[R\lambda|C|(F_hF_{\bar{h}})^{1/2}]. \tag{5.1.3.8}$$

This length plays a very important role in the dynamical theory of diffraction by both perfect and deformed crystals. For example, it is 15.3 μm for the 220 reflection of silicon, with Mo $K\alpha$ radiation and a symmetric reflection.

In *transmission* geometry, it gives the period of the interference between the two excited wavefields which constitutes the *Pendellösung* effect first described by Ewald (1917) (see Section 5.1.6.3); Λ_o in this case is called the *Pendellösung distance*, denoted Λ_L hereafter. Its geometrical interpretation, in the zero-absorption case, is the inverse of the diameter A_2A_1 of the dispersion surface in a direction defined by the cosines γ_h and γ_o with respect to the reflected and incident directions, respectively (Fig. 5.1.3.4). It reduces to the inverse of $A_{o2}A_{o1}$ (5.1.2.23) in the symmetric case.

In *reflection* geometry, it gives the absorption distance in the total-reflection domain and is called the *extinction* distance, denoted Λ_B (see Section 5.1.7.1). Its geometrical interpretation in the zero-absorption case is the inverse of the length $I_{o1}I_{h1} = I_{h2}I_{o2}$, Fig. 5.1.3.5.

In a *deformed* crystal, if distortions are of the order of the width of the rocking curve over a distance Λ_o, the crystal is considered to be slightly deformed, and ray theory (Penning & Polder, 1961; Kato, 1963, 1964*a*,*b*) can be used to describe the propagation of wavefields. If the distortions are larger, new wavefields may be generated by interbranch scattering (Authier & Balibar, 1970) and generalized dynamical diffraction theory such as that developed by Takagi (1962, 1969) should be used.

Using (5.1.3.8), expressions (5.1.3.5) and (5.1.3.6) can be rewritten in the very useful form:

$$\begin{aligned}
&\eta = (\Delta\theta - \Delta\theta_o)\Lambda_o \sin 2\theta/(\lambda|\gamma_h|), \\
&\delta = \lambda|\gamma_h|/(\Lambda_o \sin 2\theta).
\end{aligned} \tag{5.1.3.9}$$

The order of magnitude of the Darwin width 2δ ranges from a fraction of a second of an arc to ten or more seconds, and

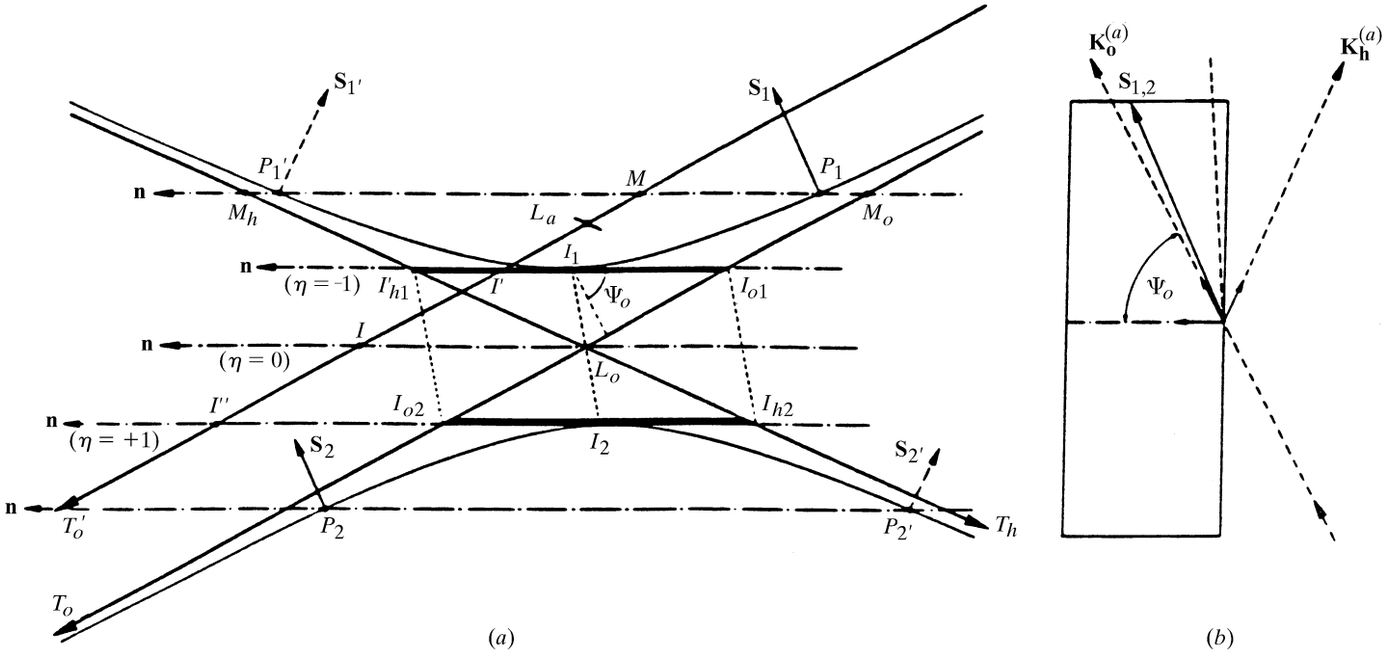

Fig. 5.1.3.5. Boundary conditions at the entrance surface for reflection geometry. (*a*) Reciprocal space; (*b*) direct space.

increases with increasing wavelength and increasing structure factor. For example, for the 220 reflection of silicon and Cu $K\alpha$ radiation, it is 5.2 seconds.

5.1.3.6. Solution of the dynamical theory

The coordinates of the tie points excited by the incident wave are obtained by looking for the intersection of the dispersion surface, (5.1.2.22), with the normal **Mz** to the crystal surface (Figs. 5.1.3.4 and 5.1.3.5). The ratio ξ of the amplitudes of the waves of the corresponding wavefields is related to these coordinates by (5.1.2.24) and is found to be

$$\begin{aligned}\xi_j &= D_{hj}/D_{oj} \\ &= -\mathrm{S}(C)\mathrm{S}(\gamma_h)[(F_h F_{\bar{h}})^{1/2}/F_{\bar{h}}] \\ &\quad \times \left\{\eta \pm \left[\eta^2 + \mathrm{S}(\gamma_h)\right]^{1/2}\right\}/(|\gamma|)^{1/2},\end{aligned} \tag{5.1.3.10}$$

where the plus sign corresponds to a tie point on branch 1 ($j = 1$) and the minus sign to a tie point on branch 2 ($j = 2$), and $\mathrm{S}(\gamma_h)$ is the sign of γ_h (+1 in transmission geometry, -1 in reflection geometry).

5.1.3.7. Geometrical interpretation of the solution in the zero-absorption case

5.1.3.7.1. Transmission geometry

In this case (Fig. 5.1.3.4) $\mathrm{S}(\gamma_h)$ is +1 and (5.1.3.10) may be written

$$\xi_j = -\mathrm{S}(C)\left[\eta \pm (\eta^2 + 1)^{1/2}\right]/\gamma^{1/2}. \tag{5.1.3.11}$$

Let A_1 and A_2 be the intersections of the normal to the crystal surface drawn from the Lorentz point L_o with the two branches of the dispersion surface (Fig. 5.1.3.4). From Sections 5.1.3.3 and 5.1.3.4, they are the tie points excited for $\eta = 0$ and correspond to the middle of the reflection domain. Let us further consider the tangents to the dispersion surface at A_1 and A_2 and let I_{o1}, I_{o2} and I_{h1}, I_{h2} be their intersections with T_o and T_h, respectively. It can be shown that $\overline{I_{o1}I_{h2}}$ and $\overline{I_{o2}I_{h1}}$ intersect the dispersion surface at the tie points excited for $\eta = -1$ and $\eta = +1$, respectively, and that the *Pendellösung* distance $\Lambda_\mathrm{L} = 1/\overline{A_2A_1}$, the width of the rocking curve $2\delta = \overline{I_{o1}I_{o2}}/k$ and the deviation parameter $\eta = \overline{M_oM_h}/\overline{A_2A_1}$, where M_o and M_h are the intersections of the normal to the crystal surface drawn from the extremity of any incident wavevector **OM** with T_o and T_h, respectively.

5.1.3.7.2. Reflection geometry

In this case (Fig. 5.1.3.5) $\mathrm{S}(\gamma_h)$ is now -1 and (5.1.3.10) may be written

$$\xi_j = \mathrm{S}(C)\left[\eta \pm (\eta^2 - 1)^{1/2}\right]/|\gamma|^{1/2}. \tag{5.1.3.12}$$

Now, let I_1 and I_2 be the points of the dispersion surface where the tangent is parallel to the normal to the crystal surface, and further let I_{o1}, I_{h1}, I' and I_{o2}, I_{h2}, I'' be the intersections of these two tangents with T_o, T_h and T'_o, respectively. For an incident wave of wavevector **OM** where M lies between I' and I'', the normal to the crystal surface drawn from M has no real intersection with the dispersion surface and $\overline{I'I''}$ defines the total-reflection domain. The tie points I_1 and I_2 correspond to $\eta = -1$ and $\eta = +1$, respectively, the extinction distance $\Lambda_\mathrm{L} = 1/\overline{I_{o1}I_{h1}}$, the width of the total-reflection domain $2\delta = \overline{I_{o1}I_{o2}}/k = \overline{I'I''}/k$ and the deviation parameter $\eta = -\overline{M_oM_h}/\overline{I_{o1}I_{h1}}$, where M_o and M_h are the intersections with T_o and T_h of the normal to the crystal surface drawn from the extremity of any incident wavevector **OM**.

5.1.4. Standing waves

The various waves in a wavefield are coherent and interfere. In the two-beam case, the intensity of the wavefield, using (5.1.2.14) and (5.1.2.24), is

$$\begin{aligned}|D|^2 &= |D_o|^2 \exp(4\pi\mathbf{K_{oi}}\cdot\mathbf{r}) \\ &\quad \times [1 + |\xi|^2 + 2C|\xi|\cos 2\pi(\mathbf{h}\cdot\mathbf{r} + \Psi)],\end{aligned} \tag{5.1.4.1}$$

where Ψ is the phase of ξ,

$$\xi = |\xi|\exp(i\Psi). \tag{5.1.4.2}$$

Equation (5.1.4.1) shows that the interference between the two waves is the origin of *standing waves*. The corresponding nodes lie on planes such that $\mathbf{h}\cdot\mathbf{r}$ is a constant. These planes are therefore parallel to the diffraction planes and their periodicity is equal to d_{hkl} (defined in the caption for Fig. 5.1.2.1*a*). Their position within the unit cell is given by the value of the phase Ψ.

In the Laue case, Ψ is equal to $\pi + \varphi_h$ for branch 1 and to φ_h for branch 2, where φ_h is the phase of the structure factor, (5.1.2.6). This means that the *nodes* of standing waves lie on the maxima of the *hkl* Fourier component of the electron density for branch 1 while the *anti-nodes* lie on the maxima for branch 2.

In the Bragg case, Ψ varies continuously from $\pi + \varphi_h$ to φ_h as the angle of incidence is varied from the low-angle side to the high-angle side of the reflection domain by rocking the crystal. The nodes lie on the maxima of the *hkl* Fourier components of the electron density on the low-angle side of the rocking curve. As the crystal is rocked, they are progressively shifted by half a lattice spacing until the anti-nodes lie on the maxima of the electron density on the high-angle side of the rocking curve.

Standing waves are the origin of the phenomenon of anomalous absorption, which is one of the specific properties of wavefields (Section 5.1.5). Anomalous scattering is also used for the location of atoms in the unit cell at the vicinity of the crystal surface: when X-rays are absorbed, fluorescent radiation and photoelectrons are emitted. Detection of this emission for a known angular position of the crystal with respect to the rocking curve and therefore for a known value of the phase Ψ enables the emitting atom within the unit cell to be located. The principle of this method is due to Batterman (1964, 1969). For reviews, see Golovchenko *et al.* (1982), Materlik & Zegenhagen (1984), Kovalchuk & Kohn (1986), Bedzyk (1988), Authier (1989), Zegenhagen (1993), Patel (1996), Patel & Fontes (1996), Lagomarsino (1996), Zegenhagen *et al.* (1997), Vartanyants & Zegenhagen (1999) and Vartanyants & Koval'chuk (2001).

5.1.5. Anomalous absorption

It was shown in Section 5.1.2.2 that the wavevectors of a given wavefield all have the same imaginary part (5.1.2.17) and therefore the same absorption coefficient μ (5.1.2.19). Borrmann (1950, 1954) showed that this coefficient is much smaller than the normal one (μ_o) for wavefields whose tie points lie on branch 1 of the dispersion surface and much larger for wavefields whose tie points lie on branch 2. The former case corresponds to the *anomalous transmission effect*, or *Borrmann effect*. As in favourable cases the minimum absorption coefficient may be as low as a few per cent of μ_o, this effect is very important from both a fundamental and a practical point of view.

The physical interpretation of the Borrmann effect is to be found in the standing waves described in Section 5.1.4. When the

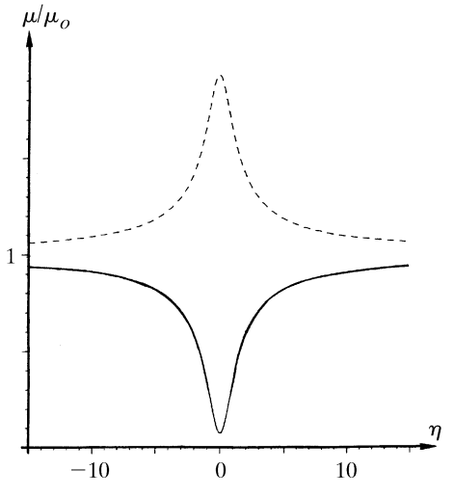

Fig. 5.1.6.1. Variation of the effective absorption with the deviation parameter in the transmission case for the 400 reflection of GaAs using Cu $K\alpha$ radiation. Solid curve: branch 1; broken curve: branch 2.

nodes of the electric field lie on the planes corresponding to the maxima of the *hkl* component of the electron density, the wavefields are absorbed anomalously less than when there is no diffraction. Just the opposite occurs for branch 2 wavefields, whose anti-nodes lie on the maxima of the electron density and which are absorbed more than normal.

The effective absorption coefficient μ is related to the imaginary part of the wavevectors through (5.1.2.19),

$$\mu = -4\pi\gamma_o K_{oi},$$

and to the imaginary part of the ratio of the amplitude of the reflected to the incident wave through

$$\mu = \mu_o - 4\pi X_{oi}, \tag{5.1.5.1}$$

where X_{oi} is the imaginary part of X_o, which, using (5.1.2.24) and (5.1.3.10), is given by

$$X_o = R\lambda|C|\mathrm{S}(\gamma_h)(F_h F_{\bar{h}})^{1/2} \times \{\eta \pm [\eta^2 + \mathrm{S}(\gamma_h)]^{1/2}\}\big/\big[2\pi V(|\gamma|)^{1/2}\big]. \tag{5.1.5.2}$$

Taking the upper sign (+) for the $\pm$ term corresponds to tie points on branch 1 and taking the lower sign (−) corresponds to tie points on branch 2.

The calculation of the imaginary part X_{oi} is different in the Laue and in the Bragg cases. In the former case, the imaginary part of $(\eta^2+1)^{1/2}$ is small and can be approximated while in the latter, the imaginary part of $(\eta^2-1)^{1/2}$ is large when the real part of the deviation parameter, η_r, lies between 1 and −1, and cannot be calculated using the same approximation.

5.1.6. Intensities of plane waves in transmission geometry

5.1.6.1. Absorption coefficient

In transmission geometry, the imaginary part of X_o is small and, using a first-order approximation for the expansion of $(\eta^2+1)^{1/2}$, (5.1.5.1) and (5.1.5.2), the effective absorption coefficient in the absorption case is

$$\mu_j = \mu_o\left[\tfrac{1}{2}(1+\gamma^{-1}) \mp \frac{(\eta_r/2)(1-\gamma^{-1}) + |C|(\gamma^{-1})^{1/2}|F_{ih}/F_{io}|\cos\varphi}{(\eta_r^2+1)^{1/2}}\right], \tag{5.1.6.1}$$

where $\varphi = \varphi_{rh} - \varphi_{ih}$ is the phase difference between F_{rh} and F_{ih} [equation (5.1.2.10)], the upper sign (−) for the $\mp$ term corresponds to branch 1 and the lower sign (+) corresponds to branch 2 of the dispersion surface. In the symmetric Laue case ($\gamma = 1$, reflecting planes normal to the crystal surface), equation (5.1.6.1) reduces to

$$\mu_j = \mu_o\left[1 \mp \frac{|C||F_{ih}/F_{io}|\cos\varphi}{(\eta_r^2+1)^{1/2}}\right].$$

Fig. 5.1.6.1 shows the variations of the effective absorption coefficient μ_j with η_r for wavefields belonging to branches 1 and 2 in the case of the 400 reflection of GaAs with Cu $K\alpha$ radiation. It can be seen that for $\eta_r = 0$ the absorption coefficient for branch 1 becomes significantly smaller than the normal absorption coefficient, μ_o. The minimum absorption coefficient, $\mu_o(1 - |CF_{ih}/F_{io}|\cos\varphi)$, depends on the nature of the reflection through the structure factor and on the temperature through the Debye–Waller factor included in F_{ih} [equation (5.1.2.10*b*)] (Ohtsuki, 1964, 1965). For instance, in diamond-type structures, it is smaller for reflections with even indices than for reflections with odd indices. The influence of temperature is very important when $|F_{ih}/F_{io}|$ is close to one; for example, for germanium 220 and Mo $K\alpha$ radiation, the minimum absorption coefficient at 5 K is reduced to about 1% of its normal value, μ_o (Ludewig, 1969).

5.1.6.2. Boundary conditions for the amplitudes at the entrance surface – intensities of the reflected and refracted waves

Let us consider an infinite plane wave incident on a crystal plane surface of infinite lateral extension. As has been shown in Section 5.1.3, two wavefields are excited in the crystal, with tie points P_1 and P_2, and amplitudes D_{o1}, D_{h1} and D_{o2}, D_{h2}, respectively. Maxwell's boundary conditions (see Section A5.1.1.2 of the Appendix) imply continuity of the tangential component of the electric field and of the normal component of the electric displacement across the boundary. Because the index of refraction is so close to unity, one can assume to a very good approximation that there is continuity of the three components of both the electric field and the electric displacement. As a consequence, it can easily be shown that, *along the entrance surface*, for all components of the electric displacement

$$\begin{aligned} D_o^{(a)} &= D_{o1} + D_{o2} \\ 0 &= D_{h1} + D_{h2}, \end{aligned} \tag{5.1.6.2}$$

where $D_o^{(a)}$ is the amplitude of the incident wave.

Using (5.1.3.11), (5.1.5.2) and (5.1.6.2), it can be shown that the *intensities* of the four waves are

$$\begin{aligned} |D_{oj}|^2 &= |D_o^{(a)}|^2 \exp(-\mu_j z/\gamma_o)\big[(1+\eta_r^2)^{1/2} \mp \eta_r\big]^2 \times [4(1+\eta_r^2)]^{-1}, \\ |D_{hj}|^2 &= |D_o^{(a)}|^2 \exp(-\mu_j z/\gamma_o)|F_h/F_{\bar{h}}|[4\gamma(1+\eta_r^2)]^{-1}; \end{aligned} \tag{5.1.6.3}$$

top sign: $j = 1$; bottom sign: $j = 2$.

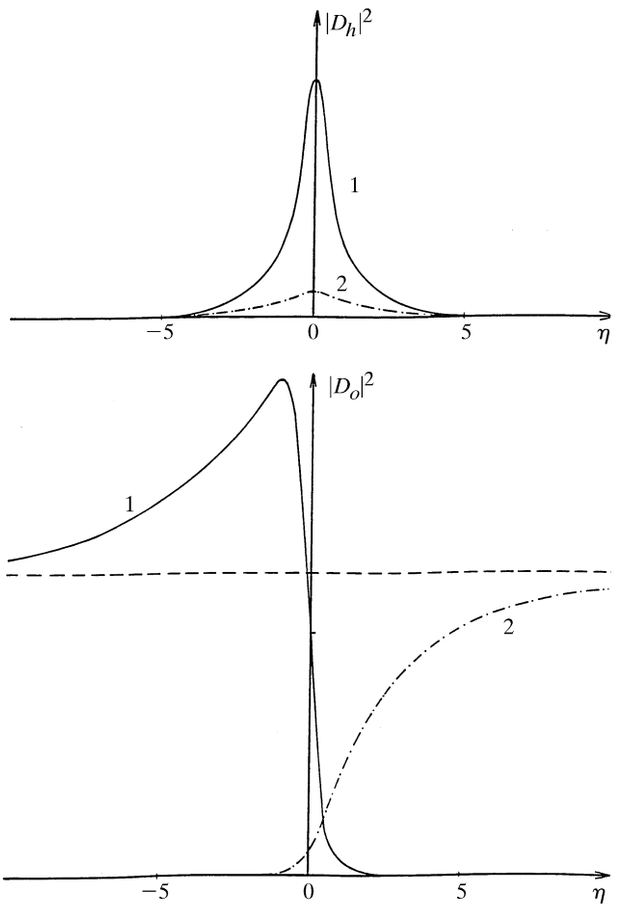

Fig. 5.1.6.2. Variation of the intensities of the reflected and refracted waves in an absorbing crystal for the 220 reflection of Si using Mo $K\alpha$ radiation, t = 1 mm (μt = 1.42). Solid curve: branch 1; dashed curve: branch 2.

Fig. 5.1.6.2 represents the variations of these four intensities with the deviation parameter. Far from the reflection domain, $|D_{h1}|^2$ and $|D_{h2}|^2$ tend toward zero, as is normal, while

$$|D_{o1}|^2 \gg |D_{o2}|^2 \text{ for } \eta_r \Rightarrow -\infty,$$
$$|D_{o1}|^2 \ll |D_{o2}|^2 \text{ for } \eta_r \Rightarrow +\infty.$$

This result shows that the wavefield of highest intensity 'jumps' from one branch of the dispersion surface to the other across the reflection domain. This is an important property of dynamical theory which also holds in the Bragg case and when a wavefield crosses a highly distorted region in a deformed crystal [the so-called *interbranch scattering*: see, for instance, Authier & Balibar (1970) and Authier & Malgrange (1998)].

5.1.6.3. Boundary conditions at the exit surface

5.1.6.3.1. Wavevectors

When a wavefield reaches the exit surface, it breaks up into its two constituent waves. Their wavevectors are obtained by applying again the condition of the continuity of their tangential components along the crystal surface. The extremities, M_j and N_j, of these wavevectors

$$\mathbf{OM}_j = \mathbf{K}_{\mathbf{o}j}^{(d)} \qquad \mathbf{HN}_j = \mathbf{K}_{\mathbf{h}j}^{(d)}$$

lie at the intersections of the spheres of radius k centred at O and H, respectively, with the normal $\mathbf{n}'$ to the crystal exit surface drawn from P_j (j = 1 and 2) (Fig. 5.1.6.3).

If the crystal is wedge-shaped and the normals $\mathbf{n}$ and $\mathbf{n}'$ to the entrance and exit surfaces are not parallel, the wavevectors of the waves generated by the two wavefields are not parallel. This effect is due to the refraction properties associated with the dispersion surface.

5.1.6.3.2. Amplitudes – Pendellösung

We shall assume from now on that the crystal is plane parallel. Two wavefields arrive at any point of the exit surface. Their constituent waves interfere and generate emerging waves in the refracted and reflected directions (Fig. 5.1.6.4). Their respective amplitudes are given by the boundary conditions

$$\begin{aligned} D_o^{(d)} \exp(-2\pi i \mathbf{K}_{\mathbf{o}}^{(d)} \cdot \mathbf{r}) &= D_{o1} \exp(-2\pi i \mathbf{K}_{\mathbf{o}1} \cdot \mathbf{r}) \\ &\quad + D_{o2} \exp(-2\pi i \mathbf{K}_{\mathbf{o}2} \cdot \mathbf{r}) \\ D_h^{(d)} \exp(-2\pi i \mathbf{K}_{\mathbf{h}}^{(d)} \cdot \mathbf{r}) &= D_{h1} \exp(-2\pi i \mathbf{K}_{\mathbf{h}1} \cdot \mathbf{r}) \\ &\quad + D_{h2} \exp(-2\pi i \mathbf{K}_{\mathbf{h}2} \cdot \mathbf{r}), \end{aligned} \tag{5.1.6.4}$$

where $\mathbf{r}$ is the position vector of a point on the exit surface, the origin of phases being taken at the entrance surface.

In a plane-parallel crystal, (5.1.6.4) reduces to

$$D_o^{(d)} = D_{o1} \exp\left(-2\pi i \overline{MP_1} \cdot t\right) + D_{o2} \exp\left(-2\pi i \overline{MP_2} \cdot t\right)$$
$$D_h^{(d)} = D_{h1} \exp\left(-2\pi i \overline{MP_1} \cdot t\right) + D_{h2} \exp\left(-2\pi i \overline{MP_2} \cdot t\right),$$

where t is the crystal thickness.

In a *non-absorbing* crystal, the amplitudes squared are of the form

$$\left|D_o^{(d)}\right|^2 = |D_{o1}|^2 + |D_{o2}|^2 + 2D_{o1}D_{o2} \cos 2\pi \overline{P_2P_1} t.$$

This expression shows that the intensities of the refracted and reflected beams are oscillating functions of crystal thickness. The period of the oscillations is called the *Pendellösung* distance and is

$$\Lambda = 1/\overline{P_2P_1} = \Lambda_L/(1 + \eta_r^2)^{1/2}.$$

5.1.6.4. Reflecting power

For an *absorbing* crystal, the intensities of the reflected and refracted waves are

$$\begin{aligned} \left|D_o^{(d)}\right|^2 &= \left|D_o^{(a)}\right|^2 A_\eta \Big\{ \cosh(2v + \mu_a t) \\ &\quad + \cos\left[2\pi t \Lambda^{-1} - 2\eta_i (1 + \eta_r^2)^{-1/2}\right] \Big\} \\ \left|D_h^{(d)}\right|^2 &= \left|D_o^{(a)}\right|^2 |F_h/F_{\bar{h}}| \gamma^{-1} A_\eta \left[\cosh(\mu_a t) - \cos(2\pi t \Lambda^{-1})\right], \end{aligned} \tag{5.1.6.5}$$

where

$$A_\eta = \left[\exp -\mu_o t(\gamma_o^{-1} + \gamma_h^{-1})\right]/2(1 + \eta_r^2),$$
$$\mu_a = \mu_j \Big[1/2(\gamma_o^{-1} - \gamma_h^{-1})\eta_r + |C||F_{ih}/F_{io}| \cos\varphi/(\gamma_o\gamma_h)^{1/2}\Big](1 + \eta_r^2)^{-1/2},$$
$$v = \operatorname{arg\,sinh} \eta_r$$

and μ_j is given by equation (5.1.6.1).

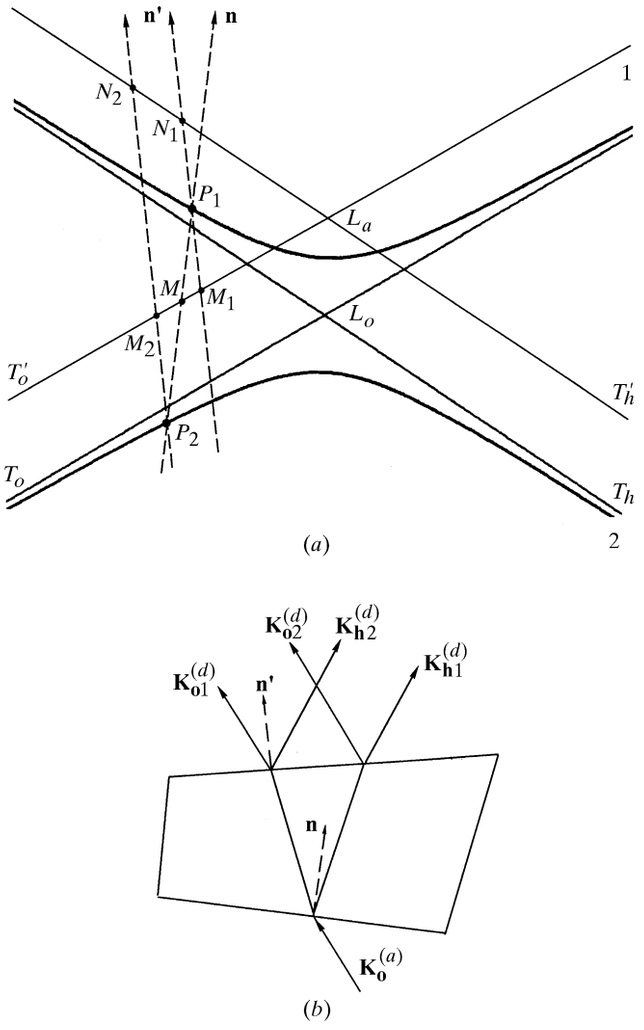

Fig. 5.1.6.3. Boundary condition for the wavevectors at the exit surface. (*a*) Reciprocal space. The wavevectors of the emerging waves are determined by the intersections M_1, M_2, N_1 and N_2 of the normals $\mathbf{n}'$ to the exit surface, drawn from the tie points P_1 and P_2 of the wavefields, with the tangents T'_o and T'_h to the spheres centred at O and H and of radius k, respectively. (*b*) Direct space.

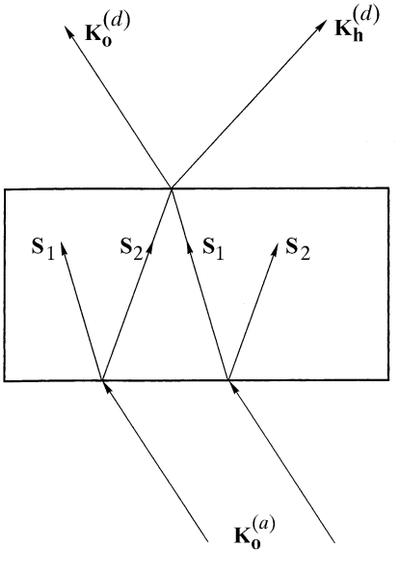

Fig. 5.1.6.4. Decomposition of a wavefield into its two components when it reaches the exit surface. $\mathbf{S}_1$ and $\mathbf{S}_2$ are the Poynting vectors of the two wavefields propagating in the crystal belonging to branches 1 and 2 of the dispersion surface, respectively, and interfering at the exit surface.

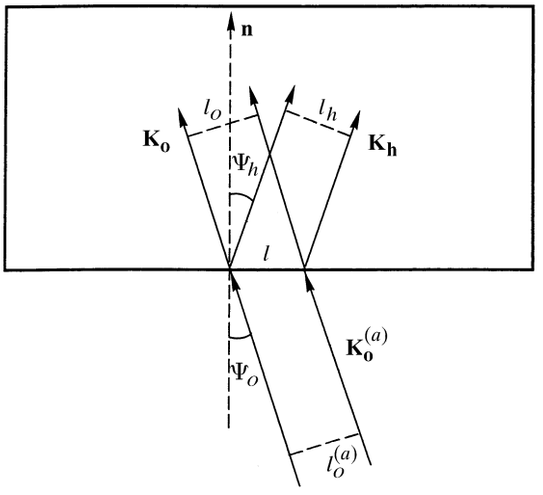

Fig. 5.1.6.5. Cross sections of the incident, $\mathbf{K}_o^{(a)}$, refracted, $\mathbf{K}_o$, and reflected, $\mathbf{K}_h$, waves.

Depending on the absorption coefficient, the cosine terms are more or less important relative to the hyperbolic cosine term and the oscillations due to *Pendellösung* have more or less contrast.

For a non-absorbing crystal, these expressions reduce to

$$\begin{aligned}\left|D_o^{(d)}\right|^2 &= \left|D_o^{(a)}\right|^2\left[\frac{1+2\eta^2+\cos(2\pi t\Lambda^{-1})}{2(1+\eta_r^2)}\right],\\ \left|D_h^{(d)}\right|^2 &= \left|D_o^{(a)}\right|^2\left[\frac{1-\cos(2\pi t\Lambda^{-1})}{2\gamma(1+\eta_r^2)}\right].\end{aligned} \tag{5.1.6.6}$$

What is actually measured in a counter receiving the reflected or the refracted beam is the *reflecting power*, namely the ratio of the energy of the reflected or refracted beam on the one hand and the energy of the incident beam on the other. The energy of a beam is obtained by multiplying its intensity by its cross section. If l is the width of the trace of the beam on the crystal surface, the cross sections of the incident (or refracted) and reflected beams are proportional to (Fig. 5.1.6.5) $l_o = l\gamma_o$ and $l_h = l\gamma_h$, respectively.

The reflecting powers are therefore:

$$\begin{aligned}\text{Refracted beam: } I_o &= l_o\left|D_o^{(d)}\right|^2 \Big/ l_o\left|D_o^{(a)}\right|^2 = \left|D_o^{(d)}\right|^2 \Big/ \left|D_o^{(a)}\right|^2,\\ \text{Reflected beam: } I_h &= l_h\left|D_h^{(d)}\right|^2 \Big/ l_o\left|D_o^{(a)}\right|^2 = \gamma\left|D_h^{(d)}\right|^2 \Big/ \left|D_o^{(a)}\right|^2.\end{aligned} \tag{5.1.6.7}$$

Using (5.1.6.6), it is easy to check that $I_o + I_h = 1$ in the non-absorbing case; that is, that conservation of energy is satisfied. Equations (5.1.6.6) show that there is a periodic exchange of energy between the refracted and the reflected waves as the beam penetrates the crystal; this is why Ewald introduced the expression *Pendellösung*.

The oscillations in the rocking curve were first observed by Lefeld-Sosnowska & Malgrange (1968, 1969). Their periodicity can be used for accurate measurements of the form factor [see, for instance, Bonse & Teworte (1980)]. Fig. 5.1.6.6 shows the shape of the rocking curve for various values of t/Λ_L.

The *width at half-height of the rocking curve*, averaged over the *Pendellösung* oscillations, corresponds in the non-absorbing case to $\Delta\eta = 2$, that is, to $\Delta\theta = 2\delta$, where δ is given by (5.1.3.6).

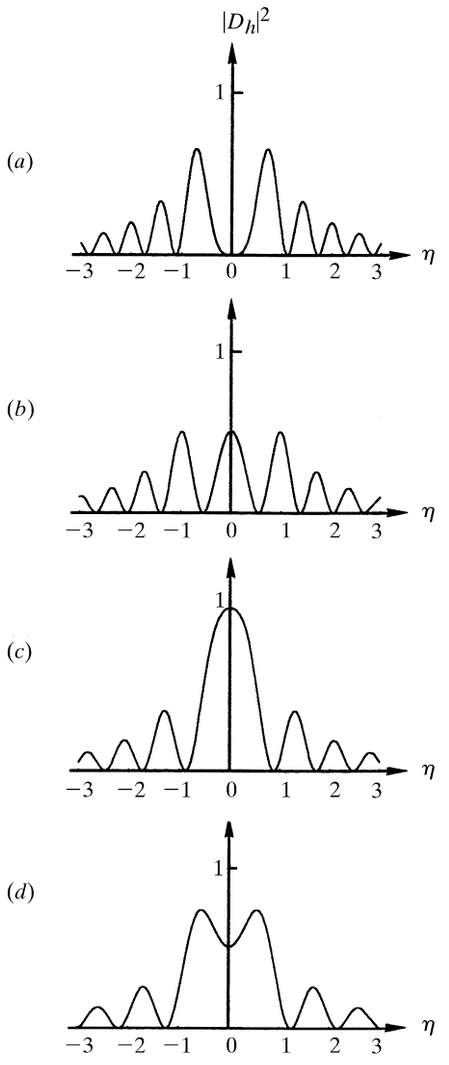

Fig. 5.1.6.6. Theoretical rocking curves in the transmission case for non-absorbing crystals and for various values of t/Λ_L: (*a*) $t/\Lambda_L = 1.25$; (*b*) $t/\Lambda_L = 1.5$; (*c*) $t/\Lambda_L = 1.75$; (*d*) $t/\Lambda_L = 2.0$.

5.1.6.5. Integrated intensity

5.1.6.5.1. Non-absorbing crystals

The integrated intensity is the ratio of the total energy recorded in the counter when the crystal is rocked to the intensity of the incident beam. It is proportional to the area under the line profile:

$$I_{hi} = \int_{-\infty}^{+\infty} I_h \, \mathrm{d}(\Delta\theta). \qquad (5.1.6.8)$$

The integration was performed by von Laue (1960). Using (5.1.3.5), (5.1.6.6) and (5.1.6.7) gives

$$I_{hi} = A \int_0^{2\pi t\Lambda_L^{-1}} J_0(z) \, \mathrm{d}z,$$

where $J_0(z)$ is the zeroth-order Bessel function and

$$A = \frac{R\lambda^2 |CF_h|(\gamma)^{1/2}}{2V \sin 2\theta}.$$

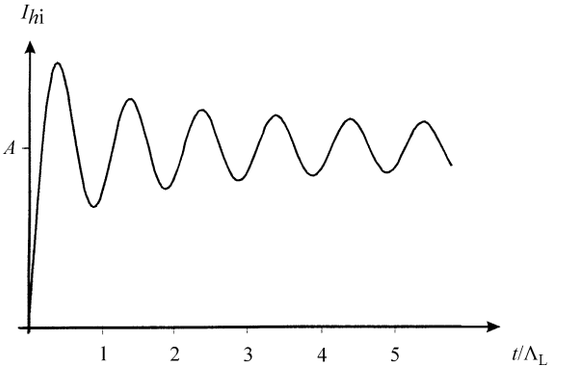

Fig. 5.1.6.7. Variations with crystal thickness of the integrated intensity in the transmission case (no absorption) (arbitrary units). The expression for A is given in the text.

Fig. 5.1.6.7 shows the variations of the integrated intensity with t/Λ_L.

5.1.6.5.2. Absorbing crystals

The integration was performed for absorbing crystals by Kato (1955). The integrated intensity in this case is given by

$$I_{hi} = A|F_h/F_{\bar{h}}| \exp\left[-1/2\mu_o t(\gamma_o^{-1} + \gamma_h^{-1})\right] \times \left[\int_0^{2\pi t\Lambda_L^{-1}} J_0(z) \, \mathrm{d}z - 1 + I_0(\zeta)\right],$$

where

$$\zeta = \mu_o t\left\{\left[|C|^2|F_{ih}/F_{io}|^2 \cos^2\varphi + (\gamma_h - \gamma_o)/(4\gamma_o\gamma_h)\right]/(\gamma_o\gamma_h)\right\}^{1/2}$$

and $I_0(\zeta)$ is a modified Bessel function of zeroth order.

5.1.6.6. Thin crystals – comparison with geometrical theory

Using (5.1.6.6) and (5.1.6.7), the reflecting power of the reflected beam may also be written

$$I_h = \pi^2 t^2 \Lambda_o^{-2} f(\eta),$$

where

$$f(\eta) = \left[\frac{\sin U(1+\eta^2)^{1/2}}{U(1+\eta^2)^{1/2}}\right]^2$$

and

$$U = \pi t \Lambda_o^{-1}.$$

When $t\Lambda_o^{-1}$ is very small, $f(\eta)$ tends asymptotically towards the function

$$f_1(\eta) = \left[\frac{\sin U\eta}{U\eta}\right]^2$$

and I_h towards the value given by geometrical theory. The condition for geometrical theory to apply is, therefore, that the crystal thickness be much smaller than the *Pendellösung* distance. In practice, the two theories agree to within a few per cent for a

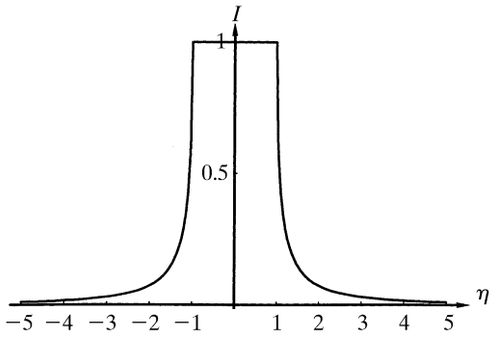

Fig. 5.1.7.1. Theoretical rocking curve in the reflection case for a non-absorbing thick crystal in terms of the deviation parameter.

crystal thickness smaller than or equal to a third of the *Pendellösung* distance [see Authier & Malgrange (1998)].

5.1.7. Intensity of plane waves in reflection geometry

5.1.7.1. Thick crystals

5.1.7.1.1. Non-absorbing crystals

Rocking curve. The geometrical construction in Fig. 5.1.3.5 shows that, in the Bragg case, the normal to the crystal surface drawn from the extremity of the incident wavevector intersects the dispersion surface either at two points of the same branch, P_1, P_1', for branch 1, P_2, P_2' for branch 2, or at imaginary points. It was shown in Section 5.1.2.6 that the propagation of the wavefields inside the crystal is along the normal to the dispersion surface at the corresponding tie points. Fig. 5.1.3.5 shows that this direction is oriented towards the outside of the crystal for tie points P_1' and P_2'. In a very thick crystal, these wavefields cannot exist because there is always a small amount of absorption. One concludes that in the thick-crystal case and in reflection geometry, only one wavefield is excited inside the crystal. It corresponds to branch 1 on the low-angle side of the rocking curve and to branch 2 on the high-angle side. Using the same approximations as in Section 5.1.6.2, the amplitude $\mathbf{D}_\mathbf{h}^{(a)}$ of the wave reflected at the crystal surface is obtained by applying the boundary conditions, which are particularly simple in this case:

$$\mathbf{D}_\mathbf{o} = \mathbf{D}_\mathbf{o}^{(a)},\ \mathbf{D}_\mathbf{h}^{(a)} = \mathbf{D}_\mathbf{h}.$$

The reflecting power is given by an expression similar to (5.1.6.7):

$$I_h = |\gamma||\xi_j|^2,$$

where the expression for ξ_j is given by (5.1.3.12), and $j = 1$ or 2 depending on which wavefield propagates towards the inside of the crystal. When the normal to the entrance surface intersects the dispersion surface at imaginary points, *i.e.* when $-1 < \eta < +1$,

$$|\xi|^2 = |\gamma|^{-1},\ I_h = 1, \tag{5.1.7.1}$$

and there is *total reflection*. Outside the total-reflection domain, the reflecting power is given by

$$I_h = \left[|\eta| - (\eta^2 - 1)^{1/2}\right]^2. \tag{5.1.7.2}$$

The rocking curve has the well known top-hat shape (Fig. 5.1.7.1). Far from the total-reflection domain, the curve can be approximated by the function

$$I_h \simeq 1/(4\eta^2).$$

Width of the total-reflection domain. The width of the total-reflection domain is equal to $\Delta\eta = 2$ and its angular width is therefore equal, using (5.1.3.5), to 2δ, where δ is given by (5.1.3.6). It is proportional to the structure factor, the polarization factor C and the square root of the asymmetry factor $|\gamma|$. Using an asymmetric reflection, it is therefore possible to decrease the width at wish. This is used in monochromators to produce a pseudo plane wave [see, for instance, Kikuta & Kohra (1970)]. It is possible to deduce the value of the form factor from very accurate measurements of the rocking curve; see, for instance, Kikuta (1971).

Integrated intensity. The integrated intensity is defined by (5.1.6.8):

$$I_{h\mathrm{i}} = 8\delta/3. \tag{5.1.7.3}$$

Penetration depth. Within the domain of total reflection, there are two wavefields propagating inside the crystal with imaginary wavevectors, one towards the inside of the crystal and the other one in the opposite direction, so that they cancel out and, globally, no energy penetrates the crystal. The absorption coefficient of the waves penetrating the crystal is

$$\mu = -4\pi K_{o\mathrm{i}}\gamma_o = 2\pi\gamma_o(1 - \eta^2)^{1/2}/\Lambda_\mathrm{B}, \tag{5.1.7.4}$$

where Λ_B is the value taken by Λ_o [equation (5.1.3.8)] in the Bragg case.

The penetration depth is a minimum at the middle of the reflection domain and at this point it is equal to $\Lambda_\mathrm{B}/2\pi$. This attenuation effect is called *extinction*, and Λ_B is called the *extinction length.* It is a specific property owing to the existence of wavefields. The resulting propagation direction of energy is parallel to the crystal surface, but with a cross section equal to zero: it is an *evanescent wave* [see, for instance, Cowan *et al.* (1986)].

5.1.7.1.2. Absorbing crystals

Rocking curve. Since the sign of γ is negative, $[\eta^2 + \mathrm{S}(\gamma h)]^{1/2}$ in (5.1.3.10) has a very large imaginary part when $|\eta_\mathrm{r}| \leq 1$. It cannot be calculated using the same approximations as in the Laue case. Let us set

$$Z\exp(i\Psi') = \eta \mp (\eta^2 - 1)^{1/2}. \tag{5.1.7.5}$$

The reflecting power is

$$I_h = (F_h/F_{\bar{\mathbf{h}}})^{1/2}Z^2, \tag{5.1.7.6}$$

where $Z = [L - (L^2 - 1)^{1/2}]^{1/2}$, $L = |\eta|^2 + \rho^2$ and $\rho = |\eta^2 - 1|$ is the modulus of expression (5.1.7.5) where the sign is chosen in such a way that Z is smaller than 1.

The expression for the reflected intensity in the absorbing Bragg case was first given by Prins (1930). The way of representing it given here was first used by Hirsch & Ramachandran (1950). The properties of the rocking curve have been described by Fingerland (1971).

There is no longer a total-reflection domain and energy penetrates the crystal at all incidence angles, although with a very

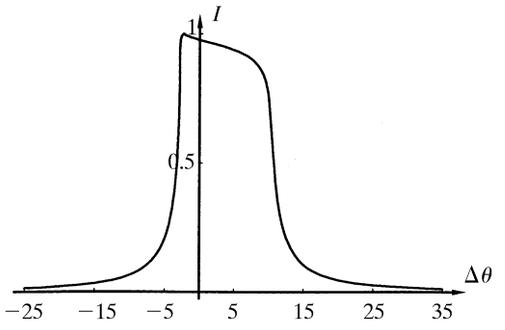

Fig. 5.1.7.2. Theoretical rocking curve in the reflection case for a thick absorbing crystal. The 400 reflection of GaAs using Cu $K\alpha$ radiation is shown.

high absorption coefficient within the domain $|\eta_r| \leq 1$. Fig. 5.1.7.2 gives an example of a rocking curve for a thick absorbing crystal. It was first observed by Renninger (1955). The shape is asymmetric and is due to the anomalous-absorption effect: it is lower than normal on the low-angle side, which is associated with wavefields belonging to branch 1 of the dispersion surface, and larger than normal on the high-angle side, which is associated with branch 2 wavefields. The amount of asymmetry depends on the value of the ratio A/B of the coefficients in the expression for the imaginary part of the deviation parameter in (5.1.3.7): the smaller this ratio, the more important the asymmetry.

Absorption coefficient. The effective absorption coefficient, taking into account both the Borrmann effect and extinction, is given by (Authier, 1986)

$$\mu = \mu_o + 2(|F_h F_{\bar{h}}|)^{1/2} \frac{R\lambda}{V(|\gamma|)^{1/2}} Z \sin(\beta + \Psi'),$$

where β is defined in equation (5.1.3.7) and Ψ' in equation (5.1.7.5), and where the sign is chosen in such a way that Z converges. Fig. 5.1.7.3 shows the variation of the penetration depth $z_o = \gamma_o/\mu$ with the deviation parameter.

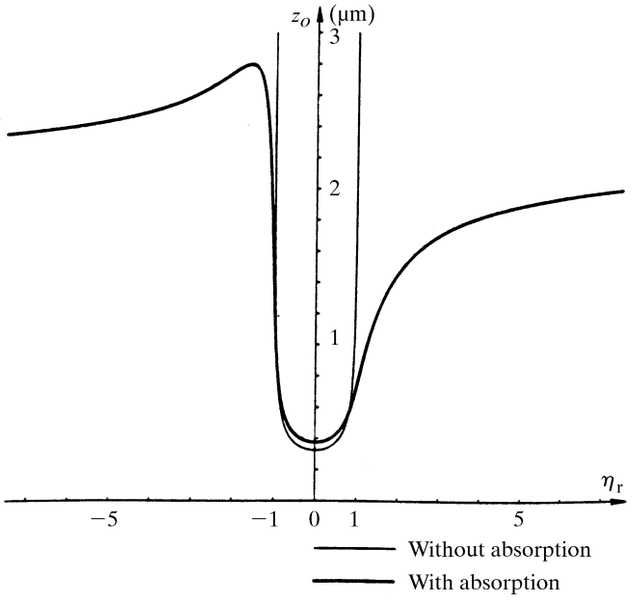

Fig. 5.1.7.3. Bragg case: thick crystals. Variation of the penetration depth with incidence angle (represented here by the dimensionless deviation parameter η). Thin curve: without absorption; thick curve: with absorption for the 400 reflection of GaAs using Cu $K\alpha$ radiation.

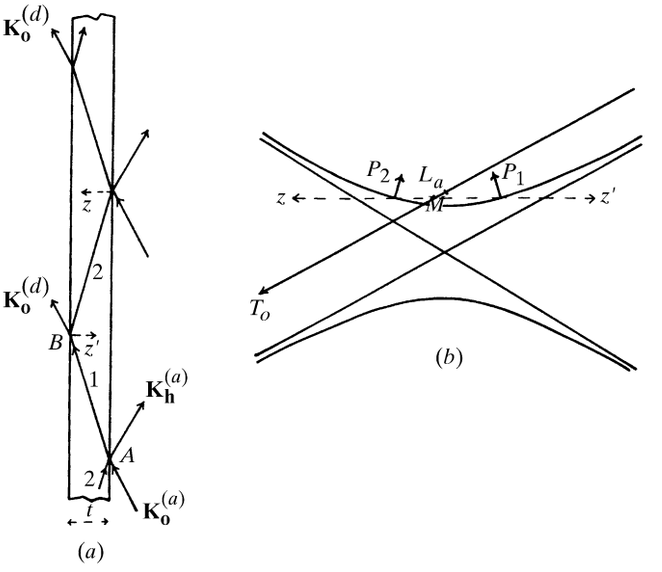

Fig. 5.1.7.4. Bragg case: thin crystals. Two wavefields propagate in the crystal. (*a*) Direct space; (*b*) reciprocal space.

5.1.7.2. Thin crystals

5.1.7.2.1. Non-absorbing crystals

Boundary conditions. If the crystal is thin, the wavefield created at the reflecting surface at A and penetrating inside can reach the back surface at B (Fig. 5.1.7.4*a*). The *incident* direction there points towards the *outside* of the crystal, while the *reflected* direction points towards the inside. The wavefield propagating along AB will therefore generate at B:

(i) *a partially transmitted wave* outside the crystal, $\mathbf{D}_\mathbf{o}^{(d)} \exp(-2\pi i \mathbf{K}_\mathbf{o}^{(d)} \cdot \mathbf{r})$;

(ii) *a partially reflected wavefield* inside the crystal.

The corresponding tiepoints are obtained by applying the usual condition of the continuity of the tangential components of wavevectors (Fig. 5.1.7.4*b*). If the crystal is a plane-parallel slab, these points are M and P_2, respectively, and $\mathbf{K}_\mathbf{o}^{(d)} = \mathbf{K}_\mathbf{o}^{(a)}$.

The boundary conditions are then written:

(i) entrance surface:

$$D_{o1} + D_{o2} = D_o^{(a)}, \;\; D_{h1} + D_{h2} = D_h^{(a)};$$

(ii) back surface:

$$\begin{aligned} &D_{o1} \exp(-2\pi i \mathbf{K}_{\mathbf{o}1} \cdot \mathbf{r}) + D_{o2} \exp(-2\pi i \mathbf{K}_{\mathbf{o}2} \cdot \mathbf{r}) \\ &\quad = D_o^{(a)} \exp\big(-2\pi i \mathbf{K}_\mathbf{o}^{(d)} \cdot \mathbf{r}\big), \\ &D_{h1} \exp(-2\pi i \mathbf{K}_{\mathbf{h}1} \cdot \mathbf{r}) + D_{h2} \exp(-2\pi i \mathbf{K}_{\mathbf{h}2} \cdot \mathbf{r}) = 0. \end{aligned}$$

Rocking curve. Using (5.1.3.10), it can be shown that the expressions for the intensities reflected at the entrance surface and transmitted at the back surface, I_h and I_o, respectively, are given by different expressions within total reflection and outside it:

(i) $|\eta| < 1$:

$$\begin{aligned} I_h &= |\gamma| \frac{|D_h^{(a)}|^2}{|D_o^{(a)}|^2} = \frac{\cosh^2[\pi(t/\Lambda_\mathrm{B})(1-\eta^2)^{1/2}] - 1}{\cosh^2[\pi(t/\Lambda_\mathrm{B})(1-\eta^2)^{1/2}] - \eta^2} \\ I_o &= \frac{|D_o^{(d)}|^2}{|D_o^{(a)}|^2} = \frac{1-\eta^2}{\cosh^2[\pi(t/\Lambda_\mathrm{B})(1-\eta^2)^{1/2}] - \eta^2}, \end{aligned} \qquad (5.1.7.7a)$$

where Λ_B is the value taken by Λ_o [equation (5.1.3.8)] in the Bragg case.

There is no longer a total-reflection domain but the extinction effect still exists, as is shown by the hyperbolic cosine term. The maximum height of the rocking curve decreases as the thickness of the crystal decreases.

(ii) $|\eta| > 1$:

$$I_h = \frac{1 - \cos^2[\pi(t/\Lambda_B)(\eta^2-1)^{1/2}]}{\eta^2 - \cos^2[\pi(t/\Lambda_B)(\eta^2-1)^{1/2}]},$$
$$I_o = \frac{\eta^2 - 1}{\eta^2 - \cos^2[\pi(t/\Lambda_B)(\eta^2-1)^{1/2}]}. \quad (5.1.7.7b)$$

The cosine terms show that the two wavefields propagating within the crystal interfere, giving rise to *Pendellösung* fringes in the rocking curve. These fringes were observed for the first time by Batterman & Hildebrandt (1967, 1968). The angular positions of the minima of the reflected beam are given by

$$\eta = \mp(K^2\Lambda_B^2 t^{-2} + 1)^{1/2},$$

where K is an integer.

Integrated intensity. The integrated intensity is

$$I_{hi} = \pi\delta \tanh[\pi t/\Lambda_B], \quad (5.1.7.8)$$

where t is the crystal thickness. When this thickness becomes very large, the integrated intensity tends towards

$$I_{hi} = \pi\delta. \quad (5.1.7.9)$$

This expression differs from (5.1.7.3) by the factor π, which appears here in place of 8/3. von Laue (1960) pointed out that because of the differences between the two expressions for the reflecting power, (5.1.7.2) and (5.1.7.7*b*), perfect agreement could not be expected. Since some absorption is always present, expression (5.1.7.3), which includes the factor 8/3, should be used for very thick crystals. In the presence of absorption, however, expression (5.1.7.8) for the reflected intensity for thin crystals does tend towards that for thick crystals as the crystal thickness increases.

Comparison with geometrical theory. When t/Λ_B is very small (thin crystals or weak reflections), (5.1.7.8) tends towards

$$I_{hi} = R^2\lambda^2 t|F_h|^2 \big/ (V^2\gamma_o \sin 2\theta), \quad (5.1.7.10)$$

which is the expression given by geometrical theory. If we call this intensity I_{hi}(geom.), comparison of expressions (5.1.7.8) and (5.1.7.10) shows that the integrated intensity for crystals of intermediate thickness can be written

$$I_{hi} = I_{hi}(\text{geom.})\frac{\tanh(\pi t/\Lambda_B)}{(\pi t/\Lambda_B)}, \quad (5.1.7.11)$$

which is the expression given by Darwin (1922) for primary extinction.

5.1.7.2.2. Absorbing crystals

Reflected intensity. The intensity of the reflected wave for a thin absorbing crystal is

$$I_h = |\gamma|\left|\frac{D_h^{(a)}}{D_o^{(a)}}\right|^2 = \left|\frac{F_h}{F_{\bar{h}}}\right| \frac{\cosh 2b - \cos 2a}{L\cosh 2b + (L^2-1)^{1/2}\sinh 2b - \cos(2a + 2\Psi')}, \quad (5.1.7.12)$$

where

$$2a = [\pi t/\Lambda_B]\rho\cos(\beta+\omega),$$
$$2b = [\pi t/\Lambda_B]\rho\sin(\beta+\omega).$$

L, ρ and ψ' are defined in (5.1.7.5), β is defined in (5.1.3.7) and ω is the phase angle of $(\eta^2-1)^{1/2}$.

Comparison with geometrical theory. When t/Λ_B decreases towards zero, expression (5.1.7.12) tends towards $[\sin(\pi t\eta/\Lambda_B)/\eta]^2$; using (5.1.3.5) and (5.1.3.8), it can be shown that expression (5.1.7.12) can be written, in the non-absorbing symmetric case, as

$$I_h = \frac{R^2\lambda^2 C^2|F_h|^2 t^2}{V^2\sin^2\theta}\left\{\frac{\sin[2\pi k\cos(\theta)t\Delta\theta]}{[2\pi k\cos(\theta)t\Delta\theta]}\right\}^2, \quad (5.1.7.13)$$

where d is the lattice spacing and $\Delta\theta$ is the difference between the angle of incidence and the middle of the reflection domain. This expression is the classical expression given by geometrical theory [see, for instance, James (1950)].

5.1.8. Real waves

5.1.8.1. Introduction

The preceding sections have dealt with the diffraction of a plane wave by a semi-infinite perfect crystal. This situation is actually never encountered in practice, although with various devices, in particular using synchrotron radiation, it is possible to produce highly collimated monochromated waves which behave like pseudo plane waves. The wave from an X-ray tube is best represented by a spherical wave. The first experimental proof of this fact is due to Kato & Lang (1959) in the transmission case. Kato extended the dynamical theory to spherical waves for non-absorbing (Kato, 1961*a*,*b*) and absorbing crystals (Kato, 1968*a*,*b*). He expanded the incident spherical wave into plane waves by a Fourier transform, applied plane-wave dynamical theory to each of these components and took the Fourier transform of the result again in order to obtain the final solution. Another method for treating the problem was used by Takagi (1962, 1969), who solved the propagation equation in a medium where the lateral extension of the incident wave is limited and where the wave amplitudes depend on the lateral coordinates. He showed that in this case the set of fundamental linear equations (5.1.2.20) should be replaced by a set of partial differential equations. This treatment can be applied equally well to a perfect or to an imperfect crystal. In the case of a perfect crystal, Takagi showed that these equations have an analytical solution that is identical with Kato's result. Uragami (1969, 1970) observed the spherical wave in the Bragg (reflection) case, interpreting the observed intensity distribution using Takagi's theory. Saka *et al.* (1973) subsequently extended Kato's theory to the Bragg case.

Without using any mathematical treatment, it is possible to make some elementary remarks by considering the fact that the divergence of the incident beam falling on the crystal from the source is much larger than the angular width of the reflection domain. Fig. 5.1.8.1(*a*) shows a spatially collimated beam falling

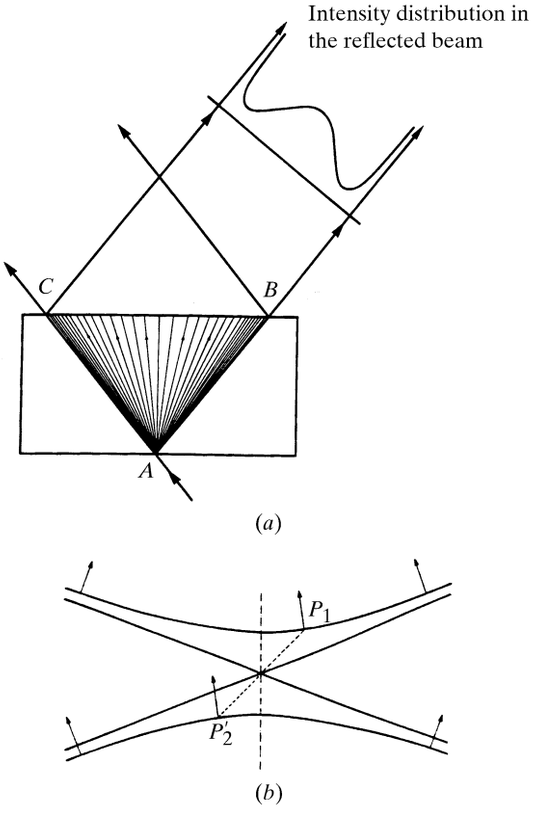

Fig. 5.1.8.1. Borrmann triangle. When the incident beam is divergent, the whole dispersion surface is excited and the wavefields excited inside the crystal propagate within a triangle filling all the space between the incident direction, AC, and the reflected direction, AB. Along any direction Ap within this triangle two wavefields propagate, having as tie points two conjugate points, P and P', at the extremities of a diameter of the dispersion surface. (*a*) Direct space; (*b*) reciprocal space.

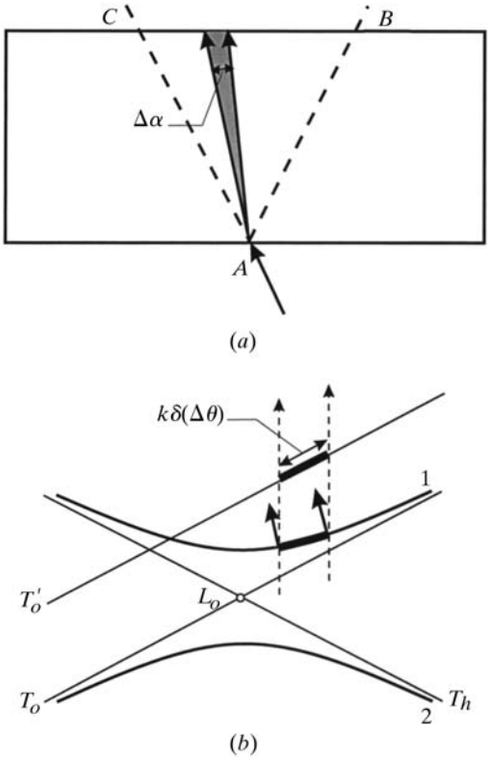

Fig. 5.1.8.2. Packet of wavefields of divergence $\Delta\alpha$ excited in the crystal by an incident wavepacket of angular width $\delta(\Delta\theta)$. (*a*) Direct space; (*b*) reciprocal space.

on a crystal in the transmission case and Fig. 5.1.8.1(*b*) represents the corresponding situation in reciprocal space. Since the divergence of the incident beam is larger than the angular width of the dispersion surface, the plane waves of its Fourier expansion will excite every point of both branches of the dispersion surface. The propagation directions of the corresponding wavefields will cover the angular range between those of the incident and reflected beams (Fig. 5.1.8.1*a*) and fill what is called the *Borrmann triangle*. The intensity distribution within this triangle has interesting properties, as described in the next two sections.

5.1.8.2. Borrmann triangle

The first property of the Borrmann triangle is that the angular density of the wavefield paths is inversely proportional to the curvature of the dispersion surface around their tie points. Let us consider an incident wavepacket of angular width $\delta(\Delta\theta)$. It will generate a packet of wavefields propagating within the Borrmann triangle. The angular width $\Delta\alpha$ (Fig. 5.1.8.2) between the paths of the corresponding wavefields is related to the radius of curvature $\mathcal{R}$ of the dispersion surface by

$$\mathcal{A} = \Delta\alpha/\delta(\Delta\theta) = k\cos\theta(\mathcal{R}\cos\alpha), \qquad (5.1.8.1)$$

where α is the angle between the wavefield path and the lattice planes [equation (5.1.2.26)] and $\mathcal{A}$ is called the amplification ratio. In the middle of the reflecting domain, the radius of curvature of the dispersion surface is very much shorter than its value, k, far from it (about 10^4 times shorter) and the amplification ratio is therefore very large. As a consequence, the energy of a wavepacket of width $\delta(\Delta\theta)$ in reciprocal space is spread in direct space over an angle $\Delta\alpha$ given by (5.1.8.1). The intensity distribution on the exit surface BC (Fig. 5.1.8.1*a*) is therefore proportional to $I_h/\mathcal{A}$. It is represented in Fig. 5.1.8.3 for several values of the absorption coefficient:

(i) Small values of $\mu_o t$ (less than 2 or 3) (Fig. 5.1.8.3*a*). The intensity distribution presents a wide minimum in the centre where the density of wavefields is small and increases very sharply at the edges where the density of wavefields is large, although it is the reverse for the reflecting power I_{hj}. This effect, called the *margin effect*, was predicted qualitatively by Borrmann (1959) and von Laue (1960), demonstrated experimentally by Kato & Lang (1959), and calculated by Kato (1960).

(ii) Large values of $\mu_o t$ (of the order of 6 or more) (Fig. 5.1.8.3*b*). The predominant factor is now anomalous absorption. The wavefields propagating along the edges of the Borrmann triangle undergo normal absorption, while those propagating parallel to the lattice planes (or nearly parallel) correspond to tie points in the centre of the dispersion surface and undergo anomalously low absorption. The intensity distribution now has a maximum in the centre. For values of μt larger than 10 or so, practically only the wavefields propagating parallel to the lattice planes go through the crystal, which acts as a wave guide: this is the Borrmann effect.

5.1.8.3. Spherical-wave Pendellösung

Fig. 5.1.8.4 shows that along any path Ap inside the Borrmann triangle two wavefields propagate, one with tie point P_1, on branch 1, the other with the point P'_2, on branch 2. These two points lie on the extremities of a diameter of the dispersion surface. The two wavefields interfere, giving rise to *Pendellösung* fringes, which were first observed by Kato & Lang (1959), and calculated by Kato (1961*b*). These fringes are of course quite different from the plane-wave *Pendellösung* fringes predicted by Ewald (Section 5.1.6.3) because the tie points of the interfering wavefields are different and their period is also different, but they have in common the fact that they result from interference

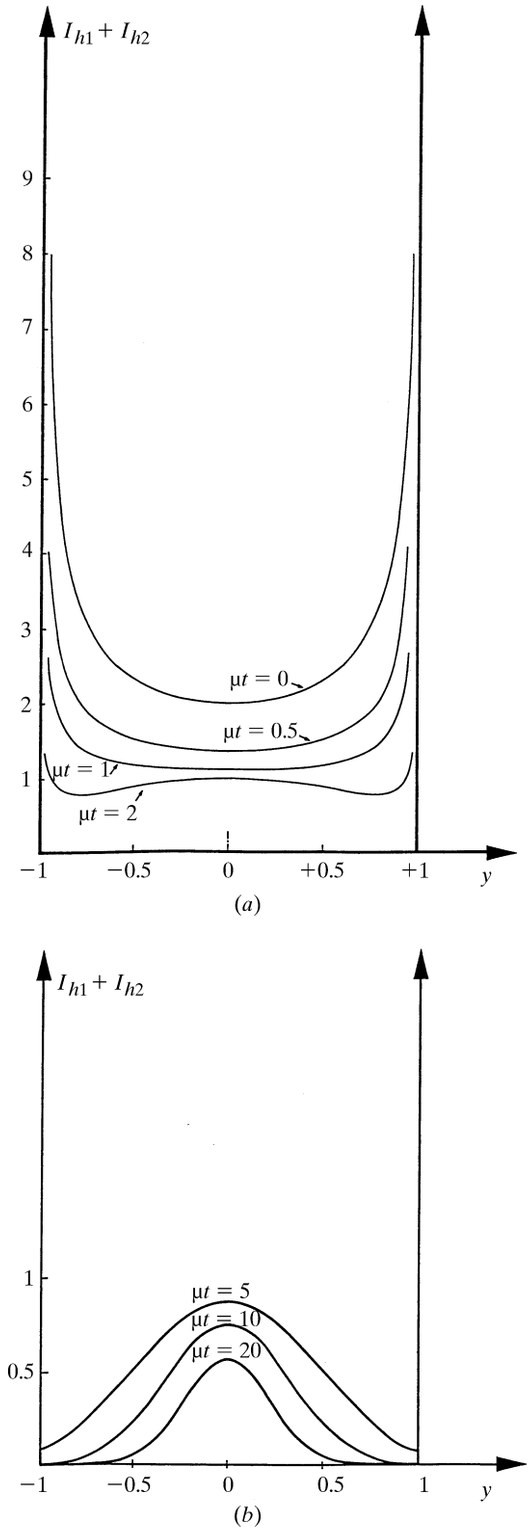

Fig. 5.1.8.3. Intensity distribution along the base of the Borrmann triangle. y is a normalized coordinate along BC. (*a*) Small values of μt. The interference (spherical-wave *Pendellösung*) between branch 1 and branch 2 is neglected. (*b*) Large values of μt.

between wavefields belonging to different branches of the dispersion surface.

Kato has shown that the intensity distribution at any point at the base of the Borrmann triangle is proportional to

$$\left\{J_o\left[A(x_o x_h)^{1/2}\right]\right\}^2,$$

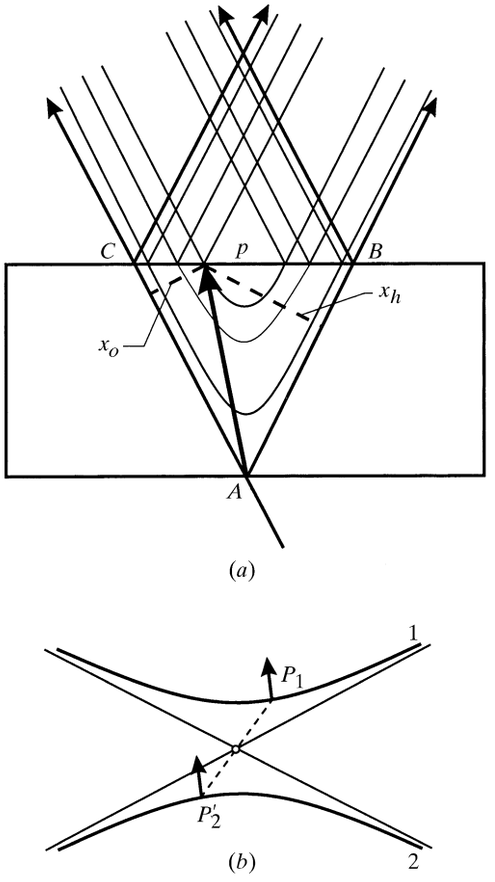

Fig. 5.1.8.4. Interference at the origin of the *Pendellösung* fringes in the case of an incident spherical wave. (*a*) Direct space; (*b*) reciprocal space.

where $A = 2\pi(\gamma_o\gamma_h)^{1/2}/(\Lambda_L \sin\theta)$ and x_o and x_h are the distances of p from the sides AB and AC of the Borrmann triangle (Fig. 5.1.8.4). The equal-intensity fringes are therefore located along the locus of the points in the triangle for which the product of the distances to the sides is constant, that is hyperbolas having AB and AC as asymptotes (Fig. 5.1.8.4*b*). These fringes can be observed on a section topograph of a wedge-shaped crystal (Fig. 5.1.8.5). The technique of section topography is described in *IT* C, Section 2.7.2.2. The *Pendellösung* distance Λ_L depends on the polarization state [see equation (5.1.3.8)]. If the incident wave is unpolarized, one observes the superposition of the *Pendellösung* fringes corresponding to the two states of polarization, parallel and perpendicular to the plane of incidence. This results in a beat effect, which is clearly visible in Fig. 5.1.8.5.

APPENDIX A5.1.1
Basic equations

A5.1.1.1. Dielectric susceptibility – classical derivation

Under the influence of the incident electromagnetic radiation, the medium becomes polarized. The dielectric susceptibility, which relates this polarization to the electric field, thus characterizes the interaction of the medium and the electromagnetic wave. The classical derivation of the dielectric susceptibility, χ, which is summarized here is only valid for a very high frequency which is also far from an absorption edge. Let us consider an electromagnetic wave,

$$\mathbf{E} = \mathbf{E_o} \exp 2\pi i(\nu t - \mathbf{k}\cdot\mathbf{r}),$$

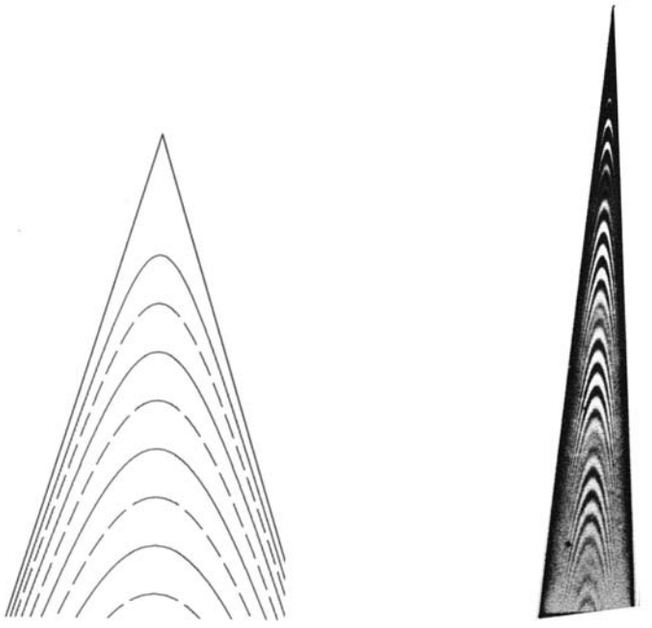

Fig. 5.1.8.5. Spherical-wave *Pendellösung* fringes observed on a wedge-shaped crystal. (*a*) Computer simulation (solid lines: maxima; dashed lines: minima). (*b*) X-ray section topograph of a wedge-shaped silicon crystal (444 reflection, Mo $K\alpha$ radiation).

incident on a bound electron. The electron behaves as if it were held by a spring with a linear restoring force and is an oscillator with a resonant frequency ν_o. The equation of its motion is written in the following way:

$$m\,\mathrm{d}^2\mathbf{a}/\mathrm{d}t^2 = -4\pi^2\nu_o^2 m\mathbf{a} = \mathbf{F},$$

where the driving force $\mathbf{F}$ is due to the electric field of the wave and is equal to $-e\mathbf{E}$. The magnetic interaction is neglected here.

The solution of the equation of motion is

$$\mathbf{a} = -e\mathbf{E}/[4\pi^2 m(\nu_o^2 - \nu^2)].$$

The resonant frequencies of the electrons in atoms are of the order of the ultraviolet frequencies and are therefore much smaller than X-ray frequencies. They can be neglected and the expression of the amplitude of the electron reduces to

$$\mathbf{a} = e\mathbf{E}/(4\pi^2\nu^2).$$

The dipolar moment is therefore

$$\mathcal{M} = -e\mathbf{a} = -e^2\mathbf{E}/(4\pi^2\nu^2 m).$$

von Laue assumes that the negative charge is distributed continuously all over space and that the charge of a volume element $\mathrm{d}\tau$ is $-e\rho\,\mathrm{d}\tau$, where ρ is the electronic density. The electric moment of the volume element is

$$\mathrm{d}\mathcal{M} = -e^2\rho\mathbf{E}\,\mathrm{d}\tau/(4\pi^2\nu^2 m).$$

The polarization is equal to the moment per unit volume:

$$\mathbf{P} = \mathrm{d}\mathcal{M}/\mathrm{d}\tau = -e^2\rho\mathbf{E}/(4\pi^2\nu^2 m).$$

It is related to the electric field and electric displacement through

$$\mathbf{D} = \varepsilon_o\mathbf{E} + \mathbf{P} = \varepsilon_o(1+\chi)\mathbf{E}. \qquad \text{(A5.1.1.1)}$$

We finally obtain the expression of the dielectric susceptibility,

$$\chi = -e^2\rho/(4\pi^2\varepsilon_o\nu^2 m) = -R\lambda^2\rho/\pi, \qquad \text{(A5.1.1.2)}$$

where $R = e^2/(4\pi\varepsilon_o mc^2)$ ($= 2.81794 \times 10^{-15}$ m) is the classical radius of the electron.

A5.1.1.2. Maxwell's equations

The electromagnetic field is represented by two vectors, $\mathbf{E}$ and $\mathbf{B}$, which are the electric field and the magnetic induction, respectively. To describe the interaction of the field with matter, three other vectors must be taken into account, the electrical current density, $\mathbf{j}$, the electric displacement, $\mathbf{D}$, and the magnetic field, $\mathbf{H}$. The space and time derivatives of these vectors are related in a continuous medium by Maxwell's equations:

$$\begin{aligned} \mathrm{curl}\ \mathbf{E} &= -\partial\mathbf{B}/\partial t \\ \mathrm{curl}\ \mathbf{H} &= \partial\mathbf{D}/\partial t + \mathbf{j} \\ \mathrm{div}\ \mathbf{D} &= \rho \\ \mathrm{div}\ \mathbf{B} &= 0, \end{aligned} \qquad \text{(A5.1.1.3)}$$

where ρ is the electric charge density.

The electric field and the electric displacement on the one hand, and the magnetic field and the magnetic induction on the other hand, are related by the so-called *material relations*, which describe the reaction of the medium to the electromagnetic field:

$$\begin{aligned} \mathbf{D} &= \varepsilon\mathbf{E} \\ \mathbf{B} &= \mu\mathbf{H}, \end{aligned}$$

where ε and μ are the dielectric constant and the magnetic permeability, respectively.

These equations are complemented by the following boundary conditions at the surface between two neighbouring media:

$$\begin{aligned} \mathbf{E}_{T1} - \mathbf{E}_{T2} &= 0 \quad \mathbf{D}_{N1} - \mathbf{D}_{N2} = 0 \\ \mathbf{H}_{T1} - \mathbf{H}_{T2} &= 0 \quad \mathbf{B}_{N1} - \mathbf{B}_{N2} = 0. \end{aligned} \qquad \text{(A5.1.1.4)}$$

From the second and the third equations of (A5.1.1.3), and using the identity

$$\mathrm{div}\ (\mathrm{curl}\ \mathbf{y}) = 0,$$

it follows that

$$\mathrm{div}\ \mathbf{j} + \partial\rho/\partial t = 0. \qquad \text{(A5.1.1.5)}$$

A5.1.1.3. Propagation equation

In a vacuum, ρ and $\mathbf{j}$ are equal to zero, and the first two equations of (A5.1.1.3) can be written

$$\text{curl } \mathbf{E} = -\mu_0 \partial \mathbf{E}/\partial t$$
$$\text{curl } \mathbf{H} = \varepsilon_0 \partial \mathbf{H}/\partial t,$$

where ε_0 and μ_0 are the dielectric constant and the magnetic permeability of a vacuum, respectively.

By taking the curl of both sides of the second equation, it follows that

$$\text{curl curl } \mathbf{E} = -\varepsilon_0 \mu_0 \partial^2 \mathbf{E}/\partial t^2.$$

Using the identity curl curl $\mathbf{E}$ = grad div $\mathbf{E} - \Delta \mathbf{E}$, the relation $\varepsilon_0 \mu_0 = 1/c^2$, where c is the velocity of light, and noting that div $\mathbf{E}$ = div $\mathbf{D} = 0$, one finally obtains the equation of propagation of an electromagnetic wave in a vacuum:

$$\Delta \mathbf{E} = \frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2}. \qquad \text{(A5.1.1.6)}$$

Its simplest solution is a plane wave:

$$\mathbf{E} = \mathbf{E_0} \exp 2\pi i(\nu t - \mathbf{k} \cdot \mathbf{r}),$$

of which the wavenumber $k = 1/\lambda$ and the frequency ν are related by

$$k = \nu/c.$$

The basic properties of the electromagnetic field are described, for instance, in Born & Wolf (1983).

The propagation equation of X-rays in a crystalline medium is derived following von Laue (1960). The interaction of X-rays with charged particles is inversely proportional to the mass of the particle and the interaction with the nuclei can be neglected. As a first approximation, it is also assumed that the magnetic interaction of X-rays with matter is neglected, and that the magnetic permeability μ can be taken as equal to the magnetic permeability of a vacuum, μ_0. It is further assumed that the negative and positive charges are both continuously distributed and compensate each other in such a way that there is neutrality and no current everywhere: ρ and $\mathbf{j}$ are equal to zero and div $\mathbf{D}$ is therefore also equal to zero. The electric displacement is related to the electric field by (A5.1.1.1) and the electric part of the interaction of X-rays with matter is expressed through the dielectric susceptibility χ, which is given by (A5.1.1.2). This quantity is proportional to the electron density and varies with the space coordinates. It is therefore concluded that div $\mathbf{E}$ is different from zero, as opposed to what happens in a vacuum. For this reason, the propagation equation of X-rays in a crystalline medium is expressed in terms of the electric displacement rather than in terms of the electric field. It is obtained by eliminating $\mathbf{H}$, $\mathbf{B}$ and $\mathbf{E}$ in Maxwell's equations and taking into account the above assumptions:

$$\Delta \mathbf{D} + \text{curl curl } \chi \mathbf{D} = \frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2}. \qquad \text{(A5.1.1.7)}$$

Only coherent scattering is taken into account here, that is, scattering without frequency change. The solution is therefore a wave of the form

$$\mathbf{D}(\mathbf{r}) \exp 2\pi i \nu t.$$

By replacing $\mathbf{D}$ with this expression in equation (A5.1.1.7), one finally obtains the propagation equation (5.1.2.2) (Section 5.1.2.1).

In a crystalline medium, χ is a triply periodic function of the space coordinates and the solutions of this equation are given in terms of Fourier series which can be interpreted as sums of electromagnetic plane waves. Each of these waves is characterized by its wavevector, $\mathbf{K_h}$, its electric displacement, $\mathbf{D_h}$, its electric field, $\mathbf{E_h}$, and its magnetic field, $\mathbf{H_h}$. It can be shown that, as a consequence of the fact that div $\mathbf{D} = 0$ and div $\mathbf{E} \neq 0$, $\mathbf{D_h}$ is a transverse wave ($\mathbf{D_h}$, $\mathbf{H_h}$ and $\mathbf{K_h}$ and are mutually orthogonal) while $\mathbf{E_h}$ is not. The electric displacement is therefore a more suitable vector for describing the state of the field inside the crystal than the electric field.

A5.1.1.4. Poynting vector

The propagation direction of the energy of an electromagnetic wave is given by that of the Poynting vector defined by (see Born & Wolf, 1983)

$$\mathbf{S} = \mathcal{R}(\mathbf{E} \wedge \mathbf{H}^*), \qquad \text{(A5.1.1.8)}$$

where $\mathcal{R}(\,)$ means real part of ( ).

The intensity I of the radiation is equal to the energy crossing unit area per second in the direction normal to that area. It is given by the value of the Poynting vector averaged over a period of time long compared with $1/\nu$:

$$\mathbf{I} = |\mathbf{S}| = c\varepsilon |\mathbf{E}|^2 = c|\mathbf{D}|^2/\varepsilon.$$

5.2. Dynamical theory of electron diffraction

By A. F. Moodie, J. M. Cowley† and P. Goodman†

5.2.1. Introduction

Since electrons are charged, they interact strongly with matter, so that the single scattering approximation has a validity restricted to thin crystals composed of atoms of low atomic number. Further, at energies of above a few tens of keV, the wavelength of the electron is so short that the geometry of two-beam diffraction can be approximated in only small unit cells.

It is therefore necessary to develop a scattering theory specific to electrons and, preferably, applicable to imaging as well as to diffraction. The development, started by Born (1926) and Bethe (1928), and continuing into the present time, is the subject of an extensive literature, which includes reviews [for instance: Howie (1978), Humphreys (1979)] and historical accounts (Goodman, 1981), and is incorporated in Chapter 5.1. Here, an attempt will be made to present only that outline of the main formulations which, it is hoped, will help the nonspecialist in the use of the tables. No attempt will be made to follow the historical development, which has been tortuous and not always logical, but rather to seek the simplest and most transparent approach that is consistent with brevity. Only key points in proofs will be sketched in an attempt to display the nature, rather than the rigorous foundations of the arguments.

5.2.2. The defining equations

No many-body effects have yet been detected in the diffraction of fast electrons, but the velocities lie well within the relativistic region. The one-body Dirac equation would therefore appear to be the appropriate starting point. Fujiwara (1962), using the scattering matrix, carried through the analysis for forward scattering, and found that, to a very good approximation, the effects of spin are negligible, and that the solution is the same as that obtained from the Schrödinger equation provided that the relativistic values for wavelength and mass are used. In effect a Klein–Gordon equation (Messiah, 1965) can be used in electron diffraction (Buxton, 1978) in the form

$$\nabla^2\psi_\mathrm{b} + \frac{8\pi^2 m|e|\varphi}{h^2}\psi_\mathrm{b} + \frac{8\pi^2 m_0|e|W}{h^2}\left(1+\frac{|e|W}{2m_0c^2}\right)\psi_\mathrm{b} = 0.$$

Here, W is the accelerating voltage and φ, the potential in the crystal, is defined as being positive. The relativistic values for mass and wavelength are given by $m = m_0(1 - v^2/c^2)^{-1/2}$, and taking '$e$' now to represent the modulus of the electronic charge, $|e|$,

$$\lambda = h[2m_0eW(1 + eW/2m_0c^2)]^{-1/2},$$

and the wavefunction is labelled with the subscript b in order to indicate that it still includes back scattering, of central importance to LEED (low-energy electron diffraction).

In more compact notation,

$$[\nabla^2 + k^2(1+\varphi/W)]\psi_\mathrm{b} = (\nabla^2 + k^2 + 2k\sigma\varphi)\psi_\mathrm{b} = 0. \quad (5.2.2.1)$$

Here $k = |\mathbf{k}|$ is the scalar wavenumber of magnitude $2\pi/\lambda$, and the interaction constant $\sigma = 2\pi me\lambda/h^2$. This constant is approximately 10^{-3} for 100 kV electrons.

For fast electrons, φ/W is a slowly varying function on a scale of wavelength, and is small compared with unity. The scattering will therefore be peaked about the direction defined by the incident beam, and further simplification is possible, leading to a forward-scattering solution appropriate to HEED (high-energy electron diffraction).

5.2.3. Forward scattering

A great deal of geometric detail can arise at this point and, further, there is no generally accepted method for approximation, the various procedures leading to numerically negligible differences and to expressions of precisely the same form. Detailed descriptions of the geometry are given in the references.

The entrance surface of the specimen, in the form of a plate, is chosen as the x, y plane, and the direction of the incident beam is taken to be close to the z axis. Components of the wavevector are labelled with suffixes in the conventional way; $\mathbf{K}_0 = \mathbf{k}_x + \mathbf{k}_y$ is the transverse wavevector, which will be very small compared to $\mathbf{k}_z$. In this notation, the excitation error for the reflection is given by

$$\zeta_\mathbf{h} = \frac{K_0^2 - |\mathbf{K}_0 + 2\pi\mathbf{h}|^2}{4\pi|\mathbf{k}_z|}.$$

An intuitive method argues that, since $\varphi/W \ll 1$, then the component of the motion along z is little changed by scattering. Hence, making the substitution $\psi_\mathrm{b} = \psi\exp\{ik_z z\}$ and neglecting $\partial^2\psi/\partial z^2$, equation (5.2.2.1) becomes

$$\frac{\partial\psi}{\partial z} = i\left[\frac{1}{2k_z}(\nabla_{x,y}^2 + K_0^2) + \sigma\varphi\right]\psi, \quad (5.2.3.1)$$

where

$$\nabla_{x,y}^2 \equiv \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2},$$

and $\psi(x, y, 0) = \exp\{i(k_x x + k_y y)\}$.

Equation (5.2.3.1) is of the form of a two-dimensional time-dependent Schrödinger equation, with the z coordinate replacing time. This form has been extensively discussed. For instance, Howie (1966) derived what is essentially this equation using an expansion in Bloch waves, Berry (1971) used a Green function in a detailed and rigorous derivation, and Goodman & Moodie (1974), using methods due to Feynman, derived the equation as the limit of the multislice recurrence relation. A method due to Corones *et al.* (1982) brings out the relationship between the HEED and LEED equations. Equation (5.2.2.1) is cast in the form of a first-order system,

$$\frac{\partial}{\partial z}\begin{pmatrix}\psi_\mathrm{b}\\ \partial\psi_\mathrm{b}/\partial z\end{pmatrix} = \begin{pmatrix}0 & 1\\ -(\nabla_{x,y}^2 + k^2 + 2k\sigma\varphi) & 0\end{pmatrix}\begin{pmatrix}\psi_\mathrm{b}\\ \partial\psi_\mathrm{b}/\partial z\end{pmatrix}.$$

† Deceased.

Copyright © 2010 International Union of Crystallography

A splitting matrix is introduced to separate the wavefunction into the forward and backward components, $\psi_b^{\pm}$, and the fast part of the phase is factored out, so that $\psi_b^{\pm} = \psi^{\pm} \exp\{\pm ik_z z\}$. In the resulting matrix differential equation, the off-diagonal terms are seen to be small for fast electrons, and equation (5.2.2.1) reduces to the pair of equations

$$\frac{\partial \psi^{\pm}}{\partial z} = \pm i\left[\frac{1}{2k_z}(\nabla_{x,y}^2 + K_0^2) + \sigma\varphi\right]\psi^{\pm}. \qquad (5.2.3.2)$$

The equation for $\psi^{\pm}$ is the Lontovich & Fock (1946) parabolic equation.

5.2.4. Evolution operator

Equation (5.2.3.1) is a standard and much studied form, so that many techniques are available for the construction of solutions. One of the most direct utilizes the causal evolution operator. A recent account is given by Gratias & Portier (1983).

In terms of the 'Hamiltonian' of the two-dimensional system,

$$-\mathbf{H}(z) \equiv \frac{1}{2k_z}(\nabla_{x,y}^2 + K_0^2) + \sigma\varphi,$$

the evolution operator $\mathbf{U}(z, z_0)$, defined by $\psi(z) = \mathbf{U}(z, z_0)\psi_0$, satisfies

$$i\frac{\partial}{\partial z}\mathbf{U}(z, z_0) = \mathbf{H}(z)\mathbf{U}(z, z_0), \qquad (5.2.4.1a)$$

or

$$\mathbf{U}(z, z_0) = 1 - i\int_{z_0}^{z} \mathbf{U}(z, z_1)\mathbf{H}(z_1)\,\mathrm{d}z_1. \qquad (5.2.4.1b)$$

5.2.5. Projection approximation – real-space solution

Many of the features of the more general solutions are retained in the practically important projection approximation in which $\varphi(x, y, z)$ is replaced by its projected mean value $\varphi_p(x, y)$, so that the corresponding Hamiltonian $\mathbf{H}_p$ does not depend on z. Equation (5.2.4.1b) can then be solved directly by iteration to give

$$\mathbf{U}_p(z, z_0) = \exp\{-i\mathbf{H}_p(z - z_0)\}, \qquad (5.2.5.1)$$

and the solution may be verified by substitution into equation (5.2.4.1a).

Many of the results of dynamical theory can be obtained by expansion of equation (5.2.5.1) as

$$\mathbf{U}_p \equiv \mathbf{1} - i\mathbf{H}_p(z - z_0) + \frac{i^2}{2!}\mathbf{H}_p^2(z - z_0) - \ldots,$$

followed by the direct evaluation of the differentials. Such expressions can be used, for instance, to explore symmetries in image space.

5.2.6. Semi-reciprocal space

In the derivation of electron-diffraction equations, it is more usual to work in semi-reciprocal space (Tournarie, 1962). This can be achieved by transforming equation (5.2.2.1) with respect to x and y but not with respect to z, to obtain Tournarie's equation

$$\frac{\mathrm{d}^2|U\rangle}{\mathrm{d}z^2} = -\mathbf{M}_b(z)|U\rangle. \qquad (5.2.6.1a)$$

Here $|U\rangle$ is the column vector of scattering amplitudes and $\mathbf{M}_b(z)$ is a matrix, appropriate to LEED, with $\mathbf{k}$ vectors as diagonal elements and Fourier coefficients of the potential as nondiagonal elements.

This equation is factorized in a manner parallel to that used on the real-space equation [equation (5.2.3.1)] (Lynch & Moodie, 1972) to obtain Tournarie's forward-scattering equation

$$\frac{\mathrm{d}|U^{\pm}\rangle}{\mathrm{d}z} = \pm i\mathbf{M}^{\pm}(z)|U^{\pm}\rangle, \qquad (5.2.6.1b)$$

where

$$\mathbf{M}^{\pm}(z) = \pm[\mathbf{K} + (1/2)\mathbf{K}^{-1}V(z)],$$
$$[K_{ij}] = \delta_{ij}K_i,$$

and

$$[V_{ij}] = 2k_z\sum_l V_{i-j}\exp\{-2\pi ilz\},$$

where $V_i \equiv \sigma v_i$ are the scattering coefficients and v_i are the structure amplitudes in volts. In order to simplify the electron-diffraction expression, the third crystallographic index 'l' is taken to represent the periodicity along the z direction.

The double solution involving $\mathbf{M}$ of equation (5.2.6.1b) is of interest in displaying the symmetry of reciprocity, and may be compared with the double solution obtained for the real-space equation [equation (5.2.3.2)]. Normally the $\mathbf{M}^+$ solution will be followed through to give the fast-electron forward-scattering equations appropriate in HEED. $\mathbf{M}^-$, however, represents the equivalent set of equations corresponding to the z reversed reciprocity configuration. Reciprocity solutions will yield diffraction symmetries in the forward direction when coupled with crystal-inverting symmetries (Section 2.5.3).

Once again we set out to solve the forward-scattering equation (5.2.6.1a,b) now in semi-reciprocal space, and define an operator $\mathbf{Q}(z)$ [compare with equation (5.2.4.1a)] such that

$$|U_z\rangle = \mathbf{Q}_z|U_0\rangle \quad \text{with} \quad U_0 = |0\rangle;$$

i.e., $\mathbf{Q}_z$ is an operator that, when acting on the incident wavevector, generates the wavefunction in semi-reciprocal space.

Again, the differential equation can be transformed into an integral equation, and once again this can be iterated. In the projection approximation, with $\mathbf{M}$ independent of z, the solution can be written as

$$\mathbf{Q}_p = \exp\{i\mathbf{M}_p(z - z_0)\}.$$

A typical off-diagonal element is given by $V_{i-j}/\cos\theta_i$, where θ_i is the angle through which the beam is scattered. It is usual in the literature to find that $\cos\theta_i$ has been approximated as unity, since even the most accurate measurements are, so far, in error by much more than this amount.

This expression for $\mathbf{Q}_p$ is Sturkey's (1957) solution, a most useful relation, written explicitly as

$$|U\rangle = \exp\{i\mathbf{M}_\mathrm{p}T\}|0\rangle \tag{5.2.6.2}$$

with T the thickness of the crystal, and $|0\rangle$, the incident state, a column vector with the first entry unity and the rest zero.

$$\mathbf{S} = \exp\{i\mathbf{M}_\mathrm{p}T\}$$

is a unitary matrix, so that in this formulation scattering is described as rotation in Hilbert space.

5.2.7. Two-beam approximation

In the two-beam approximation, as an elementary example, equation (5.2.6.2) takes the form

$$\begin{pmatrix} u_0 \\ u_\mathbf{h} \end{pmatrix} = \exp\left\{ i \begin{pmatrix} 0 & V^*(\mathbf{h}) \\ V(\mathbf{h}) & K_\mathbf{h} \end{pmatrix} T \right\} \begin{pmatrix} 0 \\ 1 \end{pmatrix}. \tag{5.2.7.1}$$

If this expression is expanded directly as a Taylor series, it proves surprisingly difficult to sum. However, the symmetries of Clifford algebra can be exploited by summing in a Pauli basis thus,

$$\begin{aligned} &\exp\left\{ i \begin{pmatrix} 0 & V^*(\mathbf{h}) \\ V(\mathbf{h}) & K_\mathbf{h} \end{pmatrix} T \right\} \\ &\quad = \exp\left\{ i\frac{K_\mathbf{h}T}{2} \right\} \mathbf{E} \exp\left\{ i\left(\frac{K_\mathbf{h}}{2}\boldsymbol{\sigma}_3 + V^\mathrm{R}\boldsymbol{\sigma}_1 - V^\mathrm{I}\boldsymbol{\sigma}_2 \right) T \right\}. \end{aligned}$$

Here, the $\boldsymbol{\sigma}_i$ are the Pauli matrices

$$\boldsymbol{\sigma}_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \ \boldsymbol{\sigma}_2 = \begin{pmatrix} 0 & i \\ -i & 0 \end{pmatrix}, \ \boldsymbol{\sigma}_3 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},$$
$$\mathbf{E} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

and V^R, V^I are the real and imaginary parts of the complex scattering coefficients appropriate to a noncentrosymmetric crystal, *i.e.* $V_\mathbf{h} = V^\mathrm{R} + iV^\mathrm{I}$. Expanding,

$$\begin{aligned} &\exp\left\{ i\left(\frac{K_\mathbf{h}}{2}\boldsymbol{\sigma}_3 + V^\mathrm{R}\boldsymbol{\sigma}_1 - V^\mathrm{I}\boldsymbol{\sigma}_2 \right) T \right\} \\ &\quad = \mathbf{E} + i\left(\frac{K_\mathbf{h}}{2}\boldsymbol{\sigma}_3 + V^\mathrm{R}\boldsymbol{\sigma}_1 - V^\mathrm{I}\boldsymbol{\sigma}_2 \right) T \\ &\qquad - \frac{1}{2}\left(\frac{K_\mathbf{h}}{2}\boldsymbol{\sigma}_3 + V^\mathrm{R}\boldsymbol{\sigma}_1 - V^\mathrm{I}\boldsymbol{\sigma}_2 \right)^2 T^2 + \ldots, \end{aligned}$$

using the anti-commuting properties of $\boldsymbol{\sigma}_i$:

$$\left.\begin{aligned} \boldsymbol{\sigma}_i\boldsymbol{\sigma}_j + \boldsymbol{\sigma}_j\boldsymbol{\sigma}_i &= 0 \\ \boldsymbol{\sigma}_i\boldsymbol{\sigma}_i &= 1 \end{aligned}\right\}$$

and putting $[(K_\mathbf{h}/2)^2 + V(\mathbf{h})V^*(\mathbf{h})] = \Omega$, $\mathbf{M}_2 = [(K_\mathbf{h}/2)\boldsymbol{\sigma}_3 + V^\mathrm{R}\boldsymbol{\sigma}_1 - V^\mathrm{I}\boldsymbol{\sigma}_2]$, so that $\mathbf{M}_2^2 = \Omega\mathbf{E}$ and $\mathbf{M}_2^3 = \Omega\mathbf{M}_2$, the powers of the matrix can easily be evaluated. They fall into odd and even series, corresponding to sine and cosine, and the classical two-beam approximation is obtained in the form

$$\mathbf{Q}_2 = \exp\{i(K_\mathbf{h}/2)T\}\mathbf{E}\left[(\cos\Omega^{1/2}T)\mathbf{E} + i\left(\frac{\sin\Omega^{1/2}T}{\Omega^{1/2}} \right)\mathbf{M}_2 \right]. \tag{5.2.7.2}$$

This result was first obtained by Blackman (1939), using Bethe's dispersion formulation. Ewald and, independently, Darwin, each with different techniques, had, in establishing the theoretical foundations for X-ray diffraction, obtained analogous results (see Section 5.1.3).

The two-beam approximation, despite its simplicity, exemplifies some of the characteristics of the full dynamical theory, for instance in the coupling between beams. As Ewald pointed out, a formal analogy can be found in classical mechanics with the motion of coupled pendulums. In addition, the functional form $(\sin ax)/x$, deriving from the shape function of the crystal emerges, as it does, albeit less obviously, in the N-beam theory.

This derivation of equation (5.2.7.2) exhibits two-beam diffraction as a typical two-level system having analogies with, for instance, lasers and nuclear magnetic resonance and exhibiting the symmetries of the special unitary group SU(2) (Gilmore, 1974).

5.2.8. Eigenvalue approach

In terms of the eigenvalues and eigenvectors, defined by

$$\mathbf{H}_\mathrm{p}|j\rangle = \gamma_j|j\rangle,$$

the evolution operator can be written as

$$\mathbf{U}(z, z_0) = \int |j\rangle \exp\{\gamma_j(z - z_0)\}\langle j|\,\mathrm{d}j.$$

This integration becomes a summation over discrete eigen states when an infinitely periodic potential is considered.

Despite the early developments by Bethe (1928), an N-beam expression for a transmitted wavefunction in terms of the eigenvalues and eigenvectors of the problem was not obtained until Fujimoto (1959) derived the expression

$$U_\mathbf{h} = \sum_j \psi_0^{j*}\psi_\mathbf{h}^j \exp\{-i2\pi\gamma_j T\}, \tag{5.2.8.1}$$

where $\psi_\mathbf{h}^j$ is the h component of the j eigenvector with eigenvalue γ_j.

This expression can now be related to those obtained in the other formulations. For example, Sylvester's theorem (Frazer *et al.*, 1963) in the form

$$f(\mathbf{M}) = \sum_j \mathbf{A}_j f(\gamma_j)$$

when applied to Sturkey's solution yields

$$\boldsymbol{\Phi}_\mathbf{h} = \exp(i\mathbf{M}_\mathrm{p}z) = \sum \mathbf{P}_j \exp\{i2\pi\gamma_j z\}$$

(Kainuma, 1968; Hurley *et al.*, 1978). Here, the $\mathbf{P}_j$ are projection operators, typically of the form

$$\mathbf{P}_j = \prod_{n\neq j} \frac{(\mathbf{M}_\mathrm{p} - \mathbf{E}\gamma_n)}{\gamma_j - \gamma_n}.$$

On changing to a lattice basis, these transform to $\psi_0^{j*}\psi_{\mathbf{h}}^{j}$.

Alternatively, the semi-reciprocal differential equation can be uncoupled by diagonalizing $\mathbf{M}_{\rm p}$ (Goodman & Moodie, 1974), a process which involves the solution of the characteristic equation

$$|\mathbf{M}_{\rm p} - \gamma_j \mathbf{E}| = 0. \tag{5.2.8.2}$$

5.2.9. Translational invariance

An important result deriving from Bethe's initial analysis, and not made explicit in the preceding formulations, is that the fundamental symmetry of a crystal, namely translational invariance, by itself imposes a specific form on wavefunctions satisfying Schrödinger's equation.

Suppose that, in a one-dimensional description, the potential in a Hamiltonian $\mathbf{H}_t(x)$ is periodic, with period t. Then,

$$\varphi(x + t) = \varphi(x)$$

and

$$\mathbf{H}_t\psi(x) = \mathbf{E}\psi(x).$$

Now define a translation operator

$$\mathbf{\Gamma} f(x) = f(x + t),$$

for arbitrary $f(x)$. Then, since $\mathbf{\Gamma}\varphi(x) = \varphi(x)$, and ∇^2 is invariant under translation,

$$\mathbf{\Gamma}\mathbf{H}_t(x) = \mathbf{H}_t(x)$$

and

$$\mathbf{\Gamma}\mathbf{H}_t(x)\psi(x) = \mathbf{H}_t(x + t)\psi(x + t) = \mathbf{H}_t(x)\mathbf{\Gamma}\psi(x).$$

Thus, the translation operator and the Hamiltonian commute, and therefore have the same eigenfunctions (but not of course the same eigenvalues), *i.e.*

$$\mathbf{\Gamma}\psi(x) = \alpha\psi(x).$$

This is a simpler equation to deal with than that involving the Hamiltonian, since raising the operator to an arbitrary power simply increments the argument

$$\mathbf{\Gamma}^m\psi(x) = \psi(x + mt) = \alpha^m\psi(x).$$

But $\psi(x)$ is bounded over the entire range of its argument, positive and negative, so that $|\alpha| = 1$, and α must be of the form $\exp\{i2\pi kt\}$.

Thus, $\psi(x + t) = \mathbf{\Gamma}\psi(x) = \exp\{i2\pi kt\}\psi(x)$, for which the solution is

$$\psi(x) = \exp\{i2\pi kt\}q(x)$$

with $q(x + t) = q(x)$.

This is the result derived independently by Bethe and Bloch. Functions of this form constitute bases for the translation group, and are generally known as Bloch functions. When extended in a direct fashion into three dimensions, functions of this form ultimately embody the symmetries of the Bravais lattice; *i.e.* Bloch functions are the irreducible representations of the translational component of the space group.

5.2.10. Bloch-wave formulations

In developing the theory from the beginning by eigenvalue techniques, it is usual to invoke the periodicity of the crystal in order to show that the solutions to the wave equation for a given wavevector $\mathbf{k}$ are Bloch waves of the form

$$\psi = C(\mathbf{r})\exp\{i\mathbf{k}\cdot\mathbf{r}\},$$

where $C(\mathbf{r})$ has the periodicity of the lattice, and hence may be expanded in a Fourier series to give

$$\psi = \sum_{\mathbf{h}} C_{\mathbf{h}}(\mathbf{k})\exp\{i(\mathbf{k} + 2\pi\mathbf{h})\cdot\mathbf{r}\}. \tag{5.2.10.1}$$

The $C_{\mathbf{h}}(\mathbf{k})$ are determined by equations of consistency obtained by substitution of equation (5.2.10.1) into the wave equation.

If N terms are selected in equation (5.2.10.1) there will be N Bloch waves where wavevectors differ only in their components normal to the crystal surface, and the total wavefunction will consist of a linear combination of these Bloch waves. The problem is now reduced to the problem of equation (5.2.8.2).

The development of solutions for particular geometries follows that for the X-ray case, Chapter 5.1, with the notable differences that:

(1) The two-beam solution is not adequate except as a first approximation for particular orientations of crystals having small unit cells and for accelerating voltages not greater than about 100 keV. In general, many-beam solutions must be sought.

(2) For transmission HEED, the scattering angles are sufficiently small to allow the use of a small-angle forward-scattering approximation.

(3) Polarization effects are negligible except for very low energy electrons.

Humphreys (1979) compares the action of the crystal, in the Bloch-wave formalism, with that of an interferometer, the incident beam being partitioned into a set of Bloch waves of different wavevectors. 'As each Bloch wave propagates it becomes out of phase with its neighbours (due to its different wavevector). Hence interference occurs. For example, if the crystal thickness varies, interference fringes known as thickness fringes are formed.' For the two-beam case, these are the fringes of the pendulum solution referred to previously.

5.2.11. Dispersion surfaces

One of the important constructs of the Bloch-wave formalism is the dispersion surface, a plot of the permitted values of the z component of a Bloch wavevector against the component of the incident wavevector parallel to the crystal surface. The curve for a particular Bloch wave is called a branch. Thus, for fast electrons, the two-beam approximation has two branches, one for each eigenvalue, and the N-beam approximation has N.

A detailed treatment of the extensive and powerful theory that has grown from Bethe's initial paper is to be found, for example, in Hirsch *et al.* (1965). Apart from its fundamental importance as a theoretical tool, this formulation provides the basis for one of the most commonly used numerical techniques, the essential step being the estimation of the eigenvalues from equation (5.2.8.2) [see *IT* C (2004, Section 4.3.6.2)].

5.2.12. Multislice

Multislice derives from a formulation that generates a solution in the form of a Born series (Cowley & Moodie, 1962). The crystal is treated as a series of scattering planes on to which the potential from the slice between z and $z + \Delta z$ is projected, separated by vacuum gaps Δz, not necessarily corresponding to any planes or spacings of the material structure. The phase change in the electron beam produced by passage through a slice is given by

$$q = \exp\left\{-i\sigma \int_{z_1}^{z_1+\Delta z} \varphi(x, y, z)\,\mathrm{d}z\right\},$$

and the phase distribution in the x, y plane resulting from propagation between slices is given by

$$p = \exp\left\{\frac{ik(x^2 + y^2)}{2\Delta z}\right\},$$

where the wavefront has been approximated by a paraboloid. Thus, the wavefunction for the $(n + 1)$th slice is given by

$$\begin{aligned}\psi_{n+1} &= \left[\psi_n * \exp\left\{\frac{ik(x^2 + y^2)}{2\Delta z}\right\}\right] \exp\{-i\sigma\varphi_{n+1}\} \\ &= [\psi_n * p]q, \end{aligned} \tag{5.2.12.1}$$

where $*$ is the convolution operator (Cowley, 1981).

This equation can be regarded as the finite difference form of the Schrödinger equation derived by Feynman's (1948) method. The calculation need be correct only to first order in Δz. Writing the convolution in equation (5.2.12.1) explicitly, and expanding in a Taylor series, the integrals can be evaluated to yield equation (5.2.3.1) (Goodman & Moodie, 1974).

If equation (5.2.12.1) is Fourier transformed with respect to x and y, the resulting recurrence relation is of the form

$$U_{n+1} = [U_n P] * Q_n, \tag{5.2.12.2}$$

where P and Q are obtained by Fourier transforming p and q above. This form is convenient for numerical work since, for a perfect crystal, it is: discrete, as distinct from equation (5.2.12.1) which is continuous in the variables [see *IT* C (2004, Section 4.3.6.1)]; numerically stable at least up to 5000 beams; fast; and only requires a computer memory proportional to the number of beams (Goodman & Moodie, 1974).

5.2.13. Born series

In the impulse limit of equation (5.2.12.2), the integrals can be evaluated to give the Born series (Cowley & Moodie, 1957)

$$U(h, k) = \sum_n U_n(h, k),$$

where

$$\begin{aligned} U_n(h, k) = \sum_l \sum_{h_1 k_1 l_1} \cdots \sum_{h_{n-1} k_{n-1} l_{n-1}} & i^n V(h_1, k_1, l_1) \\ & \ldots V\left(h - \sum_{r=1}^{n-1} h_r, k - \sum_{r=1}^{n-1} k_r, l - \sum_{r=1}^{n-i} l_r\right) \\ & \times [\exp\{-2\pi i\zeta T\}/(2\pi i)^n] \\ & \times \Big(\exp\{i\pi\zeta T\}(\sin \pi\zeta T/\zeta)\big[(\zeta - \zeta_1)\ldots(\zeta - \zeta_{n-1})\big]^{-1} \\ & + \sum_{m=1}^{n-1} \exp\{i\pi\zeta_m T\}(\sin \pi\zeta_m T/\zeta_m)\big[(\zeta_m - \zeta_1) \\ & \ldots(\zeta_m - \zeta_{m-1})(\zeta_m - \zeta_{m+1})\ldots(\zeta_m - \zeta)\big]^{-1}\Big) \end{aligned} \tag{5.2.13.1a}$$

and where n is the order of interaction. Here ζ is the excitation error of the reflection with index h, k, and ζ_i are the excitation errors for the reflections with indices h_i, k_i, l_i. Thus each constituent process may be represented by a diagram, starting on the origin of reciprocal space, possibly looped, and ending on the point with coordinates (h, k).

This solution can also be obtained by iteration of the Green-function integral equation, the integrals being evaluated by means of suitably chosen contours on the complex k_z plane (Fujiwara, 1959), as well as by expansion of the scattering matrix (Fujimoto, 1959).

Clearly, two or more of the ζ_i will, in general, be equal in nearly all of the terms in equation (5.2.13.1*a*). Confluence is, however, readily described, the divided differences of arbitrary order transforming into differentials of the same order (Moodie, 1972).

The physical picture that emerges from equation (5.2.13.1*a*) is that of n-fold scattering, the initial wave being turned through $n - 1$ intermediate states, processes that can be presented by scattering diagrams in reciprocal space (Gjønnes & Moodie, 1965).

For a given scattering vector, constituent functions are evaluated for all possible paths in three dimensions, and those functions are then summed over l. There are therefore two distinct processes by which upper-layer lines can perturb wavefunctions in the zone, namely: by scattering out of the zone and then back in; and by intrusion of the effective shape function from another zone, the latter process being already operative in the first Born, or kinematical approximation.

The constituent functions to be evaluated can be transformed into many forms. One of the more readily described is that which assigns to each diagram an effective dynamical shape function. If there are no loops in the diagram of order n, this effective shape function is the $(n + 1)$th divided difference of the constituent phase-shifted kinematical shape transforms. For general diagrams, divided differences in loops are replaced by the corresponding differentials. The resulting function is multiplied by the convolution of the contributing structure amplitudes and diagrams of all orders summed (Moodie, 1972).

While scattering diagrams have no utility in numerical work, they find application in the analysis of symmetries, for instance in the determination of the presence or absence of a centre of inversion [for a recent treatment, see Moodie & Whitfield (1995)] and in the detection of screw axes and glide planes (Gjønnes & Moodie, 1965). Methods for the direct determination of all space groups are described by Goodman (1975) and by Tanaka *et al.* (1983) (see Section 2.5.3).

Equation (5.2.13.1*a*) can be rewritten in a form particularly suited to the classification of approximations, and to describing the underlying symmetry of the formulation. The equation is written for compactness as

$$U_n(h) = E_n(h)Z_n(\zeta),$$

so that $E_n(h)$ depends only on crystal structure and $Z_n(\zeta)$ only on diffraction geometry. A transformation (Cowley & Moodie, 1962) involving bialternants leads to

$$U_n = \sum_{r=0}^{\infty} E_n(h)\big[(2\pi iT)^{n+r}/(n+r)!\big]h_r(\zeta, \zeta_1 \ldots \zeta_{n-1}), \quad (5.2.13.1b)$$

where h_r is the complete homogeneous symmetric polynomial function of n variables of order r.

Upper-layer-line effects can, of course, be calculated in any of the formulations.

5.2.14. Approximations

So far, only the familiar first Born and two-beam approximations and the projection approximation have been mentioned. Several others, however, have a considerable utility.

A high-voltage limit can be calculated in standard fashion to give

$$U_{\rm HVL}(h, k) = \mathscr{F} \exp\left\{-i\sigma_c \int_0^T \varphi(x, y, z)\, {\rm d}z\right\}, \quad (5.2.14.1)$$

where $\mathscr{F}$ is the Fourier transform operator, and $\sigma_c = 2\pi m_0 e\lambda_c/h^2$ with $\lambda_c = (h/m_0 c)$, the Compton wavelength. The phase-grating approximation, which finds application in electron microscopy, involves the assumption that equation (5.2.14.1) has some range of validity when σ_c is replaced by σ. This is equivalent to ignoring the curvature of the Ewald sphere and can therefore apply to thin crystals [see Section 2.5.2 and *IT* C (2004, Section 4.3.8)].

Approximations that involve curtailing the number of beams evidently have a range of validity that depends on the size of the unit cell. The most explored case is that of three-beam interactions. Kambe (1957) has demonstrated that phase information can be obtained from the diffraction data; Gjønnes & Høier (1971) analysed the confluent case, and Hurley & Moodie (1980) have given an explicit inversion for the centrosymmetric case. Analyses of the symmetry of the defining differential equation, and of the geometry of the noncentrosymmetric case, have been given by Moodie *et al.* (1996, 1998).

Niehrs and his co-workers (*e.g.* Blume, 1966) have shown that, at or near zones, effective two-beam conditions can sometimes obtain, in that, for instance, the central beam and six equidistant beams of equal structure amplitude can exhibit two-beam behaviour when the excitation errors are equal. Group-theoretical treatments have been given by Fukuhara (1966) and by Kogiso & Takahashi (1977). Explicit reductions for all admissible noncentrosymmetric space groups have been obtained by Moodie & Whitfield (1994). Extensions of such results have application in the interpretation of lattice images and convergent-beam patterns.

The approximations near the classical limit have been extensively explored [for instance, see Berry (1971)] but channelling has effectively become a separate subject and cannot be discussed here.

5.3. Dynamical theory of neutron diffraction

By M. Schlenker and J.-P. Guigay

5.3.1. Introduction

Neutron and X-ray scattering are quite similar both in the geometry of scattering and in the orders of magnitude of the basic quantities. When the neutron spin is neglected, *i.e.* when dealing with scattering by perfect nonmagnetic crystals, the formalism and the results of the dynamical theory of X-ray scattering can be very simply transferred to the case of neutrons (Section 5.3.2). Additional features of the neutron case are related to the neutron spin and appear in diffraction by magnetic crystals (Section 5.3.3). The low intensities available, coupled with the low absorption of neutrons by most materials, make it both necessary and possible to use large samples in standard diffraction work. The effect of extinction in crystals that are neither small nor bad enough to be amenable to the kinematical approximation is therefore very important in the neutron case, and will be discussed in Section 5.3.4 together with the effect of crystal distortion. Additional possibilities arise in the neutron case because the neutrons can be manipulated from outside through applied fields (Section 5.3.5). Reasonably extensive tests of the predictions of the dynamical theory of neutron diffraction have been performed, with the handicap of the very low intensities of neutron beams as compared with X-rays: these are described in Section 5.3.6. Finally, the applications of the dynamical theory in the neutron case, and in particular neutron interferometry, are reviewed in Section 5.3.7.

5.3.2. Comparison between X-rays and neutrons with spin neglected

5.3.2.1. The neutron and its interactions

An excellent introductory presentation of the production, properties and scattering properties of neutrons is available (Scherm & Fåk, 1993, and other papers in the same book). A stimulating review on neutron optics, including diffraction by perfect crystals, has been written by Klein & Werner (1983). X-rays and neutrons are compared in terms of the basic quantities in Table 4.1.3.1 of *IT* C (2004), where Chapter 4.4 is devoted to neutron techniques.

The neutron is a massive particle for which the values relevant to diffraction are: no electric charge, rest mass $m = 1.675 \times 10^{-27}$ kg, angular momentum eigenvalues along a given direction $\pm\hbar/2$ (spin $\frac{1}{2}$) and a magnetic moment of -1.913 nuclear magneton, meaning that its component along a quantization direction z can take eigenvalues $\mu_z = \mp 0.996 \times 10^{-26}$ A m^2. The de Broglie wavelength is $\lambda = h/p$ where h is Planck's constant ($h = 2\pi\hbar = 6.625 \times 10^{-34}$ J s) and p is the linear momentum; $p = mv$ in the nonrelativistic approximation, which always applies in the context of this chapter, v being the neutron's velocity. The neutron's wavelength, λ, and kinetic energy, E_c, are thus related by $\lambda = h/(2mE_c)^{1/2}$, or, in practical units, $\lambda\,[\text{Å}] = 9.05/(E_c\,[\text{meV}])^{1/2}$. Thus, to be of interest for diffraction by materials, neutrons should have kinetic energies in the range 10^0 to 10^2 meV. In terms of the velocity, $\lambda\ [\text{Å}] = 3.956/(v\ [\text{km s}^{-1}])$.

Neutron beams are produced by nuclear reactors or by spallation sources, usually pulsed. In either case they initially have an energy in the MeV range, and have to lose most of it before they can be used. The moderation process involves inelastic interactions with materials. It results in statistical distributions of energy, hence of velocity, close to the Maxwell distribution characteristic of the temperature T of the moderator. Frequently used moderators are liquid deuterium (D_2, *i.e.* $^2H_2$) at 25 K, heavy water (D_2O) at room temperature and graphite allowed to heat up to 2400 K; the corresponding neutron distributions are termed cold, thermal and hot, respectively.

The interaction of a neutron with an atom is usually described in terms of scattering lengths or of scattering cross sections. The main contribution corresponding to the nuclear interaction is related to the strong force. The interaction with the magnetic field created by atoms with electronic magnetic moments is comparable in magnitude to the nuclear term.

5.3.2.2. Scattering lengths and refractive index

The elastic scattering amplitude for scattering vector $\mathbf{s}$, $f(\mathbf{s})$, is defined by the wave scattered by an object placed at the origin when the incident plane wave is $\Psi_i = A\exp[i(\mathbf{k}_0\cdot\mathbf{r} - \omega t)]$, written as $\Psi_s = A[f(\mathbf{s})/r]\exp[i(kr - \omega t)]$ with $k = |\mathbf{k}_0| = |\mathbf{k}_0 + \mathbf{s}| = 2\pi/\lambda$. In the case of the strong-force interaction with nuclei, the latter can be considered as point scatterers because the interaction range is very small, hence the scattering amplitude is isotropic (independent of the direction of $\mathbf{s}$). It is also independent of λ except in the vicinity of resonances. It is conventionally written as $-b$ so that most values of b, called the scattering length, are positive. A table of experimentally measured values of the scattering lengths b is given in *IT* C for the elements in their natural form as well as for many individual isotopes. It is apparent that the typical order of magnitude is the fm (femtometre, *i.e.* 10^{-15} m, or fermi), that there is no systematic variation with atomic number and that different isotopes have very different scattering lengths, including different signs. The first remark implies that scattering amplitudes of X-rays and of neutrons have comparable magnitudes, because the characteristic length for X-ray scattering (the scattering amplitude for forward scattering by one free electron) is $R = 2.8$ fm, the classical electron radius. The second and third points explain the importance of neutrons in structural crystallography, in diffuse scattering and in small-angle scattering. Scattering of neutrons by condensed matter implies the use of the bound scattering lengths, as tabulated in *IT* C. The 'free' scattering length, used in some presentations, is obtained by multiplying the bound scattering lengths by $A/(A+1)$, where A is the mass of the nucleus in atomic units.

A description in terms of an interaction potential is possible using the Fermi pseudo-potential, which in the case of the nuclear interaction with a nucleus at $\mathbf{r}_0$ can be written as $V(\mathbf{r}) = (h^2/2\pi m)b\delta(\mathbf{r} - \mathbf{r}_0)$, where δ denotes the three-dimensional Dirac distribution.

Refraction of neutrons at an interface can be conveniently described by assigning a refractive index to the material, such that the wavenumber in the material, k, is related to that in a vacuum, k_0, by $k = nk_0$. Here

$$n = \left(1 - \frac{\lambda^2}{\pi V}\sum_i b_i\right)^{1/2},$$

where the sum is over the nuclei contained in volume V. With typical values, n is very close to 1 and $1 - n = (\lambda^2/2\pi V)\sum_i b_i$ is

Copyright © 2010 International Union of Crystallography

typically of the order of 10^{-5}. This small value, in the same range as for X-rays, gives a feeling for the order of magnitude of key quantities of the dynamical theory, in particular the Darwin width 2δ as discussed in Chapter 5.1. It also makes total external reflection possible on materials for which $\sum_i b_i > 0$: this is the basis for the neutron guide tubes now installed in most research reactors, as well as for reflectometry.

The notations prevailing in X-ray and in neutron crystallography are slightly different, and the correspondence is very simple: X-ray atomic scattering factors and structure factors are numbers. When multiplied by R, the classical electron radius, they become entirely equivalent to the corresponding quantities in neutron usage, which are lengths. It should be noted that the presence of different isotopes and the effect of nuclear spin (disordered except under very special conditions) give rise to incoherent elastic neutron scattering, which has no equivalent in the X-ray case. The scattering length corresponding to R times the atomic scattering factor for X-rays is therefore the coherent scattering length, $b_{\rm coh}$, obtained by averaging the scattering length over the nuclear spin state and isotope distribution.

5.3.2.3. Absorption

Neutron absorption is related to a nuclear reaction in which the neutron combines with the absorbing nucleus to form a compound nucleus, usually in a metastable state which then decays. The scattering length describing this resonance scattering process depends on the neutron energy and contains an imaginary part associated with absorption in complete analogy with the imaginary part of the dispersion correction for the X-ray atomic scattering factors. The energies of the resonances are usually far above those of interest for crystallography, and the linear absorption coefficient varies approximately as $1/v$ or λ. It is important to note that, except for a very few cases (notably ^{3}He, ^{6}Li, ^{10}B, In, Cd, Gd), the absorption of neutrons is very small compared with that of X-rays, and even more so compared with that of electrons, and can be neglected to a first approximation.

5.3.2.4. Differences between neutron and X-ray scattering

There are major differences in the experimental aspects of neutron and X-ray scattering. Neutrons are only available in large facilities, where allocation of beam time to users is made on the basis of applications, and where admittance is restricted because of the hazards which nuclear technology can present in the hands of ill-intentioned users. Because of the radiation shielding necessary, as well as the large size of neutron detectors, neutron-scattering instrumentation is much bulkier than that for X-rays. Neutron beams are in some aspects similar to synchrotron radiation, in particular because in both cases the beams are initially 'white' and for most applications have to be monochromated. There is, however, a huge difference in the order of magnitudes of the intensities. Neutron beams are weak in comparison with laboratory X-ray sources, and weaker by many orders of magnitude than synchrotron radiation. Also, the beam sources are large in the case of neutrons, since they are essentially the moderators, whereas the source is very small in the case of synchrotron radiation, and this difference again increases the ratio of the brilliances in favour of X-rays. This encourages the use of large specimens in all neutron-scattering work, and makes the extinction problem more important than for X-rays. Furthermore, many experiments that are quick using X-rays become very slow, and give rise to impaired resolution, in the neutron case.

There are also at least two additional aspects of neutron scattering in comparison with X-ray scattering, apart from the effect of the magnetic moment associated with the intrinsic (spin) angular momentum of the neutron. On the one hand, the small velocity of neutrons, compared with the velocity of light, makes time-of-flight measurements possible, both in standard neutron diffraction and in investigations of perfect crystals. Because this velocity is of the same order of magnitude as that of ultrasound, the effect of ultrasonic excitation on neutron diffraction is slightly different from that in the X-ray case. On the other hand, the fact that neutrons have mass and a magnetic moment implies that they can be affected by external fields, such as gravity and magnetic fields, both during their propagation in air or in a vacuum and while being diffracted within crystals (Werner, 1980) (see Section 5.3.5). Experiments completely different from the X-ray case can thus be performed with perfect crystals and with neutron interferometers (see Sections 5.3.6 and 5.3.7.3).

5.3.2.5. Translating X-ray dynamical theory into the neutron case

As shown in Chapter 5.1, the basic equations of dynamical theory, *viz* Maxwell's equations for the X-ray case and the time-independent Schrödinger equation in the neutron case, have exactly the same form when the effect of the neutron spin can be neglected, *i.e.* in situations that do not involve magnetism and when no externally applied potential is taken into account. The translation scheme for the scattering factors and structure factors is described above. The one formal difference is that the wavefunction is scalar in the neutron case, hence there is no equivalent to the parallel and perpendicular polarizations of the X-ray situation: C in equation (5.1.2.20) of Chapter 5.1 should therefore be set to 1.

The physics of neutron diffraction by perfect crystals is therefore expected to be very similar to that of X-ray diffraction, with the existence of wavefields, *Pendellösung* effects, anomalous transmission, intrinsic rocking-curve shapes and reflectivity *versus* thickness behaviour in direct correspondence. All experimental tests of these predictions confirm this view (Section 5.3.6).

Basic discussions of dynamical neutron scattering are given by Stassis & Oberteuffer (1974), Sears (1978), Rauch & Petrascheck (1978) and Squires (1978).

5.3.3. Neutron spin, and diffraction by perfect magnetic crystals

5.3.3.1. Polarization of a neutron beam and the Larmor precession in a uniform magnetic field

A polarized neutron beam is represented by a two-component spinor,

$$|\varphi\rangle = \begin{pmatrix} c \\ d \end{pmatrix} = c\begin{pmatrix} 1 \\ 0 \end{pmatrix} + d\begin{pmatrix} 0 \\ 1 \end{pmatrix},$$

which is the coherent superposition of two states, of different amplitudes c and d, polarized in opposite directions along the spin-quantization axis. The spinor components c and d are generally space- and time-dependent. We suppose that $\langle\varphi|\varphi\rangle = cc^* + dd^* = 1$. The polarization vector $\mathbf{P}$ is defined as

$$\mathbf{P} = \langle\varphi|\boldsymbol{\sigma}|\varphi\rangle,$$

where the vector $\boldsymbol{\sigma}$ represents the set of Pauli matrices σ_x, σ_y and σ_z. The components of $\mathbf{P}$ are

$$\begin{aligned} P_x &= \begin{pmatrix} c^* & d^* \end{pmatrix}\sigma_x \begin{pmatrix} c \\ d \end{pmatrix} = \begin{pmatrix} c^* & d^* \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} c \\ d \end{pmatrix} \\ &= c^*d + cd^* \\ P_y &= \begin{pmatrix} c^* & d^* \end{pmatrix}\sigma_y \begin{pmatrix} c \\ d \end{pmatrix} = \begin{pmatrix} c^* & d^* \end{pmatrix}\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}\begin{pmatrix} c \\ d \end{pmatrix} \\ &= i(cd^* - c^*d) \\ P_z &= \begin{pmatrix} c^* & d^* \end{pmatrix}\sigma_z \begin{pmatrix} c \\ d \end{pmatrix} = \begin{pmatrix} c^* & d^* \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} c \\ d \end{pmatrix} \\ &= cc^* - dd^*, \end{aligned} \tag{5.3.3.1}$$

from which it is clearly seen that, unlike P_z, the polarization components P_x and P_y depend on the phase difference between the spinor components c and d.

In a region of a vacuum in which a uniform magnetic field $\mathbf{B}$ is present, a neutron beam experiences a magnetic potential energy represented by the matrix

$$-\mu_n \boldsymbol{\sigma}\cdot\mathbf{B} = \begin{pmatrix} -\mu_n B & 0 \\ 0 & \mu_n B \end{pmatrix},$$

μ_n being the neutron magnetic moment, if the directions of $\mathbf{B}$ and of the spin-quantization axis coincide. Consequently, different indices of refraction $n = 1 \pm (\mu_n B/2E)$, where E is the neutron energy, should be associated with the spinor components c and d; this induces between these spinor components a phase difference which is a linear function of the time (or, equivalently, of the distance travelled by the neutrons), hence, according to (5.3.3.1), a rotation around the magnetic field of the component of the neutron polarization perpendicular to this magnetic field. The time frequency of this so-called Larmor precession is $2\mu_n B/h$, where h is Planck's constant.

A neutron beam may be partially polarized; such a beam is conveniently represented by a spin-density matrix ρ, which is the statistical average of the spin-density matrices associated to the polarized beams which are mixed incoherently, the density matrix associated to the spinor

$$|\varphi\rangle = \begin{pmatrix} c \\ d \end{pmatrix}$$

being

$$|\varphi\rangle\langle\varphi| = \begin{pmatrix} c \\ d \end{pmatrix}\begin{pmatrix} c^* & d^* \end{pmatrix} = \begin{pmatrix} cc^* & cd^* \\ c^*d & dd^* \end{pmatrix}.$$

The polarization vector $\mathbf{P}$ is then obtained as

$$\mathbf{P} = \mathrm{Tr}(\boldsymbol{\sigma}\rho). \tag{5.3.3.2}$$

In the common case of a nonpolarized beam, the spin-density matrix is

$$\rho = \tfrac{1}{2}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

It is easily seen that all components of $\mathbf{P}$ are then equal to 0.

Equation (5.3.3.2) is therefore applicable to the general case (polarized, partially polarized or nonpolarized beam). The inverse relation giving the density matrix ρ as function of $\mathbf{P}$ is

$$\rho = \tfrac{1}{2}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \tfrac{1}{2}\mathbf{P}\cdot\boldsymbol{\sigma}. \tag{5.3.3.3}$$

5.3.3.2. Magnetic scattering by a single ion having unpaired electrons

The spin and orbital motion of unpaired electrons in an atom or ion give rise to a surrounding magnetic field $\mathbf{B}(\mathbf{r})$ which acts on the neutron *via* the magnetic potential energy $-\boldsymbol{\mu}_n\cdot\mathbf{B}(\mathbf{r})$, where $\boldsymbol{\mu}_n$ is the neutron magnetic moment. Since this is a long-range interaction, in contrast to the nuclear interaction, the magnetic scattering length p, which is proportional to the Fourier transform of the magnetic potential energy distribution $-\boldsymbol{\mu}_n\cdot\mathbf{B}(\mathbf{r})$, depends on the angle of scattering.

The classical relation $\mathrm{div}\ \mathbf{B}(\mathbf{r}) = 0$ shows clearly that the vector $\mathbf{B}(\mathbf{s})$, which is the Fourier transform of $\mathbf{B}(\mathbf{r})$, is perpendicular to the reciprocal-space vector $\mathbf{s}$. If we consider the magnetic field $\mathbf{B}(\mathbf{r})$ as resulting from a point-like magnetic moment $\boldsymbol{\mu}$ at position $\mathbf{r} = 0$, we get

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0}{4\pi}\mathrm{curl}\frac{\boldsymbol{\mu}\times\mathbf{r}}{r^3},$$

where $\mu_0 = 4\pi \times 10^{-7}$ H m^{-1} is the permittivity of a vacuum and $\times$ denotes the cross product. $\mathbf{B}(\mathbf{r})$ can be Fourier-transformed into

$$\mathbf{B}(\mathbf{s}) = \mu_0\mathbf{s}\times\frac{\boldsymbol{\mu}\times\mathbf{s}}{s^2} = \mu_0\boldsymbol{\mu}_\perp(\mathbf{s}), \tag{5.3.3.4}$$

where $\boldsymbol{\mu}_\perp(\mathbf{s})$ is the projection of $\boldsymbol{\mu}$ on the plane perpendicular to $\mathbf{s}$ (reflecting plane).

This result can be applied by volume integration to the more general case of a spatially extended magnetization distribution, which for a single magnetic ion corresponds to the atomic shell of the unpaired electrons. It is thus shown that the magnetic scattering length is proportional to $\boldsymbol{\mu}_n\cdot\boldsymbol{\mu}_{i\perp}$, where $\boldsymbol{\mu}_{i\perp}$ is the projection of the magnetic moment of the ion on the reflecting plane.

For a complete description of magnetic scattering, which involves the spin-polarization properties of the scattered beam, it is necessary to represent the neutron wavefunction in the form of a two-component spinor and the ion's magnetic moment as a spin operator which is a matrix expressed in terms of the Pauli matrices $\boldsymbol{\sigma}$ $(\sigma_x, \sigma_y, \sigma_z)$. The magnetic scattering length is therefore itself a (2×2) matrix:

$$(\mathrm{p}) = -(2\pi m/h^2)\mu_n\boldsymbol{\sigma}\cdot\mathbf{B}(\mathbf{s}) = -\mu_0(2\pi m/h^2)\mu_n\boldsymbol{\sigma}\cdot\boldsymbol{\mu}_{i\perp}(\mathbf{s})f_i(\sin\theta/\lambda), \tag{5.3.3.5}$$

where $f_i(\sin\theta/\lambda)$ is the dimensionless magnetic form factor of the ion considered and tends towards a maximum value of 1 when the scattering angle θ tends towards 0 (forward scattering). The value of $\mu_0(2\pi m/h^2)\mu_n\mu_i$ is $p_1 = 2.70 \times 10^{-15}$ m for $\mu_i = 1$ Bohr magneton.

According to (5.3.3.4) or (5.3.3.5), there is no magnetic scattering in directions such that the scattering vector $\mathbf{s}$ is in the same direction as the ion magnetic moment $\boldsymbol{\mu}_i$. Magnetic scattering effects are maximum when $\mathbf{s}$ and $\boldsymbol{\mu}_i$ are perpendicular.

The matrix (p) is diagonal if the direction of $\boldsymbol{\mu}_{i\perp}(\mathbf{s})$ is chosen as the spin-quantization axis. Therefore, there is no spin-flip scattering if the incident beam is polarized parallel or antiparallel to the direction of $\boldsymbol{\mu}_{i\perp}(\mathbf{s})$.

It is more usual to choose the spin-quantization axis (Oz) along $\boldsymbol{\mu}_i$. Let β be the angle between the vectors $\boldsymbol{\mu}_i$ and $\mathbf{s}$; the

(x, y, z) components of $\boldsymbol{\mu}_{i\perp}(\mathbf{s})$ are then $(-\mu_i \sin\beta\cos\beta,\ 0,\ \mu_i \sin^2\beta)$ if the y axis is chosen along $\boldsymbol{\mu}_i \times \mathbf{s}$. The total scattering length, which is the sum of the nuclear and the magnetic scattering lengths, is then represented by the matrix

$$(\mathrm{q}) = \begin{pmatrix} b + p\sin^2\beta & -p\sin\beta\cos\beta \\ -p\sin\beta\cos\beta & b - p\sin^2\beta \end{pmatrix}, \qquad (5.3.3.6)$$

where b is the nuclear scattering length and

$$p = -\mu_0 \frac{2\pi m}{h^2} \mu_n \mu_i f_i\left(\frac{\sin\theta}{\lambda}\right) = -p_1 \mu_i f_i\left(\frac{\sin\theta}{\lambda}\right),$$

with μ_i expressed in Bohr magnetons. The relations

$$(\mathrm{q})\begin{pmatrix}1\\0\end{pmatrix} = \begin{pmatrix} b + p\sin^2\beta \\ -p\sin\beta\cos\beta \end{pmatrix} \text{ and}$$
$$(\mathrm{q})\begin{pmatrix}0\\1\end{pmatrix} = \begin{pmatrix} -p\sin\beta\cos\beta \\ b - p\sin^2\beta \end{pmatrix}$$

show clearly that the diagonal and the nondiagonal elements of the matrix (q) are, respectively, the spin-flip and the non-spin-flip scattering lengths. It is usual to consider the scattering cross sections, which are the measurable quantities. The cross sections for neutrons polarized parallel or antiparallel to the ion magnetic moment are

$$(\mathrm{d}\sigma/\mathrm{d}\Omega)_{\pm} = b^2 \pm 2bp\sin^2\beta + (p\sin\beta)^2. \qquad (5.3.3.7)$$

These expressions are the sum of the spin-flip and non-spin-flip cross sections, which are equal to $(b \pm p\sin^2\beta)^2$ and $(p\sin\beta\cos\beta)^2$, respectively. In the case of nonpolarized neutrons, the interference term $(\pm 2bp\sin^2\beta)$ between the nuclear and the magnetic scattering disappears; the cross section is then

$$(\mathrm{d}\sigma/\mathrm{d}\Omega) = b^2 + (p\sin\beta)^2. \qquad (5.3.3.8)$$

In the general case of a partially polarized beam we can use the density-matrix representation. Let ρ_{inc} be the density matrix of the incident beam; it can be shown that the density matrix of the diffracted beam is equal to the following product of matrices: $(\mathrm{q})\rho_{inc}(\mathrm{q}^*)$. Using the relations between the density matrix and polarization vector presented in the preceding section, we can obtain a general description of the diffracted beam as a function of the polarization properties of the incident beam. Such a formalism is of interest for dealing with new experimental arrangements, in which a three-dimensional polarization analysis of the diffracted beam is possible, as shown by Tasset (1989).

5.3.3.3. Dynamical theory in the case of perfect ferromagnetic or collinear ferrimagnetic crystals

The most direct way to develop this dynamical theory in the two-beam case, which involves a single Bragg-diffracted beam of diffraction vector $\mathbf{h}$, is to consider spinor wavefunctions of the following form:

$$\varphi(\mathbf{r}) = \exp(i\mathbf{K_0}\cdot\mathbf{r})\begin{pmatrix}D_0\\E_0\end{pmatrix} + \exp[i(\mathbf{K_0}+\mathbf{h})\mathbf{r}]\begin{pmatrix}D_h\\E_h\end{pmatrix} \qquad (5.3.3.9)$$

as approximate solutions of the wave equation inside the crystal,

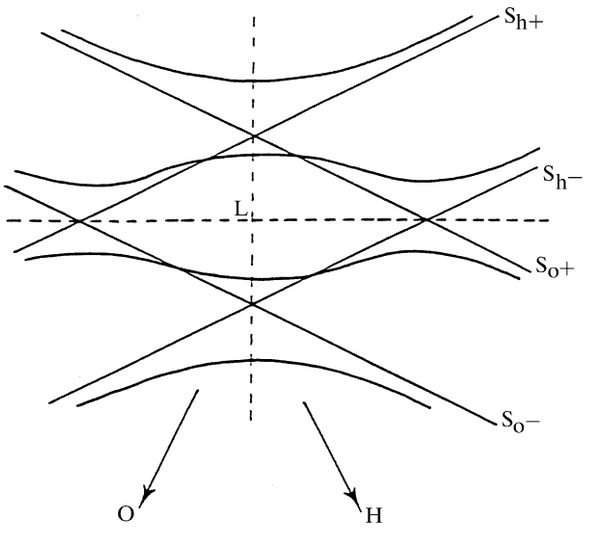

Fig. 5.3.3.1. Schematic plot of the two-beam dispersion surface in the case of a purely magnetic reflection such that $\mathbf{Q_h} = \mathbf{Q_{-h}} = \mathbf{Q_0}$ and that the angle between $\mathbf{Q_0}$ and $\mathbf{Q_h}$ is equal to $\pi/4$.

$$\Delta\varphi(\mathbf{r}) + k^2\varphi(\mathbf{r}) = [u(\mathbf{r}) - \boldsymbol{\sigma}\cdot\mathbf{Q}(\mathbf{r})]\varphi(\mathbf{r}), \qquad (5.3.3.10)$$

where $u(\mathbf{r})$ and $-\boldsymbol{\sigma}\cdot\mathbf{Q}(\mathbf{r})$ are, respectively, equal to the nuclear and the magnetic potential energies multiplied by $2m/\hbar^2$. In the calculation of $\varphi(\mathbf{r})$ in the two-beam case, we need only three terms in the expansions of the functions $u(\mathbf{r})$ and $\mathbf{Q}(\mathbf{r})$ into Fourier series:

$$u(\mathbf{r}) = u_0 + u_{\mathbf{h}}\exp(i\mathbf{h}\cdot\mathbf{r}) + u_{-\mathbf{h}}\exp(-i\mathbf{h}\cdot\mathbf{r}) + \ldots,$$
$$\mathbf{Q}(\mathbf{r}) = \mathbf{Q_0} + \mathbf{Q_h}\exp(i\mathbf{h}\cdot\mathbf{r}) + \mathbf{Q_{-h}}\exp(-i\mathbf{h}\cdot\mathbf{r}) + \ldots.$$

We suppose that the crystal is magnetically saturated by an externally applied magnetic field $\mathbf{H}_a$. $\mathbf{Q_0}$ is then proportional to the macroscopic mean magnetic field $\mathbf{B} = \mu_0(\mathbf{M} + \mathbf{H}_a + \mathbf{H}_d)$, where $\mathbf{M}$ is the magnetization vector and $\mathbf{H}_d$ is the demagnetizing field. The results of Section 5.3.3.2 show that $\mathbf{Q_h}$ and $\mathbf{Q_{-h}}$ are proportional to the projection of $\mathbf{M}$ on the reflecting plane.

The four coefficients D_0, D_h, E_0 and E_h of (5.3.3.9) are found to satisfy a system of four homogeneous linear equations. The condition that the associated determinant has to be equal to 0 defines the dispersion surface, which is of order 4 and has four branches. An incident plane wave thus excites a system of four wavefields of the form of (5.3.3.9), generally polarized in various directions. A particular example of a dispersion surface, having an unusual shape, is shown in Fig. 5.3.3.1.

This is a much more complicated situation than in the case of nonmagnetic crystals, in which one only needs to consider scalar wavefunctions which depend on two coefficients, such as D_0 and D_h, and which are related to hyperbolic dispersion surfaces of order 2, as fully described in Chapter 5.1 on X-ray diffraction.

In fact, all neutron experiments related to dynamical effects in diffraction by magnetic crystals have been performed under such conditions that the magnetization vector in the crystal is perpendicular to the diffraction vector $\mathbf{h}$. In this case, the vectors $\mathbf{Q_h}$ and $\mathbf{Q_{-h}}$ are parallel or antiparallel to the vector $\mathbf{Q_0}$ which is chosen as the spin-quantization axis. The matrices $\boldsymbol{\sigma}\cdot\mathbf{Q_0}$, $\boldsymbol{\sigma}\cdot\mathbf{Q_h}$ and $\boldsymbol{\sigma}\cdot\mathbf{Q_{-h}}$ are then all diagonal matrices, and we obtain for the two spin states $(\pm)$ separate dynamical equations which are similar to the dynamical equations for the scalar case, but with different structure factors, which are either the sum or the difference of the nuclear structure factor F_N and of the magnetic structure factor F_M:

$$F_+ = F_N + F_M \text{ and } F_- = F_N - F_M. \quad (5.3.3.11)$$

F_N and F_M are related to the scattering lengths of the ions in the unit cell of volume V_c:

$$F_N = V_c u_{\mathbf{h}} = \sum_i b_i \exp(-i\mathbf{h}\cdot\mathbf{r}_i);$$

$$F_M = V_c|\mathbf{Q}_{\mathbf{h}}| = -\frac{\mu_0 m}{2h^2}\mu_n \boldsymbol{\sigma}\cdot\sum_i \boldsymbol{\mu}_{i\perp}(\mathbf{h}) f_i\left(\frac{\sin\theta}{\lambda}\right)\exp(-i\mathbf{h}\cdot\mathbf{r}_i).$$

The dispersion surface of order 4 degenerates into two hyperbolic dispersion surfaces, each of them corresponding to one of the polarization states (±). The asymptotes are different; this is related to different values of the refractive indices for neutron polarization parallel or antiparallel to $\mathbf{Q}_0$.

In some special cases the magnitudes of F_N and F_M happen to be equal. Only one polarization state is then reflected. Magnetic crystals with such a property (reflections 111 of the Heusler alloy Cu_2MnAl, or 200 of the alloy Co–8% Fe) are very useful as polarizing monochromators and as analysers of polarization.

If the scattering vector $\mathbf{h}$ is in the same direction as the magnetization, this reflection is a purely nuclear one (with no magnetic contribution), since F_M is then equal to 0. Purely magnetic reflections (without nuclear contribution) also exist if the magnetic structure involves several sublattices.

If $\mathbf{h}$ is neither perpendicular to the average magnetization nor in the same direction, the presence of nondiagonal matrices in the dynamical equations cannot be avoided. The dynamical theory of diffraction by perfect magnetic crystals then takes the complicated form already mentioned.

Theoretical discussions of this complicated case of dynamical diffraction have been given by Stassis & Oberteuffer (1974), Mendiratta & Blume (1976), Sivardière (1975), Belyakov & Bokun (1975, 1976), Schmidt *et al.* (1975), Bokun (1979), Guigay & Schlenker (1979*a*,*b*) and Schmidt (1983). However, to our knowledge, only limited experimental work has been carried out on this subject. Successful experiments could only be performed for the simpler cases mentioned above.

5.3.3.4. The dynamical theory in the case of perfect collinear antiferromagnetic crystals

In this case, there is no average magnetization ($\mathbf{Q}_0 = 0$). It is then convenient to choose the quantization axis in the direction of $\mathbf{Q}_{\mathbf{h}}$ and $\mathbf{Q}_{-\mathbf{h}}$. The dispersion surface degenerates into two hyperbolic surfaces corresponding to each polarization state along this direction for any orientation of the diffraction vector relative to the direction of the magnetic moments of the sublattices. These two hyperbolic dispersion surfaces have the same asymptotes. Furthermore, in the case of a purely magnetic reflection, they are identical.

The possibility of observing a precession of the neutron polarization in the presence of diffraction, in spite of the fact that there is no average magnetization, has been pointed out by Baryshevskii (1976).

5.3.3.5. The flipping ratio

In polarized neutron diffraction by a magnetically saturated magnetic sample, it is usual to measure the ratio of the reflected intensities I_+ and I_- measured when the incident beam is polarized parallel or antiparallel to the magnetization in the sample. This ratio is called the flipping ratio,

$$R = I_+/I_-, \quad (5.3.3.12)$$

because its measurement involves flipping the incident-beam polarization to the opposite direction. This is an experimentally well defined quantity, because it is independent of a number of parameters such as the intensity of the incident beam, the temperature factor or the coefficient of absorption. In the case of an ideally imperfect crystal, we obtain from the kinematical expressions of the integrated reflectivities

$$R_{\text{kin}}(\mathbf{h}) = (I_+/I_-)_{\text{kin}} = \left(\frac{|F_N + F_M|}{|F_N - F_M|}\right)^2. \quad (5.3.3.13)$$

In the case of an ideally perfect thick crystal, we obtain from the dynamical expressions of the integrated reflectivities

$$R_{\text{dyn}}(\mathbf{h}) = (I_+/I_-)_{\text{dyn}} = \frac{|F_N + F_M|}{|F_N - F_M|}. \quad (5.3.3.14)$$

In general, R_{dyn} depends on the wavelength and on the crystal thickness; these dependences disappear, as seen from (5.3.3.14), if the path length in the crystal is much larger than the extinction distances for the two polarization states. It is clear that the determination of R_{kin} or R_{dyn} allows the determination of the ratio F_M/F_N, hence of F_M if F_N is known. In fact, because real crystals are neither ideally imperfect nor ideally perfect, one usually introduces an extinction factor y (extinction is discussed below, in Section 5.3.4) in order to distinguish the real crystal reflectivity from the reflectivity of the ideally imperfect crystal. Different extinction coefficients y_+ and y_- are actually expected for the two polarization states. This obviously complicates the task of the determination of F_M/F_N.

In the kinematical approximation, the flipping ratio does not depend on the wavelength, in contrast to dynamical calculations for hypothetically perfect crystals (especially for the Laue case of diffraction). Therefore, an experimental investigation of the wavelength dependence of the flipping ratio is a convenient test for the presence of extinction. Measurements of the flipping ratio have been used by Bonnet *et al.* (1976) and by Kulda *et al.* (1991) in order to test extinction models. Baruchel *et al.* (1986) have compared nuclear and magnetic extinction in a crystal of MnP.

Instead of considering only the ratio of the integrated reflectivities, it is also possible to record the flipping ratio as a function of the angular position of the crystal as it is rotated across the Bragg position. Extinction is expected to be maximum at the peak and the ratio measured on the tails of the rocking curve may approach the kinematical value. It has been found experimentally that this expectation is not of general validity, as discussed by Chakravarthy & Madhav Rao (1980). It would be valid in the case of a perfect crystal, hence in the case of pure primary extinction. It would also be valid in the case of secondary extinction of type I, but not in the case of secondary extinction of type II [following Zachariasen (1967), type II corresponds to mosaic crystals such that the diffraction pattern from each block is wider than the mosaic statistical distribution].

5.3.4. Extinction in neutron diffraction (nonmagnetic case)

The kinematical approximation, which corresponds to the first Born approximation in scattering theory, supposes that each incident neutron can be scattered only once and therefore neglects the possibility that the neutrons may be scattered several times. Because this is a simple approximation which overestimates the crystal reflectivity, the actual reduction of reflectivity, as compared to its kinematical value, is termed *extinction.* This is actually a typical dynamical effect, since it is a multiple-scattering effect.

Extinction effects can be safely neglected in the case of scattering by very small crystals; more precisely, this is possible when the path length of the neutron beam in the crystal is much smaller than $\Delta = V_c/\lambda F$, where λ is the neutron wavelength and F/V_c is the scattering length per unit volume for the reflection considered. Δ is sometimes called the 'extinction distance'.

A very important fact is that extinction effects also vanish if the crystal is imperfect enough, because each plane-wave component of the incident beam can then be Bragg-reflected in only a small volume of the sample. This is the extinction-free case of 'ideally imperfect crystals'. Conversely, extinction is maximum (smallest value of y) in the case of ideally perfect non-absorbing crystals.

Clearly, no significant extinction effects are expected if the crystal is thick but strongly absorbing, more precisely if the linear absorption coefficient μ is such that $\mu\Delta \gg 1$. Neutron diffraction usually corresponds to the opposite case ($\mu\Delta \ll 1$), in which extinction effects in nearly perfect crystals dominate absorption effects.

Extinction effects are usually described in the frame of the mosaic model, in which the crystal is considered as a juxtaposition of perfect blocks with different orientations. The relevance of this model to the case of neutron diffraction was first considered by Bacon & Lowde (1948). If the mosaic blocks are big enough there is extinction within each block; this is called *primary extinction.* Multiple scattering can also occur in different blocks if their misorientation is small enough. In this case, which is called *secondary extinction*, there is no phase coherence between the scattering events in the different blocks. The fact that empirical intensity-coupling equations are used in this case is based on this phase incoherence.

In the general case, primary and secondary extinction effects coexist. Pure secondary extinction occurs in the case of a mosaic crystal made of very small blocks. Pure primary extinction is observed in diffraction by perfect crystals.

The parameters of the mosaic model are the average size of the perfect blocks and the angular width of their misorientation distribution. The extinction theory of the mosaic model provides a relation between these parameters and the extinction coefficient, defined as the ratio of the observed reflectivity to the ideal one, which is the kinematical reflectivity in this context.

In conventional work, the crystal structure factors of different reflections and the parameters of the mosaic model are fitted together to the experimental data, which are the integrated reflectivities and the angular widths of the rocking curves. In many cases, only the weakest reflections will be free, or nearly free, from extinction. The extinction corrections thus obtained can be considered as satisfactory in cases of moderate extinction. Nevertheless, extinction remains a real problem in cases of strong extinction and in any case if a very precise determination of the crystal structure factors is required.

There exist several forms of the mosaic model of extinction. For instance, in the model developed by Kulda (1988*a*,*b*, 1991), the mosaic blocks are not considered just as simple perfect blocks but may be deformed perfect blocks. This has the advantage of including the case of macroscopically deformed crystals, such as bent crystals.

A basically different approach, free from the distinction between primary and secondary extinction, has been proposed by Kato (1980*a*,*b*). This is a wave-optical approach starting from the dynamical equations for diffraction by deformed crystals. These so-called Takagi–Taupin equations (Takagi, 1962; Taupin, 1964) contain a position-dependent phase factor related to the displacement field of the deformed crystal lattice. Kato proposed considering this phase factor as a random function with suitably defined statistical characteristics. The wave amplitudes are then also random functions, the average of which represent the coherent wavefields while their statistical fluctuations represent the incoherent intensity fields.

Modifications to the Kato formulation have been introduced by Al Haddad & Becker (1988), by Becker & Al Haddad (1990, 1992), by Guigay (1989) and by Guigay & Chukhovskii (1992, 1995). Presently, it is not easy to apply this 'statistical dynamical theory' to real experiments. The widely used methods for extinction corrections are still based on the former mosaic model, according to the formulation of Zachariasen (1967), later improved by Becker & Coppens (1974*a*,*b*, 1975).

As in the X-ray case, acoustic waves produced by ultrasonic excitation can artificially induce a transition from perfect to ideally imperfect crystal behaviour. The effect of ultrasound on the scattering behaviour of distorted crystals is quite complex. A good discussion with reference to neutron-scattering experiments is given by Zolotoyabko & Sander (1995).

The situation of crystals with a simple distortion field is less difficult than the statistical problem of extinction. Klar & Rustichelli (1973) confirmed that the Takagi–Taupin equations, originally devised for X-rays, can be used for neutron diffraction with due account of the very small absorption, and used them for computing the effect of crystal curvature.

5.3.5. Effect of external fields on neutron scattering by perfect crystals

The possibility of acting on neutrons through externally applied fields during their propagation in perfect crystals provides possibilities that are totally unknown in the X-ray case. The theory has been given by Werner (1980) using the approaches (migration of tie points, and Takagi–Taupin equations) that are customary in the treatment of imperfect crystals (see above). Zeilinger *et al.* (1986) pointed out that the effective-mass concept, familiar in describing electrons in solid-state physics, can shed new light on this behaviour: because of the curvature of the dispersion surface at a near-exact Bragg setting, effective masses five orders of magnitude smaller than the rest mass of the neutron in a vacuum can be obtained. Related experiments are discussed below.

An interesting proposal was put forward by Horne *et al.* (1988) on the coupling between the Larmor precession in a homogeneous magnetic field and the spin–orbit interaction of the neutron with nonmagnetic atoms, a term which was dismissed in Section 5.3.2 because its contribution to the scattering length is two orders of magnitude smaller than that of the nuclear term. A resonance is expected to show up as highly enhanced diffracted intensity when a perfect sample is set for Bragg scattering and the magnetic field is adjusted so that the Larmor precession period is equal to the *Pendellösung* period.

5.3.6. Experimental tests of the dynamical theory of neutron scattering

These experiments are less extensive for neutron scattering than for X-rays. The two most striking effects of dynamical theory for nonmagnetic nearly perfect crystals, *Pendellösung* behaviour and anomalous absorption, have been demonstrated in the neutron case too. *Pendellösung* measurement is described below (Section 5.3.7.2) because it is useful in the determination of scattering lengths. The anomalous transmission effect occurring when a perfect absorbing crystal is exactly at Bragg setting, *i.e.* the Borrmann effect, is often referred to in the neutron case as the suppression of the inelastic channel in resonance scattering, after Kagan & Afanas'ev (1966), who worked out the theory. A small decrease in absorption was detected in pioneering experiments on calcite by Knowles (1956) using the corresponding decrease in the emission of γ-rays and by Sippel *et al.* (1962), Shil'shtein *et al.* (1971) and Hastings *et al.* (1990) directly. Rocking curves of perfect crystals were measured by Sippel *et al.* (1964) in transmission, and by Kikuta *et al.* (1975). Integrated intensities were

measured by Lambert & Malgrange (1982). The large angular amplification associated with the curvature of the dispersion surfaces near the exact Bragg setting was demonstrated by Kikuta *et al.* (1975) and by Zeilinger & Shull (1979).

In magnetic crystals, the investigations have been restricted to the simpler geometry where the scattering vector is perpendicular to the magnetization, and to few materials. *Pendellösung* behaviour was evidenced through the variation with wavelength of the flipping ratio for polarized neutrons by Baruchel *et al.* (1982) on an yttrium iron garnet sample, with the geometry selected so that the defects would not affect the Bragg reflection used. The inclination method was used successfully by Zelepukhin *et al.* (1989), Kvardakov & Somenkov (1990) and Kvardakov *et al.* (1990*a*) for the weak ferromagnet $FeBO_3$, and in the room-temperature weak-ferromagnetic phase of hematite, α-Fe_2O_3, by Kvardakov *et al.* (1990*b*) and Kvardakov & Somenkov (1992).

Experiments on the influence of defects in nearly perfect crystals have been performed by several groups. The effect on the rocking curve was investigated by Eichhorn *et al.* (1967), the intensities were measured by Lambert & Malgrange (1982) and by Albertini, Boeuf, Cesini *et al.* (1976), and the influence on the *Pendellösung* behaviour was discussed by Kvardakov & Somenkov (1992). Boeuf & Rustichelli (1974) and Albertini *et al.* (1977) investigated silicon crystals curved by a thin surface silicon nitride layer.

Many experiments have been performed on vibrating crystals; reviews are given by Michalec *et al.* (1988) and by Kulda *et al.* (1988). Because the velocity of neutrons is of the same order of magnitude as the velocity of acoustic phonons in crystals, the effect of ultrasonic excitation on dynamical diffraction takes on some original features compared to the X-ray case (Iolin & Entin, 1983); they could to some extent be evidenced experimentally (Iolin *et al.*, 1986; Chalupa *et al.*, 1986). References to experimental work on neutron scattering by imperfect crystals under ultrasonic excitation are included in Zolotoyabko & Sander (1995).

Some experiments with no equivalent in the X-ray case could be performed. The very strong incoherent scattering of neutrons by protons, very different physically but similar in its effect to absorption, was also shown to lead to anomalous transmission effects by Sippel & Eichhorn (1968). Because the velocity of thermal neutrons in a vacuum is five orders of magnitude smaller than the velocity of light, the flight time for neutrons undergoing Bragg scattering in Laue geometry in a perfect crystal could be measured directly (Shull *et al.*, 1980). The effect of externally applied fields was measured experimentally for magnetic fields by Zeilinger & Shull (1979) and Zeilinger *et al.* (1986). Slight rotation of the crystal, introducing a Coriolis force, was used by Raum *et al.* (1995), and gravity was tested recently, with the spectacular result that some states are accelerated upwards (Zeilinger, 1995).

5.3.7. Applications of the dynamical theory of neutron scattering

5.3.7.1. Neutron optics

Most experiments in neutron scattering require an intensity-effective use of the available beam at the cost of relatively high divergence and wavelength spread. The monochromators must then be imperfect ('mosaic') crystals. In some cases, however, it is important to have a small divergence and wavelength band. One example is the search for small variations in neutron energy in inelastic scattering without the use of the neutron spin-echo principle. Perfect crystals must then be used as monochromators or analysers, and dynamical diffraction is directly involved. As in the X-ray case, special designs can lead to strong decrease in the intensity of harmonics, *i.e.* of contributions of $\lambda/2$ or $\lambda/3$ (Hart & Rodrigues, 1978). The possibility of focusing neutron beams by the use of perfect crystals with the incident beam spatially modulated in amplitude through an absorber, or in phase through an appropriate patterning of the surface, in analogy with the Bragg–Fresnel lenses developed for X-rays, was suggested by Indenbom (1979).

The use of two identical perfect crystals in nondispersive (+, −, ‖) setting provides a way of measuring the very narrow intrinsic rocking curves expected from the dynamical theory. Any divergence added between the two crystals can be sensitively measured. Thus perfect crystals provide interesting possibilities for measuring very small angle neutron scattering. This was performed by Takahashi *et al.* (1981, 1983) and Tomimitsu *et al.* (1986) on amorphous materials, and by Kvardakov *et al.* (1987) for the investigation of ferromagnetic domains in bulk silicon–iron specimens under stress, both through the variations in transmission associated with refraction on the domain walls and through small-angle scattering. Imaging applications are described in Section 5.3.7.4. Badurek *et al.* (1979) used the different deflection of the two polarization states provided by a magnetic prism placed between two perfect silicon crystals to produce polarized beams.

Curved almost-perfect crystals or crystals with a gradient in the lattice spacing can provide focusing (Albertini, Boeuf, Lagomarsino *et al.*, 1976) and vibrating crystals can give the possibility of tailoring the reflectivity of crystals, as well as of modulating beams in time (Michalec *et al.*, 1988). A double-crystal arrangement with bent crystals was shown by Eichhorn (1988) to be a flexible small-angle-neutron-scattering device.

5.3.7.2. Measurement of scattering lengths by Pendellösung effects

As in X-ray diffraction, *Pendellösung* oscillations provide an accurate way of measuring structure factors, hence coherent neutron scattering lengths. The equal-thickness fringes expected from a wedge-shaped crystal were observed by Kikuta *et al.* (1971). Three kinds of measurements were made. Sippel *et al.* (1965) measured as a function of thickness the integrated reflectivity from a perfect crystal of silicon, the thickness of which they varied by polishing after each measurement, obtaining a curve similar to Fig. 5.1.6.7, corresponding to equation 5.1.6.8. Shull (1968) restricted the measurement to wavefields that propagated along the reflecting planes, hence at exact Bragg incidence, by setting fine slits on the entrance and exit faces of 3 to 10 mm-thick silicon crystals, and measured the oscillation in diffracted intensity as he varied the wavelength of the neutrons used by rotating the crystal. Shull & Oberteuffer (1972) showed that a better interpretation of the data, when the beam is restricted to a fine slit, corresponds to the spherical wave approach (actually cylindrical wave), and the boundary conditions were discussed more generally by Arthur & Horne (1985). Somenkov *et al.* (1978) developed the inclination method, in which the integrated reflectivity is measured as the effective crystal thickness is varied nondestructively, by rotating the crystal around the diffraction vector, and used it for germanium. Belova *et al.* (1983) discuss this method in detail. The results obtained by this group for magnetic crystals are mentioned in Section 5.3.6. Structure-factor values for magnetic reflections were obtained by Kvardakov *et al.* (1995) for the weak ferromagnet $FeBO_3$.

5.3.7.3. Neutron interferometry

Because diffraction by perfect crystals provides a well defined distribution of the intensity and phase of the beam, interferometry with X-rays or neutrons is possible using ingeniously designed and carefully manufactured monolithic devices carved out of single crystals of silicon. The technical and scientific features of this family of techniques are well summarized by Bonse (1979, 1988), as well as other papers in the same volumes, and by Shull (1986).

X-ray interferometry started with the Bonse–Hart interferometer (Bonse & Hart, 1965). A typical device is the LLL skew-symmetric interferometer, where the L's stand for Laue,

indicating transmission geometry in all crystal slabs. In these slabs, which can be called the splitter, the mirrors and the recombiner, the same pair of opposite reflections, in symmetrical Laue geometry, is used three times. In the first slab, the incident beam is coherently split into a transmitted and a diffracted beam. Each of these is then diffracted in the two mirrors, and the resulting beams interfere in the recombiner, again yielding a forward-diffracted and a diffracted beam, the intensities of both of which are measured. This version, the analogue of the Mach–Zehnder interferometer in optics, offers a sizeable space (several cm of path length) where two coherent parallel beams can be submitted to various external actions. Shifting the relative phase of these beams (*e.g.* by π, introducing an optical path-length difference of $\lambda/2$) results in the intensities of the outgoing beams changing from a maximum to a minimum.

Applications of neutron interferometry range from the very useful to the very exotic. The most useful one is probably the measurement of coherent neutron scattering lengths. Unlike the *Pendellösung* method described in Section 5.3.7.2, this method does not require the measured samples to be perfect single crystals, nor indeed crystals. Placing a slab of material across one of the beams and rotating it will induce an optical path-length difference of $(1 - n)t$ if t is the effective thickness along the beam, hence a phase shift of $2\pi(1 - n)t/\lambda$. With the expression of the refractive index n as given in Section 5.3.2.2, it is clear that for an isotopically pure material the scattering length $b_{\rm coh}$ can be deduced from the measurement of intensity *versus* the rotation angle of the phase shifter. This is a very versatile and much used method. The decrease in oscillation contrast can be used to obtain information of relevance to materials science, such as statistical properties of magnetic domain distributions (Korpiun, 1966) or precipitates (Rauch & Seidl, 1987); Rauch (1995) analyses the effect in terms of the neutron coherence function.

Many elegant experiments have been performed with neutron interferometers in efforts to set an upper limit to effects than can be considered as nonexistent, or to test expectations of basic quantum physics. Many papers are found in the same volumes as Bonse (1979) and Bonse (1988); excellent reviews have been given by Klein & Werner (1983), Klein (1988) and Werner (1995). Among the topics investigated are the effect of gravity (Colella *et al.*, 1975), the Sagnac effect, *i.e.* the influence of the Earth's rotation (Werner *et al.*, 1979), the Fizeau effect, *i.e.* the effect of the movement of the material through which the neutrons are transmitted (Arif *et al.*, 1988) and the Aharonov–Casher effect, *i.e.* the dual of the Aharonov–Bohm effect for neutral particles having a magnetic moment (Cimmino *et al.*, 1989).

5.3.7.4. Neutron diffraction topography and other imaging methods

These are the neutron form of the 'topographic' or diffraction imaging techniques, in which an image of a single crystal is obtained through the local variations in Bragg-diffracted intensity due to inhomogeneities in the sample. It is briefly described in Chapter 2.8 of *IT* C. It was pioneered by Doi *et al.* (1971) and by Ando & Hosoya (1972). Like its X-ray counterpart, neutron topography can reveal isolated defects, such as dislocations (Schlenker *et al.*, 1974; Malgrange *et al.*, 1976). Because of the small neutron fluxes available, it is not very convenient for this purpose, since the resolution is poor or the exposure times are very long. On the other hand, the very low absorption of neutrons in most materials makes it quite convenient for observing the gross defect structure in samples that would be too absorbing for X-rays (Tomimitsu & Doi, 1974; Baruchel *et al.*, 1978; Tomimitsu *et al.*, 1983; Kvardakov *et al.*, 1992), or the spatial modulation of distortion due to vibration, for example in quartz (Michalec *et al.*, 1975), and resonant magnetoelastic effects (Kvardakov & Somenkov, 1991). In particular, virtual slices of bulky as-grown samples can be investigated without cutting them using neutron section topography or neutron tomography (Schlenker *et al.*, 1975; Davidson & Case, 1976).

Neutron topography also shows the salient dynamical interference effect, *viz Pendellösung*, visually, in the form of fringes (Kikuta *et al.*, 1971; Malgrange *et al.*, 1976; Tomimitsu & Zeyen, 1978). Its unique feature, however, is the possibility of observing and directly characterizing inhomogeneities in the magnetic structure, *i.e.* magnetic domains of all kinds [ferromagnetic domains (Schlenker & Shull, 1973) and antiferromagnetic domains of various sorts (Schlenker & Baruchel, 1978), including spin-density wave domains (Ando & Hosoya, 1972, 1978; Davidson *et al.*, 1974), 180° or time-reversed domains in some materials and helimagnetic or chirality domains (Baruchel *et al.*, 1990)], or coexisting phases at a first-order phase transition (Baruchel, 1989). In such cases, the contrast is primarily due to local variations in the structure factor, a situation very unusual in X-ray topography, and good crystal quality, leading to dynamical scattering behaviour, is essential in the observation process only in a few cases (Schlenker *et al.*, 1978). It is often crucial, however, for making the domain structure simple enough to be resolved, in particular in the case of antiferromagnetic domains.

Imaging can also be performed for samples that need be neither crystals nor perfect. Phase-contrast imaging of a specimen through which the neutrons are transmitted can be performed in a neutron interferometer. It has been shown to reveal thickness variations by Bauspiess *et al.* (1978) and ferromagnetic domains by Schlenker *et al.* (1980). The same papers showed that phase edges show up as contrast when one of the interferometer paths is blocked, *i.e.* when the sample is placed effectively between perfect, identical crystals set for diffraction in a nondispersive setting. Under the name of neutron radiography with refraction contrast, this technique, essentially a form of Schlieren imaging, was further developed by Podurets, Somenkov & Shil'shtein (1989), Podurets, Somenkov, Chistyakov & Shil'shtein (1989), and Podurets *et al.* (1991), who were able to image internal ferromagnetic domain walls in samples 10 mm thick.

A posteriori probability, 512
A priori probability, 504
Ab initio phase determination, 273
Abbe theory, 303
Abel summation procedure, 46
Abelian groups, 42, 79
Aberrations, 303
Absolute configuration, 282, 285
Absolutely integrable functions, 27
Absorbing crystals, 629, 637–638, 640
Absorption coefficient, 634, 639
  effective, 628
  linear, 628
  phenomenological, 303
Absorption edge, 284
Absorption function, 542
Absorption in electron diffraction, 362
Accelerated convergence, 449
  formula *via* Patterson function, 454
Acceptance domain, 596
Acentric reflections, 74
Acoustic modes, 486
Action, 68
Additive reindexing, 61
Adiabatic approximation, 484
Adjusted coefficients, 180
Affine change of coordinates, 35
Affine change of variables, 40
Affine space-group type, 177
Affine transformation, 120
Agarwal's FFT implementation of the Fourier method, 98
Alfalfa mosaic virus, 259
Algebra of functions, 75
Algebraic integers, 78, 82
Algebraic number theory, 82
Algebraic reconstruction technique (ART), 370
Aliasing, 47, 49, 93
Alignment of electron-microscopy images, 379
Allowed origins, 215
'Almost everywhere', 26
Analytical methods of probability theory, 102
Angle between two vectors, 404
Angles
  Eulerian, 262, 420
  spherical, 262
Anisotropic displacement parameters, 443
Anisotropic displacement tensors, 6
Anisotropic fluid, 547
Anisotropic Gaussian atoms, 63
Anisotropic temperature factors, 73
Anisotropic weights, 413
Annular dark-field detector, 305
Anomalous absorption, 633, 659
Anomalous difference, 288, 291
Anomalous dispersion (scattering), 255–256, 282, 284
  integration with direct methods, 237
  Patterson function, 257
Anomalous scatterers, 64, 74, 256, 284, 286
Anomalous transmission effect, 633
Antiferromagnetic domains, 661
Anti-nodes of standing waves, 633
Antisymmetric tensor, 6
Aperiodic crystals, 590
  disorder diffuse scattering from, 526
  ideal, 590
Aperiodic structure, 590
Apparent noncrystallographic symmetry, 267
Approximate helix symmetry, 570
Approximations
  adiabatic, 484
  Bethe, second, 302
  Born, first-order, 10, 300
  Born, second-order, 11
  Born–Oppenheimer, 17
  Edgeworth, 21
  forward-scattering, 301
  harmonic, 484
  kinematical, 62, 300–301, 359, 394, 583, 658
  phase-grating, 652
  phase-object, 301, 542
  projected charge-density, 305
  projection, 648
  saddlepoint, 102–103
  seven-beam, 652
  small-angle-scattering, 300
  three-beam, 652
  two-beam, 302, 649
  two-beam dynamical, 394
  weak-phase-object, 304
Area detector, 294
Argand diagram, 283
Arithmetic classes, 71
  of representations, 71
Arithmetic crystal class, 177
Arms of star, 178
ART (algebraic reconstruction technique), 370
Artificial temperature factor, 94, 100
Aspherical-atom form factor, 14
Aspherical multipole refinement, 459
Associated actions in function spaces, 69
Associativity properties of convolution, 100
Assumption of independence, 209
Assumption of uniformity, 203, 209
Astigmatism, 378
Asymmetric carbon atom, 285
Asymmetric images, 365
Asymmetric unit, 69, 72, 180
  noncrystallographic, 253
Asymmetry ratio, 631
Asymptotic crystal shape, 470
Asymptotic distribution of eigenvalues of Toeplitz forms, 45, 68
Asymptotic expansions
  and limit theorems, 103
  of Gram–Charlier and Edgeworth, 105
Atom-centred spherical harmonic expansion, 12
Atomic characteristic functions, 211
Atomic electron densities, 75
Atomic error matrix, 416
Atomic force-constant matrix, 485
Atomic form factor, 10
  X-ray, 293
Atomic scattering factor, 10, 284
  spherical, 10
Atomic scattering length, 11
Atomic surface, 590, 596
Atomic temperature factor, 17
ATOMS, 443–445
Autocorrelation, 65
Autocorrelation function, 388
Automated Patterson-map search, 389
Automorphism, 69, 71
Auxiliary basis set expansion, 479
Auxiliary basis set fitting, 459
Average difference cluster method, 518
Average intensity
  of general reflections, 195
  of zones and rows, 196
Average multiples for point groups, 197
Averaged electron density, 274
Axial disorder, 517

B-splines, 476
  approximation to trigonometric functions, 477
  derivatives of, 477
  Fourier transforms of, 477
  recursion for, 477
  tensor product, 480
B3LYP basis set, 479
Back-shift correction, 96
Back surface, 639
Background diffraction, accurate subtraction of, 575
Backprojection, 367
  filtered, 371
Backward convolution theorem, 44, 75
Bacterial rhodopsin, 274
Balls&Sticks, 443–444
BALSAC, 443–445
Banach spaces, 28
Band-limited function, 49
Base-centred lattices, 90
Bases
  Cartesian, 7
  contravariant, 5–6
  covariant, 5–6
  direct and reciprocal, relationships between, 3
  mutually reciprocal, 2–3
  primitive, 177
  reference, choice of, 7
Basic crystallographic computations, 91
Basic domain, 180
Basic structure, 591
Basis vectors, contravariant, 405
Bayesian statistical approach to the phase problem, 106
Beevers–Lipson factorization, 58, 76–77
Beevers–Lipson strips, 76, 93
Bessel's inequality, 47
Best Fourier, 91, 290
Best phase, 290
Best plane, 410
Beta distribution
  first kind, 201
  second kind, 201
Bethe approximation, second, 302
Biaxial nematic order, 549
Bieberbach theorem, 68
Bijvoet differences, 257
Bijvoet equivalents, 286–287
Bijvoet pair, 285–286
Bilder, 440
Binary systems, distortions in, 522
Binding energy, 284
Bloch-wave formulation, 650
Bloch waves, 300, 628
Bloch's theorem, 9, 486
  alternative form of, 9
Blow and Crick formulation, 290
Body-centred lattices, 90
Body-diagonal axes, 128
Bond angles, 437
Bond orientational order, 547
Booth's differential Fourier syntheses, 96
Booth's method of steepest descents, 96
Bootstrap technique, 388
Borie–Sparks method, 523
Born approximation
  first-order, 10, 300
  second-order, 11
Born–Oppenheimer approximation, 17
Born series, 300, 651
  expansion, 543
Born–von Karman boundary conditions, 177
Born–von Kármán theory, 484
Borrmann effect, 303, 633
Borrmann triangle, 641
Boundary conditions, 628, 639
  at exit surface, 635
  periodic, 479
Bounded projections, 67, 92
Bounded subset, 25
Boy's function, 471
BP (bright-field pattern), 310
Bragg case, 631
Bragg's law, departure of incident wave from, 630
Bragg–Lipson charts, 93
Branch, 485
Bravais lattices
  centred, 121
  direct and reciprocal, 121
Bright-field image intensity, 362
Bright-field pattern (BP), 310
Brillouin zone, 9, 485
  first, 178
Bulk plasmon excitation, 300
Burg entropy, 68
Burnside's theorem, 71
Butterfly loop, 53

Calculus
  of asymmetric units, 79
  operational, 28
Cameron, 443–444
CaRIne, 443–444
Carpet of cross-vectors, 260
Cartesian basis, 7
Cartesian coordinate system, 404
Cartesian coordinates, 418, 445
Cartesian frames of reference, 5
Cartesian product, 25, 42
Cartesian system, transformation to, 3
Cauchy kernel, 46
Cauchy–Schwarz inequality, 27, 47
Cauchy sequence, 26
Cauchy's theorem, 104
CBED (convergent-beam electron diffraction), 307
  coherent, 323, 333
CCP14 (Collaborative Computational Project Number 14), 443
Cell constants, 576
Central-limit theorem, 103, 198
  Lindeberg–Lévy version, 204
Central section theorem, 367
Centre-of-mass translational displacements, 525
Centre of symmetry, false, 115
Centred Bravais lattice, 121
Centred lattices, 73
Centric reflections, 73
Centring
  effect of, 196
  translations, 121
  type, 121
Centrosymmetric projections, 251–252
Centrosymmetry, status of, 123
Cesàro sum, 46
Chain rule, 99
Chain trace, 441
Chains, flexible, 436
Change-of-basis matrix, 123
Change of crystal axes, 120
Channelling pattern, 544
Characteristic functions, 102, 197, 208
  atomic, 211
Charge densities, Coulomb energy of, 474
Charge distributions, Gaussian, 461, 471–472
CHARMM, 442
CHEMGRAF, 439
Chemical correctness of polypeptide fold, 273
Chem-X, 442
Chinese remainder theorem (CRT), 54, 61, 82
  for polynomials, 57, 84
  reconstruction, 54
  reconstruction formula, 57
Chirality, 285
Choice of reference bases, 7
Cholesteryl iodide, 249
α-Chymotrypsin, 271
Circular harmonic expansions, 100
Classical Thomson scattering, 10
Classification of crystallographic groups, 70
Classification of electron-microscopy images, 381
Clebsch–Gordan coefficients, 17
Closed point group, 258
Closed subset, 25
Cluster model, 545
Clustering, 518
Clustering algorithms, 380
Clusters, 500
Cochran's Fourier method, 96
Cocycle, 85
Coherence, 434
Coherence length, 568
Coherent convergent-beam electron diffraction, 323, 333
Coherent scattering, 488
Collaborative Computational Project Number 14 (CCP14), 443
Column part, 177
Common line, 382
Communication, statistical theory of, 104
Commutative ring, 54
Compact Gaussians, 472
Compact subset, 25
Compact support, 25, 36, 44
  distributions with, 30, 40, 43–44, 47
Complement of the incomplete gamma function, 450–451
Complete normed space, 28
Complete vector spaces, 26
Completely reducible matrix group, 176
Complex antisymmetric transforms, 87
Complex scattering factor, 255
Complex symmetric transforms, 87
Components of vector products, 405
Components of vectors, 5
Composite lattice, 449, 452
Composite structure, 593
Compound nucleus, 11
Compound transformations, 429
Compton scattering, 489
Computational and algebraic aspects of mutually reciprocal bases, 4
Computational cost of Ewald direct sum, linear scaling of, 474

  to a Cartesian system, 3
  unitary, 37
  viewing, 426–427, 429–430, 432
  viewport, 426, 428
  windowing, 426
Transformed variance–covariance matrix, 407
Transforms
  complex antisymmetric, 87
  complex symmetric, 87
  Hankel, 101
  Hermitian-antisymmetric, 87
  of an axially periodic fibre, 101
  of delta functions, 40
  polynomial, 61
  pure imaginary, 87
  Radon, 366
  ray, 366
  real antisymmetric, 88
  real symmetric, 88
  real-valued, 85
Translate, 26
Translation, 18, 25, 426, 429
  part of space-group operation, 115
  part of space-group operation, intrinsic and location-dependent components of, 116
Translation, libration and screw-motion tensors, 6
Translation functions, 100, 269
  general, 269
  locked, 271
  real-space, 271
Translation subgroup, 177
Translation tensor, 18
Translation vector, 258
Translational components of noncrystallographic rotation elements, 258
Translational displacement, 18
Translational invariance, 650
Translations, conversion to phase shifts, 35
Transmission case, 631
Transmission electron microscope (TEM), 303
Transmission geometry, 631–633
  intensities of plane waves in, 634
Transmission high-energy electron diffraction (THEED), 356
Transposition formula, 80–81
  for intermediate results, 77
Triads, mutually reciprocal, 2
Triangular inequality, 27
Triclinic space groups, 89, 118
Trigonal space groups, 90, 119
Trigonometric functions
  B-spline approximation of, 477
  interpolation of, 478
  least-squares approximation of, 478
Trigonometric moment problem, 44
Trigonometric structure-factor expressions, vectors of, 104
Trigonometric structure factors, 116–117, 135
  even absolute moments of, 206
  moment of, 205
Triple-axis spectrometer, 490
Triple point, 552
Triplet relationships using structural information, 224
Triplets, search of, 231
Triply periodic, 627
Tunability, 294
Twiddle factors, 53, 58, 60, 62, 80
Two-beam approximation, 302, 649
Two-beam case, 629
Two-beam dynamical approximation, 394
Two-beam dynamical diffraction formulae, 303
Two-centre orbital products, 17
Two-centre terms, 15
Two-dimensional disorder, 514
Two-dimensional hexatic phase, 555
Two-dimensional symmetry elements, 308–310
Two-phase structure seminvariants, first rank, 229
Two-wavelength method, 293
Type of irreps, 181
Type of rotation (proper or improper), 123

Uni-arm **k** vector, 181
Uniaxial nematic order, 549
Uniformity, assumption of, 203, 209
Uniformizable space, 28
Unit cell, 178–179, 460
  dipole moment of, 461
  neutral, 461
Unit-cell parameters
  direct, 4
  reciprocal, 4
Unit cube, 42
Unitary matrix group, 176
Unitary structure factors, 218
Unitary transformations, 37
Unscrambling, 81
Uranium, 287

Valence density, 12
van der Waals surfaces, 433, 439
Van Hove correlation functions, 489
Variance, 407
Variance–covariance matrix, 406
  transformed, 407
Variances, 411–412
Vector interactions in a Patterson map, 248
Vector lattice, 177
Vector machines, 432
Vector map, 244
Vector overlap, 251
Vector processing, 61
Vector product, 405
  components of, 405
  tensor formulation of, 6
Vector radix Cooley–Tukey algorithm, 58
Vector radix FFT algorithms, 59
Vector relationships, 405
Vector-search procedures, 251
Vector space
  complete, 26
  norm on, 28
  semi-norm on, 28
  topological, 28
Vectors
  angle between two, 404
  components of, 5
  cross-Patterson, 260
  four-dimensional, 424
  interatomic, 65
  length of, 404
  of trigonometric structure-factor expressions, 104
  origin-shift, 123
  polarization, 11, 655
  Poynting, 644
  rotation, 421
  self-Patterson, 260
  translation, 258
VENUS, 443–445
Very small angle neutron scattering, 660
Vibrating crystals, 660
Vibrational–librational correlations, 525
Viewing transformation, 426–427, 429–430, 432
Viewport, 426, 428
Viewport transformation, 426, 428
Vitamin B_{12}, 286
Voronoi diagram, 373

Waller–Hartree formula, 541, 543
Warren short-range-order parameters, 520
Wavefield, 628, 630
Wavefunctions, prolate spheroidal, 39
Wavelengths, 299
Wavevectors, 635
Weak enantiomorphic images, 247
Weak-phase-object approximation, 304
Weak phase objects, 361, 583
  periodic, 364
Weighted difference map, 97, 99
Weighted lattice distribution, 44
Weighted reciprocal lattice, 114–115
  statistical properties of, 195
Weighted reciprocal-lattice distribution, 62
Weighted tangent formula, 224
Weighting factor, 289
Weights
  anisotropic, 413
  Gaussian, 413
Whole pattern (WP), 310
Width of rocking curve, 633
  at half-height, 636
Width of total-reflection domain, 633, 638
Wigner potential, 466
Wigner–Seitz cell, 178
Wilson plot, 287
Window, 426, 429, 434
Windowing, 426, 428
Windowing transformation, 426
Wing, 184
Winograd algorithms, 52, 56
Winograd small FFT algorithms, 57
Winograd small FFTs, nesting of, 60
Wintgen letter, 180
Wintgen position, 180
Wintgen symbol, 180
World coordinates, 426
WP (whole pattern), 310
Wyckoff letter, 180
Wyckoff position, 115, 180
Wyckoff symbols, 72

XmLmctep, 443–444
X-ray analysis, 287
X-ray fibre diffraction analysis, 567
  data processing, 574
  structure determination by, 576
X-ray scattering, 62, 293
  cross section, 550
  elastic component, 10
  inelastic component, 10
X-ray topographs, 626
X-rays, 293
  diffuse scattering of, 492
  interaction with matter, 626
X-Seed, 443–444
Xtal-3D, 444–445
XtalDraw, 443–444

z buffer, 433
ZAP (zone-axis pattern), 310
Zero-absorption case, 633
Zeroth-order Laue zone (ZOLZ) reflections, 308, 324
Zonal data sets
  view down the chain axis, 584
  view onto the chain axes, 585
Zone-axis pattern (ZAP), 310
Zones and rows, average intensity of, 196
